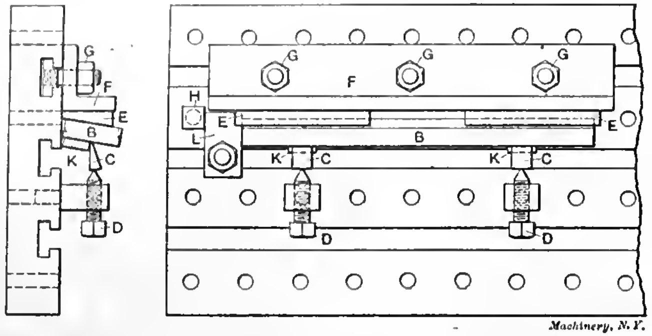
Operations for the Article in this number entitled "Machine Shop Practice—Planing and laying out a Blanking Die."

SHOP OPERATION SHEET NO. 73.

C. F. Emerson. MACHINERY, September, 1908.



To Plane the Beveled Sides of the Stock for Blanking Dies.

NOTE.—The stock for blanking dies is planed up in long strips, and subsequently cut off to correct lengths for different dies, in the hack-saw. It is assumed that, previous to the present operation, the stock has been planed on the top and bottom sides, a finishing cut being taken on the top side to make it very smooth.

1. Brush off all chips from planer table, clean out the T-slots, and fasten the knee bracket *F* on the planer table, by means of the bolts *G*.

2. Place the two 10-degree parallels *E* against the face of knee bracket *F*, resting the narrow sides of the parallels upon the bed of the planer.

3. Place the smooth side of the bar *B*, which is the work to be planed, against the parallels *E*, and hold it in place by the poppets *C* and screws *D*. Put the pieces *K* under poppets *C*, so as to bring the poppets about in the center of the stock, as shown.

4. Place a stop *L* at the end of the work *B*, to prevent it shifting forward when the tool is cutting. This stop consists of a small strap held at one end by a bolt and nut in the T-slot, and resting against the planer stop *H* at the other end. It is not shown in the end view, to avoid confusion.

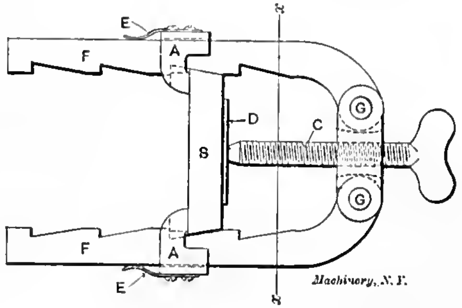
5. Take first a heavy cut, and then a light finishing cut over the top surface of *B*, with a diamond point tool.

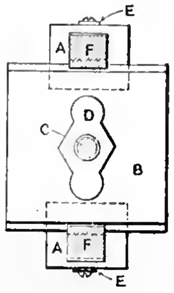
6. Loosen screws *D*, remove *B* and clean out all chips. Place the 10-degree side of the strip, just planed, on the bed of the planer, in such a manner that the smooth side again rests against parallels *E*. Tighten screws *D* as before, and repeat the planing operation on the side that is now the top side of *B*.

NOTE.—This operation can also be performed in the shaper. Place two 10-degree parallels in the shaper vise, one on each side of the work, and clamp the work between them. Then finish the top surface by taking a heavy and a light finishing cut. Turn the work around, and finish the other 10-degree surface in the same way, taking care that all chips are removed from the seating surfaces before again clamping the work in place.

SHOP OPERATION SHEET NO. 74.

C. F. Emerson. MACHINERY, September, 1908.





SECTION IN x-x

To Scribe the Outline of a Templet on a Die Blank, Using a Die-maker's Crab Clamp.

NOTE.—The die blank on which the outline of the templet or sample blank is to be scribed, has been planed on top and bottom, and the top face smoothly finished, previous to the present operation. The 10-degree beveled sides fitting into the dove-tail slide of the die-holder are also planed, as described in detail in Shop Operation Sheet No. 73.

1. Polish the face of the die blank, so that it is smooth enough to permit the scribing of the outline of the sample or templet, and heat it evenly all over, until a dark blue color is obtained. Then the blank is immersed in oil, after which it is permitted to cool slowly.

2. Place the die blank on the jaws *A* of the crab clamp, as shown in the engraving. Lay the sample or templet *D* on the face of the die blank *B*, and tighten the thumb-screw very slightly, permitting enough freedom so that the sample or templet *D* can be moved between the screw and the die blank, on the face of the latter, by tapping it lightly on the sides.

3. Adjust the templet *D* so that it is central with all four sides of die blank *B*, and in correct relation to them.

4. Tighten the thumb-screw *C* so that it holds the templet *D* securely in place.

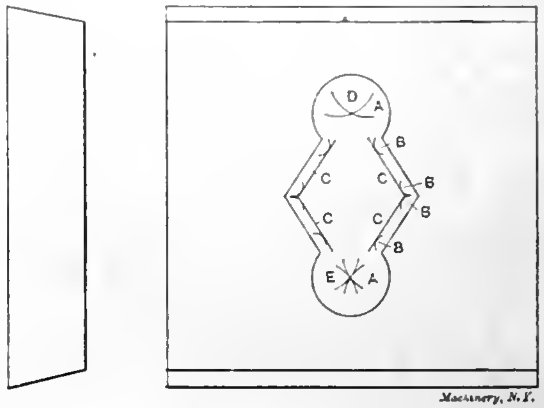
5. Scribe the outline of templet *D* on the face of die blank *B*, with a sharp scriber. Care should be taken to keep the point of the scriber close to the edges of the templet in order to insure that the dimensions and form of sample *D* are copied correctly on die blank *B*.

6. Release screw *C* from the sample *D*, remove the latter, and take the die blank out of the clamps. The die blank is now ready for working out the opening, to fit the templet *D*.

NOTE.—The design of the clamp shown in the engraving may not be familiar to all. The principal feature of this clamp is that there is no time wasted in screwing the clamp screw *C* up and down when pieces of different thicknesses are placed between the arms *F*, because the jaws *A* are made so that they can slide up and down on the arms *F*, which are provided with steps so that the jaws can rest at various places on them, as shown. The springs *E*, shown, act as frictions, and prevent the jaws from dropping when not resting on the steps. The arms *F* swing on pins *G*, thus making it possible to accommodate various widths of the die blanks.

SHOP OPERATION SHEET NO. 75.

C. F. Emerson. MACHINERY, September, 1908.



To Lay Out and Prick-punch the Drill Centers for Drilling Out the Core.

NOTE.—Previous to this operation the blank has been planed and the shape of the work laid out on its face.

1. If the diameter of holes *A* is known, the centers of these holes are found by scribing two circular arcs, with any point on the circumference as a center, as shown at *D*, having the same radii as the hole. The intersection of these two circular arcs is the center of the hole.

2. If the diameter of hole is not known, the dividers are set approximately to the radius and arcs scribed from centers located on the periphery, about 90 degrees apart. After having scribed four circular arcs, if these do not all tangent in one point, adjust the scriber according to judgment, and scribe again four arcs. When all the four arcs intersect or tangent in the same point as at *E*, this point is the center.

3. Spot and prick-punch, with a sharp prick-punch, where the scribed lines intersect.

4. To lay out the lines *C*, on which the centers of the holes drilled for removing the core are located, set the dividers to one-half the diameter of the drill to be used, then scribe circular arcs, as shown at *B*, with the centers located on the scribed outline of the die.

5. Lay a straight-edge so that it tangents these circular arcs, and scribe the lines *C*, as shown.

6. With an adjustable double prick-punch, spot the lines very lightly, adjusting the points of the double prick-punch so that the distance from one point to the other is a trifle less than the diameter of the drill to be used for removing the core, so that there will be no web between the holes when drilled.

7. With an ordinary prick-punch go over the prick-punched marks previously made, and make the spots a trifle deeper.

NOTE.—The dividers are often used to space the distance from center to center of the holes to be drilled, in place of a double prick-punch. This is not as convenient as the use of the adjustable prick-punch, although it cannot be called poor practice.

DESIGN AND CONSTRUCTION OF METAL WORKING SHOPS[*]—1.

W. P. SARGENT.[†]

W. P. Sargent.[‡]

A PERIOD of general depression may not seem timely for projects involving the expenditure of large sums, but, obviously, thorough study and discussion of tentative plans can be the better made during dull times, as the efforts of all concerned are not directed towards the crowding of production.

The great advantages in having new shops ready, or, perhaps, one may better say, the disadvantages of insufficient space when a rush in business comes on, are well known. If the fact were better appreciated that a saving equal to thirty per cent of the amount expended may easily be made by building during a time of depression rather than during a period of inflation, many corporations would not, as may now be seen on every hand, have their new shops ready for occupancy at the *termination* rather than at the *beginning* of a prosperous period.

Irrespective, however, of the time when extensive improvements are to be made by a growing concern, the problems arising are involved and seemingly numberless. Few but they who have had to meet these problems can appreciate the paucity of general precedents that are available in the planning and carrying out of extensive improvements, especially under the severe condition that but slight interference with production is permissible.

Scope of Articles.

From the premise that the desired benefits from extensions must be secured at a reasonably low cost, as quickly as the need demands and conditions permit, and without restricting production, the author proposes to discuss in the following articles the subject of industrial plant extension as applied to metal working industries, from the time when extensions are tentatively considered to the time of occupancy. Data will be given enabling the plant engineer to proceed steadily and rapidly, and also giving his employers information by which his efforts may be intelligently checked. Presumably many of the propositions advanced will meet with a variance of ideas, but wherever positive positions are taken, the author will endeavor to give sufficient reasons therefor.

Main Periods of Construction.

The time necessary for the planning of an extensive series of improvements, and for the execution of these plans, may be divided into four main periods which will be styled, the inceptive, the formative, the progressive, and the conclusive period, respectively.

The Inceptive Period.—The inceptive period covers the time of compiling the necessary data and the study of the best examples of recently constructed plants. This study will reveal to the mind the comparative advantages of different arrangements and of various types of buildings. During this period one's mind will be forming various schemes, even though sub-consciously.

The Formative Period.—During this, the mental structures assume more and more tangible and definite forms as the tentative planning, revising, the definite planning, and the securing of prices are taken up.

The Progressive Period.—During this period the contracting, constructing, and moving are carried on.

The Conclusive Period.—When the new shops are partly operative, the inevitable gaps in the general scheme are filled, and summations and comparisons of costs are made.

The chart, Fig. 1, is prepared to show more clearly the relation of the various periods and sub-periods, and also to show approximately the duration of the periods, assuming that a total of twenty months should cover the work from the commencement of the tentative planning to the completion of the work. Before going into the detailed discussion however, the author will advance the following general propositions.

General Considerations.

Engineering the construction of a series of extensive industrial improvements is decidedly a one-man job as regards control. This statement holds good whether the engineering is done by one of the many firms or individuals making a specialty of industrial plants, or by a temporary organization drawn from the staff of the owners themselves. The engineer who is to successfully carry through to completion a large project of this kind should be a high-class man, and, consequently, well paid. Generally, an engineer from outside is to be recommended, as his work will meet with less obstruction. "A prophet is never without honor save in his own country" is peculiarly applicable to this class of engineering. One can be too conciliatory in trying to prevent friction. This idea of the author's results from a recent experience with the vacillating nature of a few individuals backed by a general, narrow, insular indisposition to move from the beaten track and to accept the benefits of more efficient facilities of proven merit.

The duties of the engineer-in-charge carry a great responsibility and demand a rare combination of abilities. Given that the engineer is to have undisputed charge of the work (of course, subject to his employers' approval), and is to be the sole intermediary between his principals and the contractors, he should possess to a high degree honesty, discretion, tact, and the ability to observe closely, to analyze well, and to think honestly and methodically. He should possess executive and originative capabilities, combined with good common sense. He should have the temperament and stamina to withstand intensive and tenacious application. He must not be afraid to say "I do not know," but he should know the next time, would he secure and retain the respect and confidence of his associates and subordinates.

The efficiency of an industrial plant is *not primarily dependent upon the buildings*, but is mainly dependent upon the personnel, the equipment, the facilities for handling the materials and the product, and the arrangement of space. The buildings proper only affect the efficiency inasmuch as they do or do not provide good light, good air, sufficient headroom, and a reasonable degree of comfort for the workmen Therefore, the nature of the covering for the space is secondary, and is determinable by the three main considerations of utility, cost, and reasonable architectural effect. No one type of buildings, whether mill construction, iron covered, brick and steel, or reinforced concrete will meet all condi-

---

[†] Address: 948 Campbell Ave., Hamilton, Ohio.

[‡] William P. Sargent was born at Stoneham, Mass., 1878. He received a high school education, and then gained shop experience at Prentice Bros. Co., Worcester, Mass.; Draper Machine Tool Co., Worcester, Mass.; Lodge & Shipley Co., Cincinnati, Ohio; Pratt & Whitney Co., Hartford, Conn.; Niles Tool Works, Hamilton, Ohio; Barber-Coleman Co., Rockford, Ill. With these concerns he has filled the positions of stock-keeper; designer; superintendent of construction on large contract of automatic cheroot machines; assistant to Mr. C. Edwin Search, formerly engineer in charge of construction, Niles-Bement-Pond Co.; engineer in charge of construction, Niles Tool Works; designing engineer at Barber-Coleman Co.

tions. We will later take up the comparison of various types of buildings, and the conditions for which each is best adapted.

Successful large plants are not of mushroom growth, but have grown building by building from a single small shop. Seldom have additions been made with any thought aside from that of providing for the existing need. Consequently, many large plants are a compact, irregular collection of buildings, sometimes separated by streets, tracks or water courses. However, the floor space occupied by various branches of work, and the number of men and power consumption for various units of space, form the logical working basis either for designing a new plant on ample ground space, or for alteration and the providing of additional facilities on whatever ground is available contiguous to existing buildings. Of course, the *space per man* in some of the departments may be too little for efficient production, and care should be taken to make allowance for this factor.

The labor supply may weigh heavier than all other factors in determining the justifiable limits of extension. In one instance of a city of 30,000 inhabitants, metal working industries have enlarged in recent years to the extent that an employer of 1,100 men stated his belief that 1,500 men would be the maximum he could gather in his shops in years to come without resorting to colonization. This belief came from the knowledge of the fluctuating demand for the product, the few apprentices taken on from year to year, and the scarcity of houses rentable at a low figure. The doubling in size of this plant would be a precarious proposition compared with the same increase in Philadelphia, for instance, where the general manager of a large metal working firm stated that he had increased his force 18 per cent in two months, or in Milwaukee, where one concern increased its force 1,200 men in eight months. Both above instances were with business at its best.

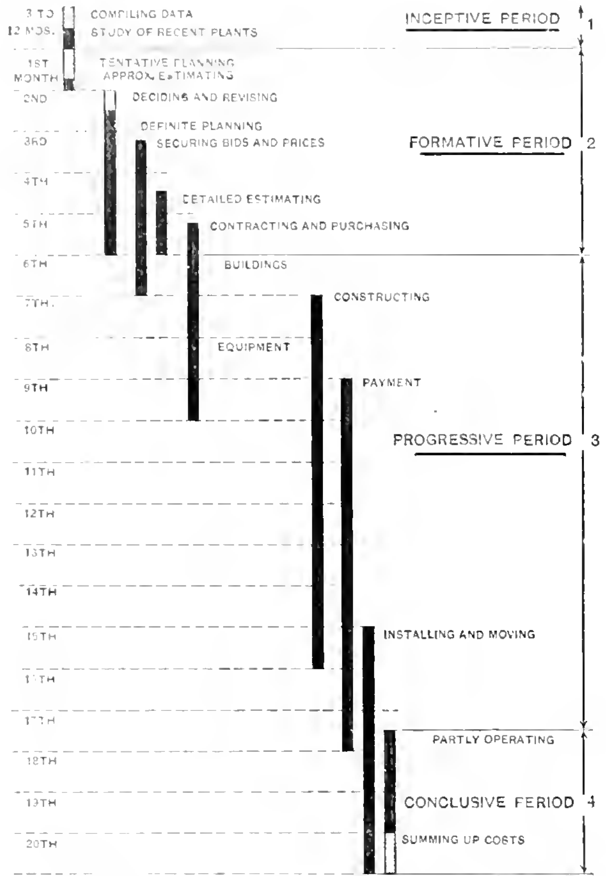

Fig 1. Relation of Different Stages of Shop Construction Work.

The sectional bookcase idea as applied to the laying out of new plants meets all the requirements of departmental balance and of future extension, the various departments corresponding to the sections, and a group of departments making up a unit. The West Allis Plant, of the Allis-Chalmers Co. in Milwaukee exemplifies this idea. The first buildings were designed for large engine work, while the recent additions were designed for both large and small work of an entirely different nature. The new buildings were slightly modified in type, yet they merge into the general scheme as naturally as rain into a river. Of course, old plants can not be changed to conform with this ideal; still, much can be done to give the product an economical routine through the works, and to arrange the departments so that future extensions could be made in conformity with a predetermined plan. Time may be profitably devoted to the critical study of recent plants. First study the main features of large plants from articles in various technical papers; these articles are generally written by men having a thorough understanding of the fundamental reasons for existing conditions. Generally, in visiting, one can only glance over the thousand and one features, and the information obtained is merely confirmative or disputative of predetermined conclusions.

Tentative plans should be comprehensive and flexible. Several solutions should develop from a thorough study of the problem, but each one of these various plans should be complete, comprising every item of work, and each item with an approximate estimate of cost. Approximate estimates based on square foot and cubic foot figures for cost of buildings, added to estimates on every item that can be thought of, will be, in total, close to actual costs even though some particular items may be within broad limits. The estimate of the total cost of a given project should never be decreased merely because some items may be excessive, for the reason that subsequent changes are more apt to increase the cost rather than to decrease it. The engineer will make a great mistake if, when the plans are decided upon and revised, he assents to the cutting of an estimate piece-meal, coupled with the expectation that the same definite quality and quantity of work is to be done. The "powers that be," in considering the tentative plans, will look at them from a business, rather than from an engineering, standpoint, and all statements must be well substantiated in order to secure an appropriation equal to the estimate. It is probable that from the several tentative schemes a definite general plan can be worked out, meeting all requirements and carrying the approval of the owners of the plant.

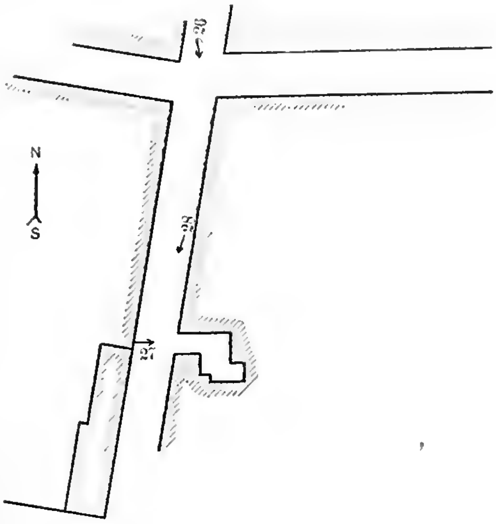
After the general plan is decided upon, the definite instructions and detailing should be rushed hard if the extensions are needed quickly, as it is economy to spend a couple of thousand dollars (on a large proposition) in correcting minor errors, if, by so doing, the plant may be in operation a month or two sooner. This latter statement should not be construed as advocating careless design, but the author does not believe in spending an excessive amount of valuable time altering and checking drawings where the monetary factor is small.

After a resumé of the items of data required and their bearing on various problems, an epitome of the leading features of recent plants will be given. The planning and construction of a large plant will then be taken up in detail.

Data Required for Planning Shops.

The following items of data have been found either a necessity or a convenience in planning alterations and in laying out new plants. In the first place, an engineer's plat of all the space within the property bounds is required. This plat should preferably be made by the city engineer's staff, or by a firm of civil engineers which can be held responsible for the accuracy of the work done, and which also is in touch with the city engineer's records and can derive exact information from deeds and records. The scale of the plat should be 1/32 inch to a foot, or some multiple of 1/32 inch. Many civil engineers will object to this requirement, as it necessitates a departure from their usual units of measurement, but their unit of a tenth of a foot is not adapted for construction work. If the total space cannot be covered by one sheet, approximately 36 x 48 inches, the plat should be made in sections. If made in sections, a street line or a witness line, not cutting any buildings, should be made the division line between the sections. For desk use, a photograph of the entire plat should be made, as it enables one to have all leading features and dimensions of a piece of property in a very convenient form for study.

The plat should show: 1. The owner's property limits. 2. The adjacent property limits and owners. 3. The block outlines of all buildings, and dimensions of the buildings outside of pilasters. 4. Accurate tape measurements between the various buildings and at all critical points. 5. Leading dimensions should all be referred to two base lines at right angles, one of these base lines paralleling the general trend of buildings. 6. Tracks should be shown with dimensions to nearest rail. 7. All municipal underground work in streets, such as sewers, water-pipes, gas-pipes, conduits, manholes, etc., should be shown in location, and their depths below the surface noted. 8. Grades or levels of floors, tracks, pits, streets, surfaces and beds of streams or ponds should be indicated. In a word, this plat should be sufficiently accurate to allow of larger scale drawings being made from it without prohibitive errors. Obviously, this plat is of most value in planning additions, as extensions can then be made without fear of encroaching on adjoining property; still it furnishes an accurate basis for comparison when designing a new plant.



Machinery, N.Y.

Fig. 2. Method of Recording Photographs on Plat.

A tracing should be made from this plat, and all underground pipes, sewers and also trackage on the owner's property should be added to the municipal underground work already laid out. Depths and location of these pipes can be obtained first from such drawings as may be available, and second by checking these drawings by boring with a 2-inch auger having an adjustable handle.

Space Data Required.

In making up details of space used for various purposes, it is better to have areas inclusive of walls, partitions and pilasters, so that the details may be totaled and checked against the gross area as obtained from the engineer's plat. The various divisions and sub-divisions of space required for the determination of the total occupied space for the extensions are indicated in the following lists. The number of square feet of floor space, and the number of men for each division must be ascertained, and from these figures may be obtained the number of square feet per man and the percentages of area of divisions compared with the space taken for machining.

Heights and spans of crane tracks affect somewhat the arrangement of space, but this will be considered later.

Methods of Keeping Data.

In order to have the data of existing plants in shape for pocket or desk use, the following sizes of sheets will be found convenient. For tabulated and other data for pocket use, Morden's loose-leaf book No. 6—pages 4 x 7½ inches—is suitable. Write with fountain pen ink on one side of the sheet. Many engineers of the author's acquaintance use books of this size, and, as the pages blue-print nicely, there is a possibility of an interchange library of data.

For desk use only, employ a loose leaf book 9 x 12 inches. This size enables one to bring together drawings 9 x 12 inches, photographs 8 x 10 inches mounted on muslin, and typewritten correspondence on standard 8½ x 11-inch letter sheets.

For drawings, sizes in multiples of 9 x 12 inches are used, as most reference drawings of details are of sufficiently large scale when drawn on 12 x 18-inch sheets, and this size sheet can be placed in a desk drawer.

For indexing photographs, use the extremely simple method of placing an arrow on an 8 x 10-inch photograph of the engineer's plat, indicating the position and direction of camera when the photographs were taken, and put the distinguishing number of the negative close by the arrow. See Figs. 2 and 3.

Fig. 3. Photograph Marked to correspond with Number on Plat.

Photograph Data Required.

The photographs required are: photograph of engineer's plat, interiors and exteriors of buildings, yard space, vacant space, trackage, prospective sites, and photographs taken during construction. These latter are invaluable in many respects. Without leaving his desk, the engineer can study and plan unhampered by the numerous questions asked in the field whenever he is in sight. The photographs will often give bits of information, or verify some little point that it would take a fifteen minutes walk to investigate on the ground. An engineering salesman can often be given a general idea of what is wanted before he is taken on the ground, making his mental impression doubly strong, and therefore securing his attention on even small matters Photographs are also incontrovertible evidence, many times, when differences arise and claims are made by contractors.

Drawings of Existing Plant.

Drawings of existing plant should preferably be made on sheets 12 x 18 inches. Simple elevations and sections of various buildings, showing door, window, and skylight spaces, crane tracks and galleries, together with plans supplemented by photographs of interior views showing walls, columns, partitions, etc., furnish a reference basis for problems of lighting, heating and headroom. Plans of wiring for cranes, power and lighting, and piping for steam, water, gas, and air, furnish data for definite conditions that hand-books could not begin to supply. Plans of shafting giving sizes, length of sections, location of hangers, used and unused sections, etc., will save their cost many times over.

Production Data.

The production of various departments per unit of space, per man, and in total, will often times show where departments are lame and what variations are necessary in establishing unit space figures. The nature and value of the various classes of product in relation to the space occupied should be considered, as the project of extension may be expected to increase the production of various classes of machines by different percentages. For instance, a plant building a varied line of tools will want to perfect and increase the production of the class for which there is the greatest demand, and in which there is the greatest profit. Production data are, naturally, confidential, and should not be kept with other data that may be accessible to the construction engineer's assistants. The average number of labor hours of each class of workmen per machine, the number of hours worked per day, the number of square feet of floor space per man, and the number of machines to be built, will afford data for the planning of improvements if the problem is stated from a production basis rather than as a percentage increase of men and space. Dimensions and weights of the largest and heaviest pieces produced help to determine the capacity and headroom necessary. Maximum heights and widths of loaded flat cars that will be accepted by the railroads will give the minimum height of lintels of doorways through which the largest pieces are shipped.

Expense Data.

The costs of handling materials, and other expense items, should be carefully collected, as successful overgrown plants generally are carrying an overhead expense that can be materially reduced when the business is established in a new plant. This reduction of overhead expense is often the principal factor in increasing the productive efficiency of a new plant, as the production per producer is high, correlative to the fact that the overgrown plant has been, generally, successful.

The problems in reducing expenses are generally of two classes, first, to lessen manual labor, and, second, to increase the efficiency of apparatus used in work chargeable to expense accounts. The importance of knowing these costs is shown by the following data from a plant employing 1,000 men: The cost of handling pig iron per ton is 23 cents; coke, 42 cents; sand, 40 cents; coal, 10 cents; and bar steel and billets, 90 cents. The total for these five items per year amounts to over $7,000, and a saving of 50 per cent can be made by installing efficient apparatus in a new plant. As many conservative managers believe that a saving of laborer's wages of $600 per year justifies the expenditure of $5,000, this saving of 50 per cent on $7,000 alone would justify an expenditure of $30,000. The heating of this same plant costs $6,000 per year, and a saving of $4,000 per year can be effected in a new plant with proper apparatus.

Power Data.

The cost of coal, supplies, water, and attendance, also the capacity and efficiency of engines, generators, boilers, condensers, transmission lines, shafting, belting, etc., should be found, and costs of power obtained under the varying conditions of day and night operation, busy times and bad times. This information will aid in settling the question of increasing or changing the power plant.

Construction Data.

Local prices of materials entering into construction, and cost of labor in the building trades, should be obtained early, as it will take some time to check and verify them sufficiently for use in close estimating. The various items of material that will be used in large quantities are as follows:

Foundation Work.—Cement; crushed rock; sand; reinforcement steel bars; expanded metal; water-proofing compounds, such as "Medusa"; lumber for form work.

Framework.—Structural steel work erected per ton; trusses; girders; columns; bracing; floor plate.

Walls.—Plain brick; face brick; bull nose brick; cut stone sills; tile coping; window frames, single, double, and triple; windows per square foot.

Roofing.—Purlins; sheathing; gravel or slag roofing; skylights per square foot; tin and copper flashing per square foot; galvanized iron and cast iron down spouts.

Floors.—Sleepers; under planking; maple top flooring.

Underground.—Piping; tile and iron sewer pipe; galvanized and black standard wrought iron pipe; electrical tile conduits.

The above heads will also serve as a guide in obtaining costs of labor. Any architect who has had experience on this class of buildings can give unit prices both of material and labor, though an engineer on good terms with contractors can obtain more definite data on labor costs.

The number of working hours per day, and the average working days per year (this latter data should be taken for a number of recent years), together with the amount of work done per day by bricklayers and carpenters, comprise the data for estimating the time necessary for the completion of the buildings.

Equipment Data.

The class and capacity or size of tools pertaining to the different lines of product, should be listed and compared with the amount of product, as this will give an idea of the necessary new equipment. The speeds and power consumption of machines will be needed in determining size of motors for group driving, and also for individual motor drive. The percentage of tools running and the power consumption for the same will give figures from which may be deduced the new power plant requirements. The data of floor space occupied by the various tools are in the best shape for future use in the form of "dummies," cut from heavy cross-section paper to a scale of 3/16 or 1/4 inch to the foot, and including the necessary clearance space for withdrawing shafts, etc. These dummies, when laying out the location of the tools, are moved around on a floor plan drawn on the same scale cross-section paper. The cross-section paper facilitates the arrangement, as definite widths of gangways and clearances between tools, walls, columns, etc., are easily maintained.

Derivation of Base Units.

That, from the known floor space per man as a base unit, a modern highly efficient plant with but few buildings can be built to take care of the production of a large number of miscellaneous types of old buildings, is shown by the comparative tables, I to IV. Table I is made up from figures derived from all of the old buildings of the Allis-Chalmers Co. The intention was to build a new plant of approximately the same productive capacity as that of the combined old shops, and to have this new shop susceptible of methodical extension. The number of men in the machine shop and erecting spaces in the old shops are considered together, on account of the difficulty of allotting any definite amount of space per man to the erectors, the erecting space being a function of the space covered by the machine being set up, and of the time taken for its erection, rather than of the number of men. Approximately one-third of the number of men, together with the unit space figures per man, was taken from Table I to form a unit (Table II) better adapted for use in planning the four main buildings of the new plant. The machine shop space in Table III is but two-thirds of that in Table I, while the erecting space is approximately the same. The smaller floor space in the machine shop is due to the fact that the modern equipment with its high efficiency was expected to increase the efficiency of the machine shop about 50 per cent. Table IV is derived from Table II, and is placed side by side with it to make comparison easy.

BRITISH MACHINE TOOLS AT THE FRANCO-BRITISH EXHIBITION.

OSKAR KYLIN *

In the English machinery section of the Franco-British Exhibition, which is now in progress in London, a few of the English machine tool manufacturers are presenting some types of their, generally, many different designs. Although not all of the machines exhibited, by far, possess any radically new features attracting the attention of the visitor, they still give a very good example of the present state of the English machine tool manufacture, and the general lines along which English makers are at present designing and building their tools. For this reason, a selection of some of the machines exhibited will undoubtedly prove interesting to American readers.

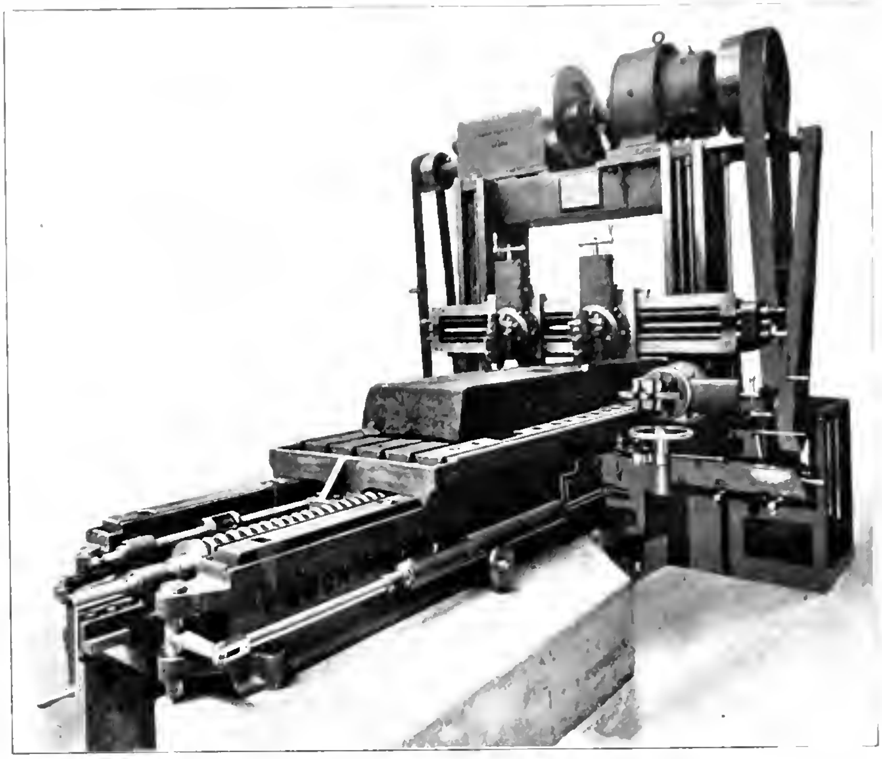

Fig. 1. Buckton & Co. Regenerative Reverse Planer.

Buckton Regenerative Reverse Planer.

Fig. 1 of the accompanying illustrations shows a heavy duty planer built by Joshua Buckton & Co., Ltd., Leeds. The difficulties of driving and reversing a heavy planer at a high speed without the consumption of excessive power is well known, and has been one of the most important problems in planer design since the introduction of high-speed steel. On account of the reciprocating motion, there is a large amount of kinetic energy which must be absorbed and redeveloped at each stroke. This absorbs an amount of power which was not determined until electric drives made its measurement possible. The sudden jump of the ammeter needle at the

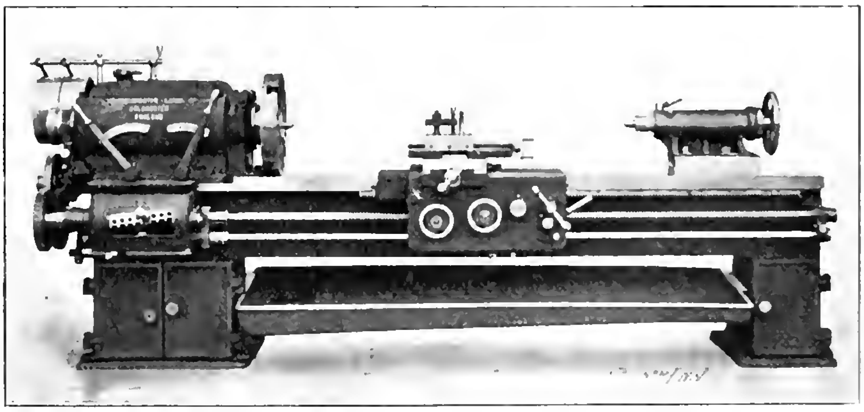

Fig. 2. Colchester Geared Head Lathe.

---

* Foreign Traveling Representative of MACHINERY.

point of reversal of a planer is well known, and every attempt to reduce the power consumed deserves consideration. The principle underlying the design of the Buckton planer is that of balancing the forces by recoil springs. These springs absorb a large amount of energy, and when the planer reverses, they restore, during the moments of acceleration, the energy which would otherwise be wasted. The planer shown is provided with a motor, the power of which need only be great enough for taking the cut, there being no overload on the motor during the return stroke, although this is at the rate of 180 feet per minute. In the illustration, a large steel ingot is placed on the table; it is claimed that the weight of the work has no measurable effect upon the accuracy with which the planer is reversed.

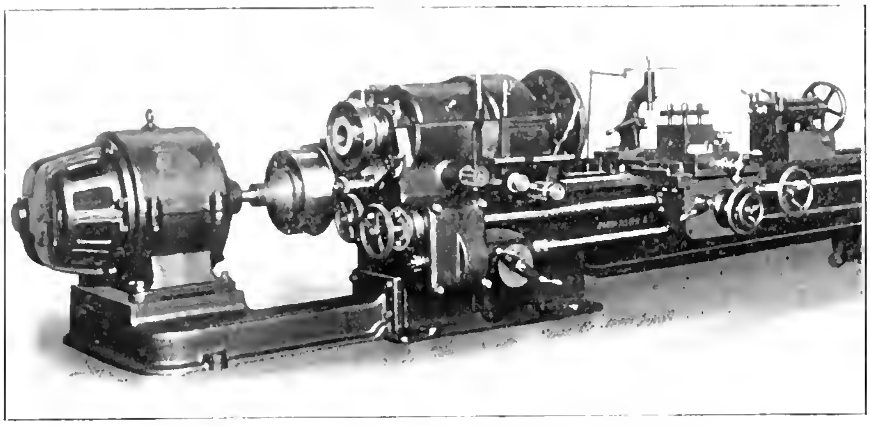

Fig. 3. High Speed Lathe built by John Stirk & Sons.

The illustration plainly shows one of the recoil springs with which the planer is provided; another spring is placed in a similar position at the other end of the machine. During the stroke, the springs remain in the position shown, and abut against one of the cross bars of the bed. Two screws pass through these springs, and extend the whole length of the bed. On these screws are placed heavy adjustable bronze nuts, and against these nuts impinge brackets attached in fixed positions to the underside of the moving table, the impact being transmitted to the springs through the screws and suitable collars. By altering the position of the nuts upon the screws, any required length and position of stroke may be obtained; the minimum length of the stroke is 12 inches. There is nothing required for the changing of the length or position of the stroke except to turn the screws around so as to bring the nuts to the required location. The stroke can be adjusted while the machine is running. It will be understood that while the return stroke of the machine takes place at a constant speed of 180 feet per minute, the cutting stroke can be varied by means of change gearing, the slowest cutting speed being 20 feet and the fastest 60 feet. In spite of the fact that the forward and return speed thus vary in the ratio of from 9 to 1 to 9 to 3, yet no adjustments are required for the spring action when using the fastest or slowest cutting speed. This is very important, because the danger in planers provided with spring buffers of any kind is that the amount of overrun is uncertain, and there is a danger of injuring the tool when planing up to a wall. It is claimed, however, that with the Buckton planer, under any circumstances, 1/8 to 3/16 inch is ample clearance.

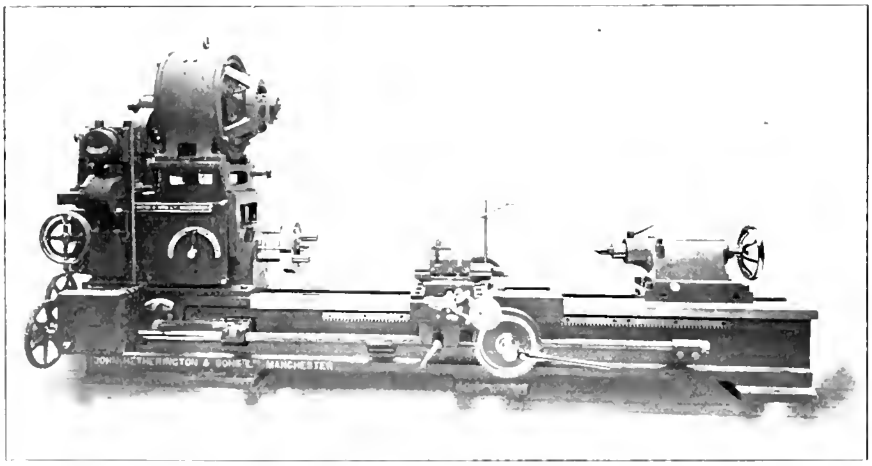

Fig. 4. John Hetherington & Sons High Speed Lathe.

Modern British Lathe Design.

The Colchester Lathe Co., Hythe, Colchester, exhibits a few lathes of which Fig. 2 represents the largest and most interesting one. The new patent geared head gives 18 spindle speeds which are obtainable by manipulating the levers conveniently placed for the operator. The mechanism consists of thirteen steel gears. In order to avoid all possibility of accidents, due care has been taken in the design of the head-stock so that it is impossible for more than one pair of gears to be in mesh at the same time. The driving pulley is 12 inches in diameter, and runs at a constant speed of 400 revolutions per minute. The head may be driven either direct from the main line shaft or coupled direct to a motor. One feature is that the carriage is made especially long, and is guided by a projecting strip or way which runs along in the front of the bed. This, the builders claim, makes it much easier to move the carriage, and eliminates the side strains which are present when the carriage is guided along the bed in the usual way. The number of feeds obtainable through the feed box shown in the illustration is 32, ranging from 0.125 to 0.008 inch per revolution. When the lathe is used for thread cutting, thirty-two different pitches of screws can be cut, ranging from 2 to 30 threads per inch.

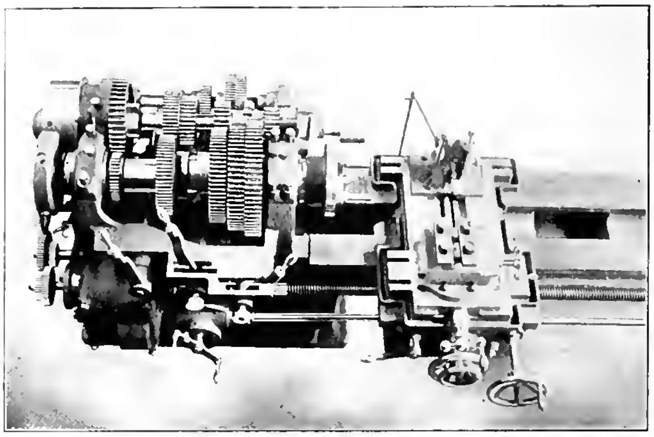

Fig. 5. The Head-stock and Carriage of Lathe shown in Fig. 3.

In Fig. 3 is shown a 20-inch high speed lathe built by John Stirk & Sons, Halifax. The engraving shows the machine direct connected to a 30-H.P. motor, but it can also be belt driven direct from the line shaft, the only change required being to remove the motor. The pulley shown in the illustration between the motor and head-stock is employed in this case. The lathe, of course, is provided with geared head, permitting sixteen changes, giving spindle speeds from 10 to 250 revolutions per minute. As will be noticed from the engraving, the head-stock is cast in one piece with the bed for the sake of obtaining great rigidity. In Fig. 5 is shown the head-stock and carriage of this lathe, the cover over the geared head being removed so as to show the arrangement of the gearing. The feeds are all obtained from the gear box shown at the front of the bed below the head in Fig. 3.

John Hetherington & Sons, Ltd., Manchester, exhibit the 28-inch lathe illustrated in Fig. 4. The bed is made of a strong box section with two flat ways on the top provided with T-slots for locking the carriage and tail-stock. The

sliding rest is designed to swivel completely around, and is well secured to the carriage by three binding bolts. The geared head is driven by a direct connected motor mounted on the top of the head-stock. The machine, however, can also be driven direct from the line shaft. The number of spindle speeds obtainable is 24, arranged in geometrical progression.

Alfred Herbert, Ltd., Coventry, Exhibit.

The part of the machinery section of the exhibit which has the most of interest to offer to the visitor is the exhibit of Alfred Herbert, Ltd. This famous English machine tool company presents a few of the types and sizes built. The machines are interesting, perhaps mainly because of the high class workmanship and their capacity in regard to output. The three different types of turret lathes built by the firm, the hexagon, the combination, and the capstan, are well represented by different sizes, and in order to give an idea of the class of work of which these machines are capable, samples of work are also exhibited. The representative machine of the turret lathe class is the No. 2 hexagon turret lathe which was illustrated and described in the March, 1907, issue of MACHINERY. Another machine exhibited by the firm is illustrated in Fig. 6, and represents the line of automatic turret lathes built. This class of machine is intended for working upon individual pieces of castings or forgings, or blanks previously cut off. The work is chucked by hand, but all the operations performed on the work are automatic, including the stopping of the machine at the completion of its cycle of operations. The head is driven by gearing and is exceptionally powerful. The pulleys provide either a two-speed automatic change, or a forward and reverse motion according to the requirements of the work. The turret slide is adjustable to four positions, according to the length of the work operated upon, the turret slide drum having a corresponding adjustment. The turret has five faces, and is provided with a rigid over-head support. The cross slide in this machine is particularly wide, the object being to provide plenty of room for the tool-holders of various types, at both front and back.

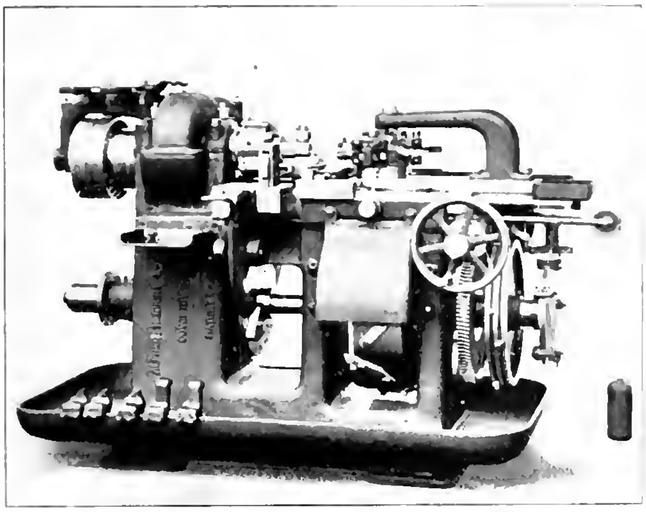

Fig. 6. Alfred Herbert, Ltd., Automatic Turret Lathe.

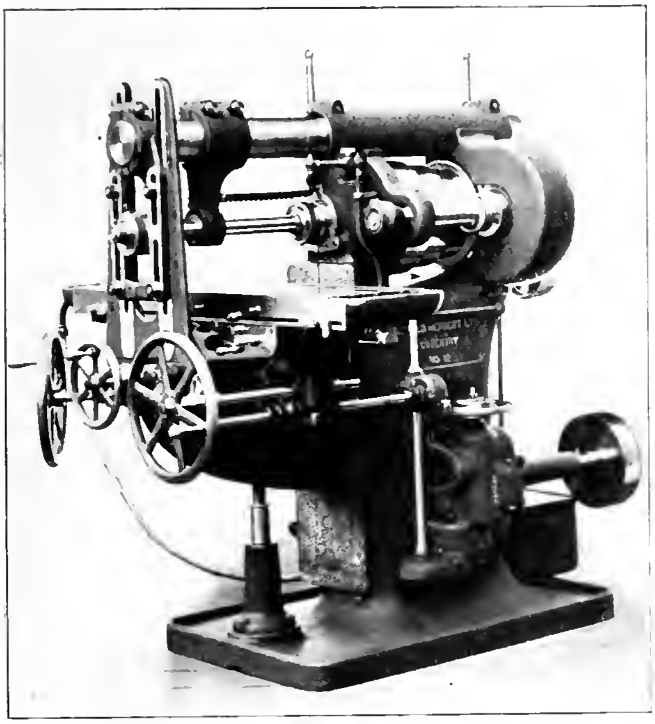

Fig. 7. Horizontal Plain Milling Machine, built by Alfred Herbert, Ltd.

The firm of Alfred Herbert is further exhibiting some vertical as well as horizontal types of milling machines. The engraving, Fig. 7, shows the horizontal plain milling machine on exhibition; the firm does not built universal milling machines. As seen from the illustration, the machine has cone pulley drive with double back gearing, permitting a great range of spindle speeds. The feed changing is accomplished by means of the Herbert patent dial feed motion of similar construction to the one used on the turret lathe and shown on the side of the column in the engraving, and the feed can be driven either independently or from the spindle. The firm recommends strongly the use of the independent drive for the feed. There is a drawback to driving the feed from the spindle, because the range of feeds becomes insufficient for the slowest and fastest spindle feeds; for instance, for slow speed and large cutters, the feed cannot be obtained coarse enough, and for high speed and small cutters it cannot be obtained fine enough, at least for certain classes of work. By driving the feed independently, however, from the counter-shaft, this drawback is eliminated. The whole machine is operated from the front and does not require the at-

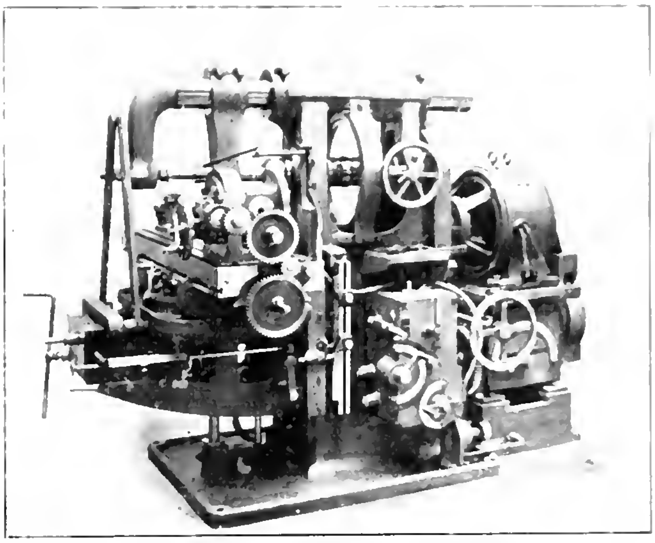

Fig. 8. Hetherington Universal Milling Machine.

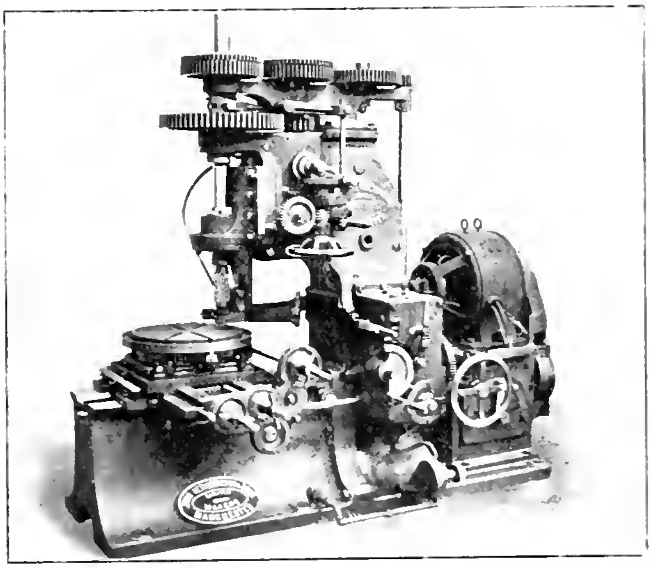

Fig. 9. Hetherington Vertical Drilling and Milling Machine.

tendant to change his position and go around to the back. All the movements are governed by hand-wheels of sufficient size to permit easy action. It will be noted from the illustration that the drive of the feed from the gear box to the knee is not by means of the ordinary telescope tube shaft and universal joints, but by means of shafts at right angles.

The John Hetherington Exhibit.

We have already mentioned the geared head motor-driven lathe exhibited by John Hetherington & Sons, Ltd., Manchester. In Figs. 8 and 9 are shown two heavy duty milling machines exhibited by these makers. These machines are both of exceptionally heavy and powerful design, and are particularly intended for heavy work. As shown in the illustrations, these machines are driven by independent motors, but they are also built to be driven by constant speed belts and tight and loose pulley. The universal milling machine shown in Fig. 8 is provided with a geared drive, the spindle having 16 speed changes which are obtained by means of an index hand-wheel and levers. The feed motions are reversible and automatic, both for the vertical, traverse, and longitudinal motions. The feed change is executed by indexing levers giving a feed variation of eight feeds to each spindle speed.

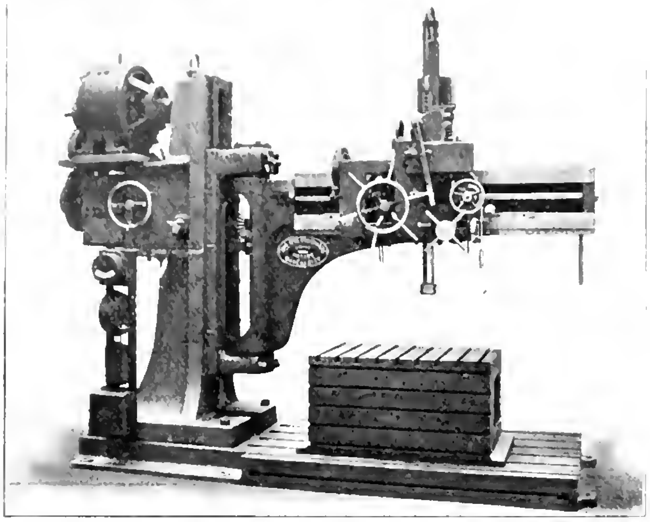

Fig. 10. High Speed Radial Drill, built by John Hetherington & Sons, Ltd

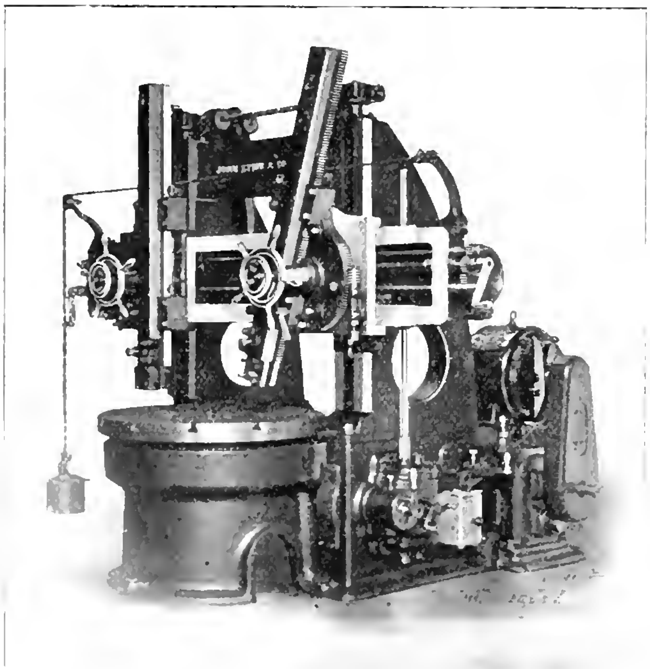

Fig. 11. Forty-eight-inch Vertical Boring and Turning Mill, built by John Stirk & Sons.

On the [illegible] milling and drilling machine shown in Fig. 9 also 16 different spindle speeds are provided, and there are also [illegible] feed variations to each spindle speed. In addition to the motions required for milling, there is also a positive and continuous drilling feed giving a variation of three feeds to each spindle speed.

This firm also exhibits the radial drill shown in Fig. 10. This machine is driven by a 14-H.P. motor, mounted as shown in the illustration, but, of course, can also be driven by a constant speed belt. The cone box for changing the spindle speeds without stopping is operated by the index hand-wheel shown in the front of the frame under the motor. The spindle is fitted with clutch reverse motion, and with speed changing device for reducing the speed for tapping. The machine is also provided with a quick hand traverse for running the spindle to and from the work. The radial arm is supported on a ball bearing and can swing through an arc of 180 degrees, the minimum radius being 3 feet, and the maximum 7 feet.

John Stirk & Sons' Exhibit.

In Fig. 11 is illustrated a vertical boring and turning mill manufactured by John Stirk & Sons, Halifax, builders of the high speed lathe already described and illustrated in Figs. 3 and 5. This 48-inch vertical boring mill is driven by a direct connected 13-H.P. motor. The tool-holders are provided with swiveling slide and counter-balancing arrangement; independent automatic positive feeds are provided for each of the two slides, nine changes of feed being obtainable in any direction. The drive of the machine is through a gear box giving eighteen changes of speed, the final motion to the table being through a multiple thread worm and gear; this ensures a perfectly steady drive. The table speeds vary from approximately 1 to 50 revolutions per minute. The general design of the machine throughout is typically English.

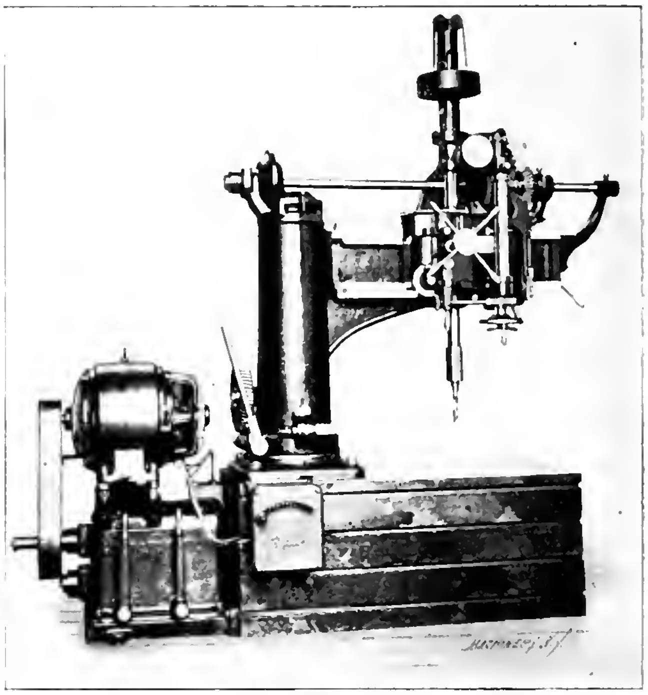

Fig. 12. High Speed Radial Drill, built by John Stirk & Sons

The same firm is also exhibiting the radial drill shown in Fig. 12. This machine is designed especially for the use of high-speed drills, and is driven by a direct connected 13-H.P. motor. The arm can be swung around on a pivot of large diameter in a complete circle. When in its lowest position, it rests on steel balls, but it can be raised 12 inches if required. The carriage is moved on the arm by rack and pinion in the usual manner. The reversing motion consists of a combination friction and positive clutch of unique design for which patents are applied for. The drive is through a gear box, giving nine changes of speed, which can be operated without stopping the machine. A back gear arrangement on the carriage doubles the number of speeds to 18, varying from 13 to 560 revolutions per minute. The gear box forms a receptacle for oil, the gears thereby running constantly lubricated. The manufacturers guarantee that this machine will drill one-inch diameter holes in mild steel at a rate of 9 inches feed per minute. The approximate weight of this machine, including the motor, is 10,000 pounds.

GEAR-CUTTING MACHINERY—9.

RALPH E. FLANDERS.[*]

This, the concluding installment of the series of articles on gear-cutting machinery, continues the discussion of methods of cutting bevel gear teeth with special reference to machines which act on the molding-generating principle.

Molding-Generating Machines Employing the Milling Operation for Cutting the Teeth of Bevel Gears.

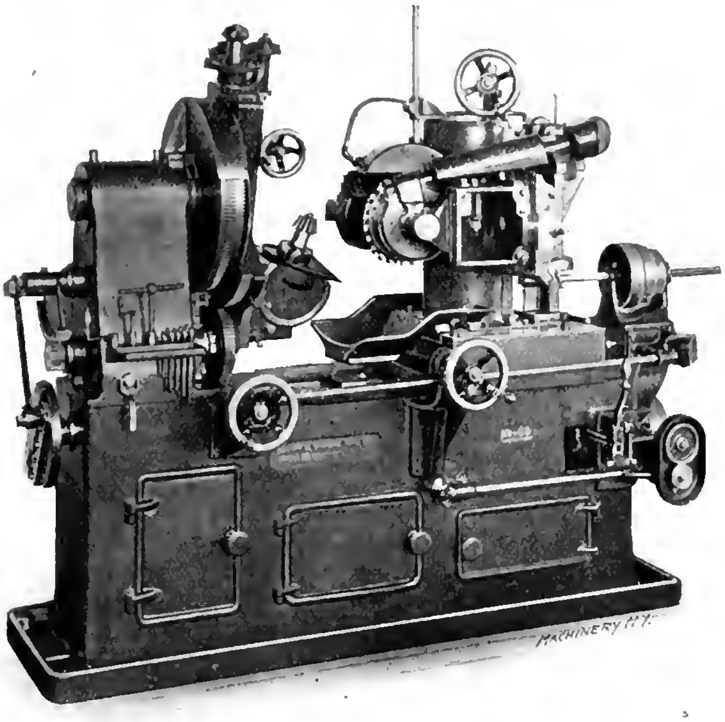

Fig. 171. Brown & Sharpe Bevel Gear Generating Machine, cutting the Teeth by the Use of Interlocking Milling Cutters of Large Diameter.

One of the most interesting and ingenious of all the machines for cutting the teeth of bevel gears is that shown in Fig. 171. It operates on the principle shown in Fig. 140, in which the sides of the crown teeth are represented by the plane faces of milling cutters. In this machine the milling cutters and the imaginary crown gear remain stationary so far as position is concerned, though, of course, the cutters revolve about their own axes. The work is held in the spindle of a head (resembling the universal head of the milling machine) which is mounted on the slide of a swinging sector at the left, which sector is rocked about a horizontal pivot in line with the axis of the imaginary crown gear. The work spindle and the rocking movement of this sector are so connected by change gearing that, as the latter is oscillated through a sufficient angle to generate the teeth, the work is rolled in the proper ratio to mesh with the imaginary crown gear, a tooth of which is represented by the milling cutters. This movement, referring to Fig. 139, is thus seen to be identical with the case in which the crown gear is stationary, while the frame is rocked, rolling the master gear on the crown gear, and the work over the tool.

The cutters used are of large diameter in proportion to the work for which the machine is intended, in order to minimize the deepening of the tooth space at the center which is characteristic of a gear cut in this way, as was explained in connection with Fig. 140. It will be seen that the teeth of the two milling cutters are set so as to interlock. In this way comparatively stiff cutting blades may be made to represent a complete crown gear tooth of very fine pitch.

The machine is universally adjustable within its range. The cutter spindles may be set to give teeth of greater or smaller pitch, and to work with gears of large or small pitch cone radius. They may also be adjusted for teeth of greater or less angularity than the 14½-degree standard involute generally used. The details of the mechanism of this machine are very interesting, but there is space here only for this description of its action. The Brown & Sharpe Mfg. Co., Providence, R. I., is the builder.

In Figs. 172 and 173 are shown views of two sides of the Warren bevel gear generating machine, first developed and built, if the writer's memory serves him, by the Pratt & Whitney Co., of Hartford, for the manufacture of chainless bicycle gears. The machine we show, however, is a design built for general manufacturing use by Ludwig Loewe & Co., of Berlin, Germany. This machine is approximately similar in its action to the one built by Brown & Sharpe, and just described. Aside from the differences in the mechanism, however, there are two important differences in its action. One is the fact that the two cutters do not cut on opposite sides of the same tooth, but on facing sides of alternate teeth, leaving a whole tooth untouched between them. The independent slides in which they are set are so arranged as to allow the plane cutting face of the cutters to be set to agree with the corresponding faces of the imaginary crown gear. The other difference is the means taken to cut a tooth space having a straight bottom, with cutters of small diameter. This is done by making the rolling of the cutter holder and the blank on each other a continuous rocking movement at a quite rapid rate. During this rapid rocking, the cutter slides are fed inward on their respective guides to form the sides of the particular teeth at that time presented to the cutters.

The cutter slides and guides are mounted on a circular head, which is rocked about the axis of the imaginary crown gear by the slotted crank and link seen at the side of the machine in Fig. 173. The upper end of this circular slide carries a segment of a crown gear, which meshes with the corresponding segment of a master gear on the work spindle, this arrangement being very similar to that of the Gleason machine shown in Fig. 170. The work and the cutters being thus rapidly rocked about each other while the cutters are slowly fed down through the tooth spaces, the sides of the teeth exposed to the action of the cutters are properly formed to the theoretical tooth curves. As in the previous case, there is no space here to go into the ingenious construction of this machine, with its provision for

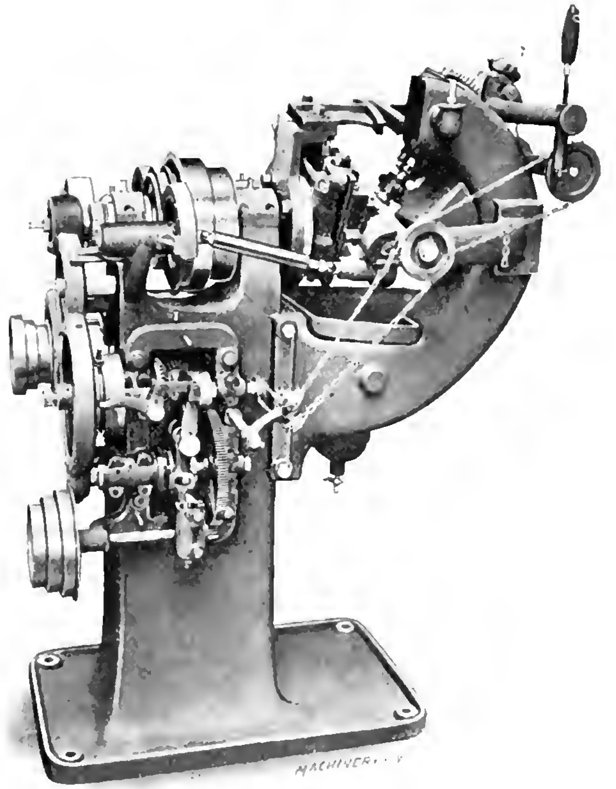

Fig. 172 The Warren Bevel Gear Generating Machine as built by Ludwig Loewe & Co., Berlin.

---

[*] Associate Editor of MACHINERY.

automatically effecting all the movements for rocking the cutter slides and the blank, feeding downward and returning, indexing, etc. nor for following out in detail the various adjustments provided for cutting gears of all kinds within the range of the machine.

Bevel Gear Cutting Machines using a Hob and Operating on the Molding-Generating Principle.

While the hobbing principle is easily and simply applied to the cutting of spur and spiral gears, as illustrated in Figs. 50 and 96, it requires but little thought to show that the application of the same principle to the cutting of bevel gears is a difficult, if not hopeless, task. Nevertheless, this problem has been attacked in two different directions. The principle of the mechanism and tools employed, however, requires to be studied with greater care than in the case of any of the machines we have previously described, if the reader is to have a clear understanding of their method of operation. The first of the two processes is that developed by M. Chambon, of Lyons, France. The operation of the machine is dependent on the principle of the hob, whose generation and finished form are illustrated in Figs. 174 to 178, inclusive.

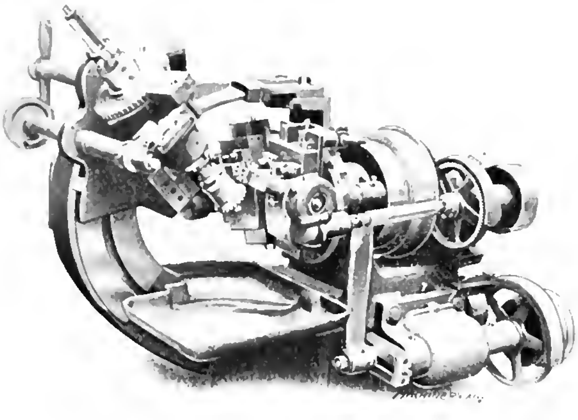

Fig. 173. The Working Side of the Warren Machine showing the Milling Cutters whose Plane Surfaces represent Sides of Adjacent Crown Gear Teeth.

In Fig. 174 is shown the basic principle of the molding-generating process applied to the cutting of bevel gears, identical in its essentials with the mechanism shown in Fig. 139, with the exception of the fact that a hob is used as a cutting tool, instead of a reciprocating planer tool. At the left of the engraving a face view of the crown gear is shown. The width of the top of the tooth at the outside diameter is W, at the inner end of the tooth w. A hob may be made, such as No. 1, having teeth whose shape on a normal section EF exactly matches the same section of a tooth of the crown wheel when the teeth of both are centered on line CD, and the hob is set at the helix angle θ. Under these circumstances, a tooth of the hob would have a width W at the top. If the hob is single-threaded, and the crown gear has, for instance, 24 teeth, the two may be revolved together, the hob making 24 revolutions to one of the crown gear. Then this tooth of the hob, which comes into action at the time it is central with line CD, will exactly match the outline at the larger end of each of the teeth of the crown gear in turn, as it revolves. To have a hob which would similarly match the teeth at the smaller or inner end, we could construct one of the same diameter and of smaller pitch, smaller helix angle θ', and a corresponding width of flat, w, at the top of the tooth, all to correspond with the shape of the inner end of the crown gear tooth. It also should revolve in the ratio of 24 to 1 with the crown gear, and the tooth which comes central with the line CD at each revolution may be made to match accurately with the outline of the inner end of the tooth. In the same way, hobs may be made to be used at any intermediate point in the length of the tooth of the crown gear, so that one of the cutting edges will match the outline of the tooth at this point, once for every revolution of the hob. The problem is to construct a single hob which will do the work of hobs No. 1 and No. 2, and of all possible intermediate hobs between the two positions.

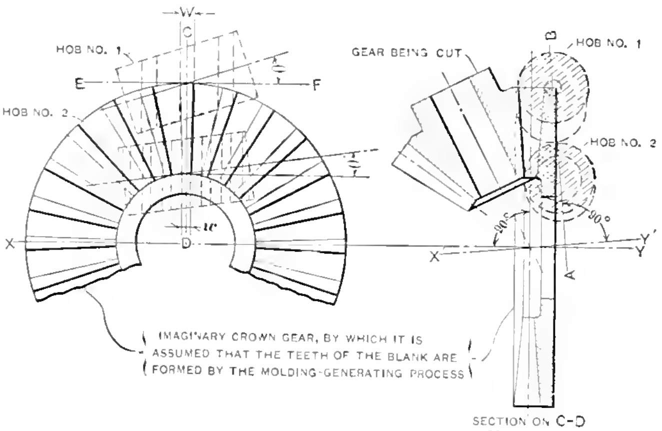

Fig. 174. Diagram showing the Possibility of Representing a Crown Gear Tooth by Teeth in a Series of Hobs of the Same Pitch Diameter, but of Varying Lead and Helix Angle.

In Fig. 175 the two hobs of Fig. 174 are shown enlarged. As previously explained, they are of the same diameter, with the normal width at the top of the teeth W and w, the same as that of the large and the small ends of the tooth of the crown gear, and with the leads of each, P and p, as required by the pitch of the large and small ends of the teeth. This gives corresponding angles, θ and θ' in the two cases. At T and V are shown axial sections of the thread for hobs Nos. 1 and 2. Since T and V correspond to the large and small ends of the teeth of a crown gear, the widths W' and w' are proportional to the leads P and p, and the angle of inclination of the sides, ϵ, is the same in each case. What we have to do now is to combine Nos. 1 and 2 into a third, which will do the work of both of the previous ones.

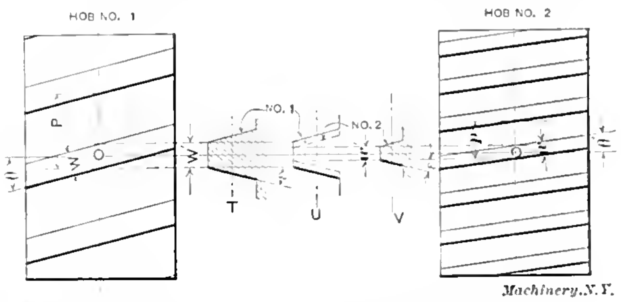

Fig. 175. Comparison of the Hobs representing the Large and Small Ends of the Crown Gear Tooth in Fig. 174.

Suppose we take a blank of the same diameter as the two hobs in Fig. 175 and thread it first with the same shape and pitch of thread as for No. 1, and second with the same pitch and shape as for No. 2, except that while the width of the top and the inclination of the sides remain the same, the cut will be carried to the full depth required for the thread of No. 1. As shown at U, in Fig. 175, the dotted section of No. 2 is the same as for V, except for its increased depth. When the hob has been thus threaded, the developed circumference at the point where the tops of the two threads cross each other will be shown in Fig. 176. Here lines FC and AH represent the top of thread No. 1, inclined at the threading angle θ as determined by the pitch, while the space included between lines AG and EC correspondingly represents the top surface of thread No. 2, inclined at angle θ'. These two threads have widths at the top of W and w, proportional to the pitch as before. The center lines of the tops of the two threads cut in the blank cross each other at point O. The top of the thread is seen to be cut in a parallelogram $ABCD$, this being the metal left after the grooves for the two different

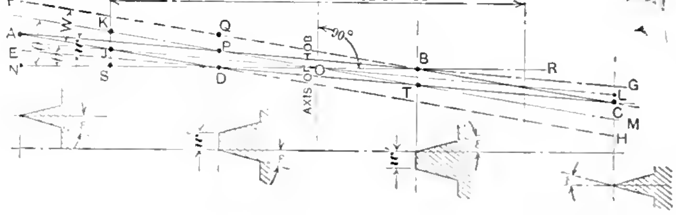

Fig. 176. Development of the Thread of a Hob of the Same Diameter as in Fig. 175, in which have been cut the Two Threads of the Two Hobs there shown

threads have been cut. Axial sections of this remaining fragment of the thread are shown on lines *FN*, *QD*, *BT* and *CH*; as may be seen, the inclination of the sides of the thread, as measured on an axial section at each of these points (and at all other points as well) is made ϵ.

A short hob, threaded as in Fig. 176, is shown in Fig. 177. Similar points in each figure have similar letters. Since the two sides of the teeth, which unite in point *B*, have the same inclination as measured on a plane passing through the axis of the hob, their intersection will also have the same inclination, and the line of intersection will pass through the axis of the hob. The same is true of point *D* on the other side of the thread. If the hob is gashed at *B* and *D*, the cutting edges thus formed are evidently common to both the large thread of width *W* and angle θ, and the small thread of width *w* and angle θ', and when properly set in the machine and rotated with the crown gear, the relation to the imaginary crown gear will correspond exactly to that gear in the position of either hob No. 1 or No. 2, in Fig. 174, the same hob thus taking the place of both.

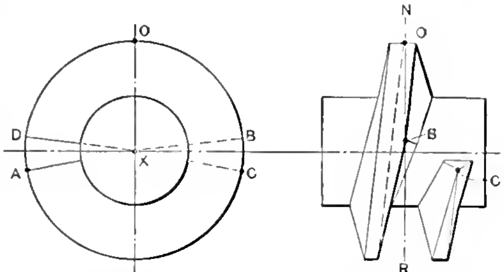

Fig. 177. Hob (ungashed) Produced by Combining the Two shown in Fig. 175; the Thread is the same as that shown Developed in Fig. 176.

It next remains to be shown that these two cutting edges at *B* and *D* in Fig. 177 can be made to correspond with all the sections of the crown gear intermediate between the large and the small ends in Fig. 174.

To prove this, we have to show that the sides of any thread cut in this hob with a center line passing through *O*, whose width of top and lead are in the same proportion as in Fig. 175, and whose sides have the same inclination as measured on an axial plane, will include the cutting edges *B* and *D*, which we have formed as described in the hob in Fig. 177. In Fig. 176 any thread of the given proportions, such as *FCAH*, will cut the horizontal line *NR* at *D*, in such a way that $OD : OS = DP : KS$. Now *DP* is half the width of the tooth on the axial section, and *KS* is half the circumferential pitch, so that $OD : OS = \frac{W'}{2} : \frac{P}{2} = W' : P$. But all the threads we are concerned with have this same ratio between *W'* and *P*, so that the sides of all of them cross line *RS* at *D*.

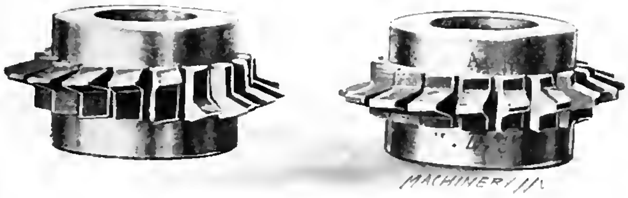

Fig. 178. The Completed Hobs as used in the Chambon Machine, Developed as shown in the Preceding Illustrations.

The same thing applies to the crossing at *B* on the upper side. The cutting edges, then, at *D* and *B* are common to all the hobs of the same diameter which will fill the required condition for the infinite number of sections between hobs Nos. 1 and 2 in Fig. 174.

In practice, the hob of Fig. 177, made as we have described, is gashed throughout the full length of the thread, as well as at the cutting edges *B* and *D*. Such a hob is shown in two positions in Fig. 178. The edges *B* and *D*, however, are the ones which are relied on to give the true shape to the teeth of the gear.

The next problem, and a somewhat complicated one, is that of providing a machine which will utilize this hob, in accordance with the principles of its construction, to take the place of the imaginary crown gear of Fig. 174 in generating teeth in a bevel gear blank. In the first place, the hob must be moved from the position occupied by No. 1 to that occupied by No. 2, changing its angle continuously meanwhile from θ to θ' to agree with the change in helix angle due to the change of pitch as the tooth grows smaller. Next, the hob and the blank being cut must be rotated with each other, so that the hob revolves during one revolution of the gear as many times as there are teeth in the latter, the hob being supposed to be single-threaded. These two conditions are easily fulfilled, but there still remains a third. The two cutting edges we have made for the hob represent the sides of each tooth of the imaginary crown gear only when each tooth in turn is passing the center line *CD*. In order to have a generating action on the blank, the imaginary teeth of the crown gear must have a cutting action over a considerable angle about *D*, on both sides of the section *CD*. This may be effected by rocking the holder which carries the hob about center *D* in either direction, meanwhile rotating the hob to keep its thread in the proper relation with the teeth of the crown gear, as if the latter was stationary. In the machine this oscillation of the hob and its carrier about *D*, on each side of *CD*, takes place continuously, while the hob is being fed down from the position occupied by No. 1 to that of No. 2, and the rotation of the hob required by this oscillation (to keep the hob and the crown gear continuously in step) is superimposed on the other rotation in unison with the imaginary crown gear and the work, the two being combined by differential gearing of the same style as required for combining the movements in spiral gear cutting machines as illustrated in Fig. 97. When this is done, a cutting edge will be provided by the hob, closely paralleling the molding action of the crown gear as shown at the right of Fig. 174.

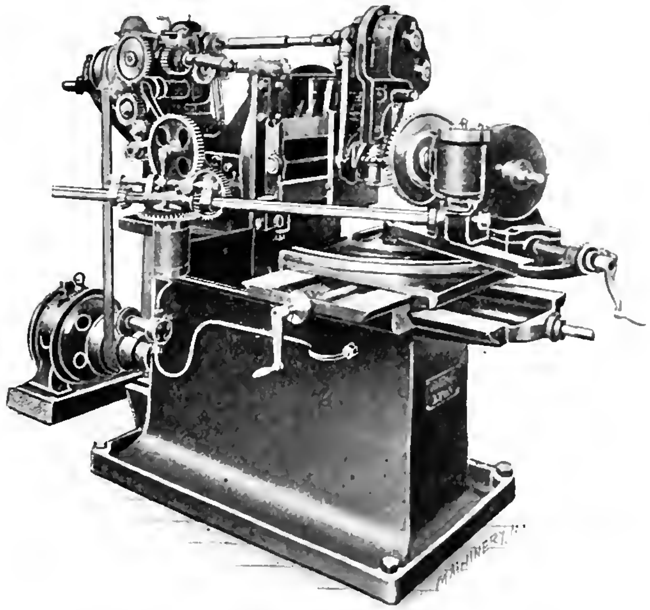

Fig. 179. The Chambon Continuous Bevel Gear Hobbing Machine, employing the Cutters shown in Fig. 178.

The machine for accomplishing all this is shown in Fig. 179. The work is mounted on an arbor, adjustable to any angle and to any axial position in relation to the hob. The spindle for the latter is mounted in a swinging carrier which slides on ways provided on the face of a head, which latter is oscillated about a horizontal axis. A suitable compensating movement is provided, so that this rocking movement is translated into the required rotary motion of the cutter, as was shown, to keep it from getting out of step with the imaginary crown gear, and for combining it properly with the constant rotation of the cutter, derived from its connection with the work-revolving mechanism. The spindle carrier feeds in along the ways of the oscillating head, being swung around by a templet as it proceeds, to change the helix angle θ as required. Suitable change gears are provided for all the movements, and one passing through of the continuously rotating hob finishes the gear complete. The mechanism is rather too

intricate to describe here in detail. A number of compensating movements are required, which add somewhat to its complexity.

We should not leave the discussion of this machine and its principle, ingenious though it is, without noting that the process involves a number of minor inaccuracies. For one thing, an error is introduced by the fact that in the machine the rocking of the spindle-head, carrying the hob, is about the axis *X′Y′*, instead of about axis *XY*, as it should be. (See Fig. 174.) This is doubtless done to avoid the complication of having to set the machine for the angle of the top of the crown tooth. The error introduced would be entirely negligible, except perhaps in the case of gears very closely approaching crown gears in their pitch cone angle. There are several other little discrepancies which, however, are scarcely worth taking into account.

In Fig. 180 is shown another machine operating on the Chambon plan, built by the Société Suisse pour la Construction des Machines-Outils Oerlikon, Oerlikon près Zurich, Switzerland. This machine employs the cutter in Fig. 179, but the mechanism is very much simpler, since the oscillating head and the connections required for operating it have been abandoned, the spindle slide being mounted directly on fixed ways on the front of the column. For this reason the generating action is not, it will be seen, fully carried out, the cutting action, however, resulting in the production of a groove tapering properly from the large to the small end and of approximately the correct shape. The machine is thus especially adapted to roughing blanks previous to finishing them in a planing machine operating on the templet or molding-generating principles. It is claimed to do its work with great rapidity, and to be capable of leaving a very small and uniform amount of stock over the whole area of the sides of the tooth.

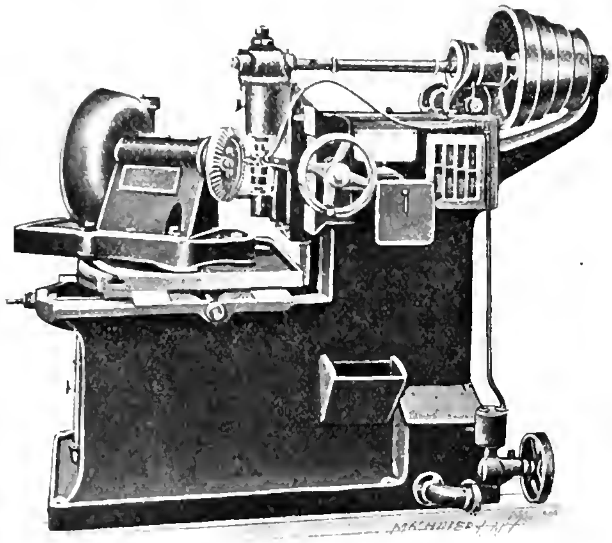

Fig. 180. The Chambon Bevel Gear Hobbing Machine as Developed by the Oerlikon Co., particularly adapted for Roughing Bevel Gears Preliminary to Planing.

Besides this Chambon process, another and, it seems to the writer, a fruitless attempt, has been made to cut the teeth of bevel gears by the molding-generating principle with a hob as the cutting tool. This method is shown in its principle in Fig. 181, the construction being referred to the imaginary crown gear and the bevel gear to be cut, as in the previous case. Also, as in the previous case, the action hinges about the design of the hob. Here we have a hob of such a taper, and with the pitch continuously decreasing in such a ratio, that the helix angle is constant. This decrease in pitch is, of course, accompanied by a correspondingly uniform and proportional decrease in the section of the thread. In the machine the hob is so set (in the "first position," for instance) that the center line of the thread in the cutting position passes through center *D* of the imaginary crown gear. Here the width of the top of the hob tooth is *W*, corresponding to the desired width at the top of the imaginary crown gear tooth. In feeding, the hob is moved, without changing the angle of its axis, along line *EF*, so that when it arrives at the inner end of the face of the imaginary crown gear, that tooth that is on the center line *CD* will be so near the small end of the hob that it has the required width at the top, *w*, and the proper pitch, to agree with the small end of the tooth in the imaginary crown gear. In a similar way, all the intervening positions match up with the teeth of the crown gear on line *CD*.

In the machine for utilizing this hob (which has been referred to in a number of English papers and described in an American contemporary*), it is mounted on a slide which is adjustable to give the line of feed, *EF*, the angle for the conditions required, while, as shown at the right of Fig. 181, the spindle of the hob is set at such an angle that its pitch cone is tangent to the pitch plane of the imaginary crown gear. The feeding movement along line *EF* is so connected with the rotating mechanism of the hob that, as it progresses from the first to the second position, the hob is rotated to keep its diminishing thread always coincident with the central tooth of the crown gear shown. In addition to the rotation thus given the hob by the feeding movement, another rotating movement is given it in connection with the work, the same as for all hobbing processes. These two rotating movements are combined by differential gearing. It will thus be seen that with the machine properly set up, the hob may be fed from the first to the second position, with the hob and work rotating together, the former being under a rotative influence from the feeding movement as well, giving somewhat the effect of the rotation of the ordinary crown gear.

What the writer feels sure, however, is a vital error in the principle of this machine, is plainly evident in Fig. 181, where it is seen that the only point where the teeth of the hob coincide with those of the imaginary crown gear is on line *CD*. At the right of *CD* and at the left of it the coincidence ceases, and the hob teeth cross the crown gear teeth at different angles, so that they must cut entirely different shaped spaces in the work. Of course, everything in the diagram shown is exaggerated, but the exaggeration only shows the principle more clearly. While it is stated that the machine and the process are beyond the experimental stage, and while, from long experience, the writer knows that it is unsafe to predict the failure of any principle until it has actually been tried out, the analysis given above is surely enough to make one skeptical as to the success of this operation, particularly in the case of gears of such large pitch cone angle as to nearly approach the crown gear. With smaller angles, down to the spur gear the action should be more nearly correct, as the blank curves away from the hob so rapidly as to avoid most of the interference, though even here the fact that the pitch is coarser at one side of the line *CD* than at the other would still prevent proper action. It would thus seem that interference would prevent the consideration of this device as a practical possibility. The inventor of this machine is Mr. F. J. Bostock, Birmingham, England.

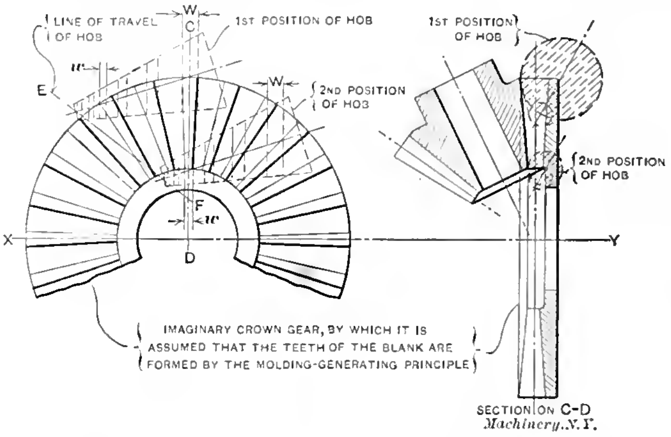

Fig. 181. The Principle of the Bostock Hobbing Process.

Comparison of Molding-Generating Machines for Bevel Gears.

It is interesting to note, in the various molding-generating machines for bevel gears, the different ways used for rolling the cutter head and the work in relation to each other. In the Bilgram machine the proper relation is maintained by

---

* American Machinist, March 5, 1908.

the rolling of the pitch surfaces of the work and the crown gear on each other, the rolling being controlled by steel tapes or wires in such a way as to make the movement positive. In the Ducommun machine the same movement is effected by spherical linkage which, while not exact in its action, is so nearly so that the error introduced is entirely negligible. The Gleason and Ludwig Loewe machines employ segments of the actual crown and master gears shown in Fig. 139, although, of course, it is not necessary to have the teeth of the master gear of the same number for the full circle, and of the same form, as those of the work, the only requirement being that the pitch cone of the master gear be coincident with that of the work. In the Ernault machine the proper ratio of movement is obtained by a system of angular slides, which automatically adjust themselves to the required ratio (which is dependent on the pitch cone angle of the gear) in the manner described in referring to Fig. 169. Finally, in the Brown & Sharpe, Chambon, and Bostock machines the proper ratio is obtained by the use of change gears.

Another interesting point relates to the considerable size and complication of each of these machines, as compared with the small size of the work they are adapted to operate on. While the principle of the molding-generating process is comparatively simple, as shown in Fig. 139, considerable mechanism is required for making a machine built according to this principle universal in its application, easily set up and operated, and automatic in its operation.

Conclusion.

This concludes this series of articles on gear-cutting machinery. The number of commercial machines of this kind is much greater than was believed possible when the series was first undertaken. It is safe to say that in no other field of the machine tool business has there been such an opportunity for the display of mechanical ingenuity and skill in designing as in that of gear cutting, and in no field have these possibilities been so fully grasped. That we have not yet reached final development in any of the various forms of this machinery is shown by the fact that the past year has been particularly prolific in new designs, as may be seen from an inspection of the New Tools Department of the various issues of MACHINERY since January, when the series was commenced. Besides these, a number of new machines are in process of development in this country and Europe, and doubtless such as are worthy of mention will be brought to the attention of the readers of MACHINERY as soon as the information concerning them is available for publication.

SUPERHEATING IN ENGLAND.

BRITISH CORRESPONDENT.

The opinions and experiences of engineers in the north of England engineering and manufacturing districts on the important subject of superheating are briefly summarized below, and may interest American readers, who will be able to compare them with American experience and with the opinions of American experts. The economy, which may be attained by superheating is now freely recognized in England, and although a great deal has yet to be learned respecting the nature of steam, the majority of steam users now exhibit less fear in the adoption of a practice which after its introduction for a time was received with disfavor. The actual steam users are not the only ones interested in superheating. Boiler and steam engine makers in England are fully alive to the fact that if steam engines are to successfully compete in efficiency with internal combustion motors, they must cooperate with each other with the object of securing the utmost possible percentage of heat units from every pound of coal put into the boiler furnaces. Even English colliery owners, who are not usually particular in the matter of fuel economy, are now beginning to recognize the fact that superheating offers too great a saving to be ignored.

In the case of gas engines, the size and the power of which are now steadily increasing in England, the problem of using the operative fluid is a comparatively simple one, and that probably accounts, to a large extent, for the success of this type of prime mover; but in the case of the steam engine, the fact that the steam may be gradually reduced to a liquid state during its stages of operation introduces risks of loss, which it has been the constant aim of engine builders to minimize, ever since the time of Watt. Multiple expansion has now been extended to its utmost limit; steam jacketing and reheating are only means to an end. Apparently, therefore, the only course left is to convert the steam temporarily into a gas by giving it such a degree of heat that there is no possibility of its condensation while passing through the cylinders of the engine. Condensation represents the principal source of loss in all reciprocating steam engines, and means of preventing it other than by superheating can only be regarded as palliatives. But it is not for reciprocating engines alone that superheating is found to pay. In the turbine engine, largely used in England in electric lighting stations, although the condensation of steam by cold external surfaces does not take place, it has been proved that superheating is an advantage. The steam in the turbine, as Prof. Watkinson, a well-known expert, has pointed out, is wet from another cause, namely, on account of the expansion it has undergone while doing work; consequently, the efficiency of this type of prime mover may be very considerably increased by superheating the steam prior to its admission to the steam chest. In the steam turbine the reduction in the amount of steam required when superheated is mainly due to the increased volume and the decreased frictional resistance between the rotating vanes and the steam. In one type of turbine in which the steam is discharged through nozzles, the flow has been found to vary or fluctuate, which is asserted to be due to partial choking of the nozzle with water. When the steam was superheated, the flow was found to be continuous and unvarying, to have a higher velocity, and consequently a much greater efficiency.

The soundness of the practice of superheating being therefore easily demonstrable, the question that faces the steam user is one of degree. It is generally understood in England that in the United States they are very conservative in regard to superheating, a "moderate superheat" being understood to mean from 100 to 150 degrees F. at the boiler, or about 100 degrees F. at the engine. This is considered in England a somewhat too moderate degree, which may probably entail reheating between the high-pressure and the low-pressure cylinders. In England, many engineers are not afraid of using higher temperatures. The engine builder is prepared for them, and the engineer is not afraid of his packings burning out or of his lubricants carbonizing. In consequence, no practical difficulties are encountered in superheating to a considerably higher extent. At the same time, it is very essential that the temperature of the superheated steam should be constant.

Early difficulties with the superheating tubes have also been overcome. Solid drawn steel is now being generally adopted in England in place of copper and cast iron, and the apparatus is therefore not only safer, but its life approximates more nearly the life of the boiler itself. The large English steam user, when invited to consider superheating, naturally asks what he may expect to save by it. On this point experiences vary very considerably, and the figures given by the makers of superheaters are subject to some discount. In a paper read some time ago before the Sheffield Municipal Electrical Association, Mr. R. S. Downe stated that, with a superheat of 500 degrees F., he could effect a saving in coal and steam amounting to between ten and twenty per cent. The saving is, of course, greater where the engines are working under uneconomical conditions, and where steam jacketing is used, or where the piping is inordinately long. A superheater attached to a boiler may abstract ten per cent of the heat in the flue gases, and reduce the efficiency of the boiler by something like the same figure, but as this extra ten per cent heat in the steam may reduce the engine losses by twenty per cent, the net gain is a substantial one, and justifies the adoption of superheating in the opinion of English users. Mr. Downe finds that the saving in steam is greater than the loss in coal, which is, of course, due to more fuel being required to obtain the superheat.

It is stated that 100 degrees F. of superheat in the steam turbine gives an extra economy of 12 per cent. and it has been estimated at 20 per cent with 350 degrees of superheat.

Superheating in the turbine secures dry steam, and freedom from the clogging of the blades and guides by water.

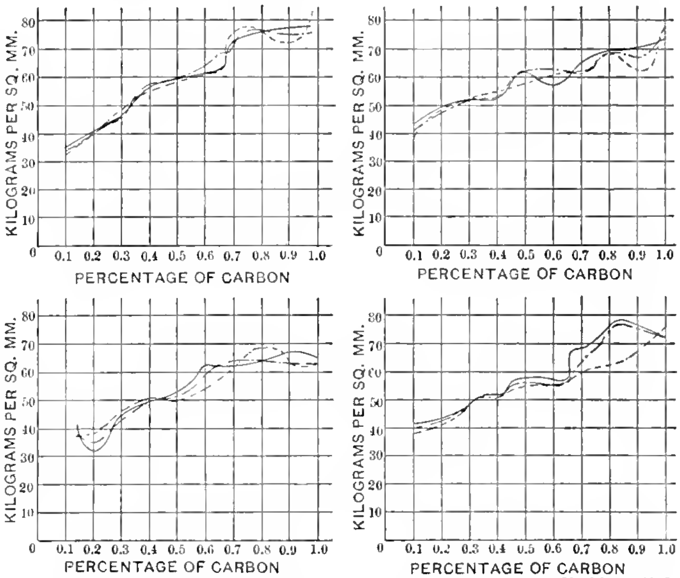
It may be of interest to add here the views of those not favorably impressed with superheating. They suggest that many practical engine builders object to superheat exceeding 150 degrees F., as valves and cylinders are apt to become scored. It is true that by adopting drop valves, instead of Corliss or slide valves, the troubles can be reduced, though not entirely avoided, but there are objections to the change. The new valves and valve gear necessitate new designs and patterns, and in addition bring along special operating troubles of their own. Most turbines have a natural advantage over the reciprocating engine so far as the use of superheated steam is concerned, because they have no bearing or rubbing surfaces under pressure exposed to the action of the superheated steam. On the other hand, the fine clearances, which are so desirable in the working parts, are more influenced and altered by superheated steam. This is especially the case in reaction turbines. In blades of certain nickel alloys, highly superheated steam has been found to produce brittleness.

As regards the economy of superheated steam, it is usually taken for granted that it effects a substantial one. Information, the opponents claim, on this point is limited, owing in part to a tendency of comparatively recent growth for engineers to speak of the performance of an engine in terms of the weight of steam consumed per horse-power. It is not so long since it was usual to estimate the performance in terms of the coal consumption at the boiler. This, of course, by introducing the unknown efficiency of the boiler as a factor, rendered comparisons of engine efficiencies a very difficult and uncertain matter. This was recognized, and in order to eliminate the boiler from the comparison, the weight of steam consumed is now generally the basis of comparison. But superheated steam contains more heat than saturated steam, and assuming that the boiler efficiency remains unaltered, it is clear that the weights of saturated and superheated steam used by the same engine are not directly of use for comparing the efficiencies in the two cases. Thus, tests show that a good steam engine or turbine will have its steam consumption reduced by about 1.7 pound of steam per kilowatt hour, or from 8 to 10 per cent of the normal steam consumption, for every 100 degrees F. of superheat. Taking the higher figure so as to allow everything possible to the superheated steam, it must be pointed out that these figures do not signify that the coal consumption is reduced by 10 per cent. With independently fired superheaters, the coal consumption is probably no less than with saturated steam. With ordinary fine or integral superheaters the effect on the coal consumption depends upon whether or not an economizer is fitted, and the position of the superheater, whether directly over the fire or in the flue, meeting the gases after leaving the boiler proper. Superheaters are most economical when there is no economizer, and in that case should never meet the hot gases before they reach the boiler heating surface.

If it be assumed that the over-all efficiency of the boiler is not affected by the superheater, then the extra heat in a given weight of steam as compared with saturated steam is about 5 per cent for 100 degrees of superheat. The decrease in the steam consumption being 10 per cent, the net economy of fuel is 5 per cent, or, say, from 0.07 to 0.1 pounds of coal per indicated horse-power hour for the main engine. The question is whether or not this saving in fuel pays for the means employed to obtain it. With a 1,000-horse-power engine for one year, the charges on the superheater for interest, depreciation and maintenance at 12½ per cent would be about £35. For each 1 per cent of the engine's maximum yearly output (continuous running day and night at full load), the saving in fuel would be from three to four tons. From this, the saving can be estimated under any given conditions of working, and for any given price of fuel. For instance, consider a mill or factory in which the engine output is 35 per cent of the maximum, coal costing 6 shillings a ton, delivered. The coal is usually slack: the greater saving in weight of four tons per 1 per cent, or 140 tons per year may, therefore, be taken. This gives a reduction in the coal bill of £42, or a saving over the fixed charges of £7 per year; with dearer coal a larger saving would result.

THE BRINELL METHOD OF TESTING THE HARDNESS OF METALS.

The method of testing the hardness of metals devised by Mr. J. A. Brinell has received very favorable attention from metallurgists in this, as well as in other countries. In 1900 Mr. Brinell, then chief engineer and technical manager of the Fagersta Iron and Steel Works in Sweden, first made public his method of testing the hardness of iron and steel, by submitting it to the Society of Swedish Engineers in Stockholm. At the meeting of the *Congrès International des Méthodes d'Essai des Matériaux de Construction* in Paris the same year the method attracted general attention, and its merits were duly acknowledged by awarding the inventor with a personal *Grand Prix* at the Paris Exposition. The method was first described in the English language by Mr. Axel Wahlberg in a paper before the Iron and Steel Institute in 1901. Since then, the practical value of this method has been amply substantiated on various occasions by means of comprehensive tests and investigations undertaken by several distinguished scientists in different countries. In working out his method, Brinell kept in view the necessity of taking into account the requirements that the method must be trustworthy, must be easy to learn and apply, and capable of being used on almost any piece of metal, and particularly, to be used on metal without in any way being destructive to the sample.



Machinery,N.Y.

Fig. 1. Diagrams showing Relation between Results Obtained by Various Methods for ascertaining the Ultimate Strength of Materials.

Principle of Method for Testing Hardness of Metals.

The Brinell method consists in partly forcing a hardened steel ball into the sample to be tested so as to effect a slight spherical impression, the dimensions of which will then serve as a basis for ascertaining the hardness of the metal. The diameter of the impression is measured, and the spherical area of the concavity calculated. On dividing the amount of pressure required in kilogrammes for effecting the impression by the area of the impression in square millimeters an expression for the hardness of the material tested is obtained, this expression or number being called the *hardness numeral.* In order to render the results thus obtained by different tests directly comparable with one another, there has been adopted a common standard as well with regard to the size of ball as to the amount of loading. The standard diameter of the ball is 10 millimeters (0.3937 inch) and the pressure 3,000 kilogrammes (6,614 pounds) in the case of iron and steel, while in the case of softer metals a pressure of 500 kilogrammes (1,102 pounds) is used. Any variation either in the size of the ball or the amount of loading will be apt to occasion more or less confusion without there being any advantage to compensate for such inconvenience. Besides, making any comparisons between results thus obtained in a different manner would be more or less troublesome, and complicated calculations would be required.

The diameter of the impression is measured by means of a microscope of suitable construction, and the hardness numeral

may be obtained without calculation directly from the table given herewith, worked out for the standard diameter of ball and pressures mentioned. The formulas employed in the calculation of this table are as follows:

$$y = 2\pi r\,(r - \sqrt{r^2 - R^2}) \qquad (1)$$

$$H = \frac{K}{y} \qquad (2)$$

In which formulas

r = radius of ball in millimeters,
R = radius of depression in millimeters,
y = superficial area of depression in square millimeters,
K = pressure on ball in kilogrammes,
H = hardness numeral.

Suppose, for instance, that the radius of the ball equals 5 millimeters (0.1968 inch), and that the test is undertaken on a piece of steel, the pressure consequently applied being 3,000 kilogrammes (6,614 pounds). Assuming that we found the diameter of the depression equal to 2 millimeters (0.7874 inch) by measurement, we have:

$$2\ \pi \times 5\ (5 - \sqrt{25 - 4}) = 13.13 = y,$$

and

$$\frac{3{,}000}{13.13} = 228 = H,$$

which as we see agrees with the figure given in our table for a 4 millimeters diameter of impression.

Relation between Hardness of Materials and Ultimate Strength.

It has been pointed out by Mr. Brinell himself that this method of testing hardness of metals offers a most ready and convenient means of ascertaining within close limits the ultimate strength of iron and steel. This, in fact, is one of the most interesting and important results of this method of measuring hardness. In order to determine the ultimate strength of iron and steel, it is only necessary to establish a constant coefficient determined by experiments which serves as a factor by which the hardness numerals are multiplied, the product being the ultimate strength. Rather comprehensive experiments were undertaken with a considerable number of specimens of annealed material obtained from various steel works for the purpose of establishing the coefficient by the present director of the Office for Testing Materials of the Royal Technical Institution at Stockholm. The results obtained were as follows:

For hardness numerals below 175, when the impression is effected transversely to the rolling direction, the coefficient equals 0.362; when the impression is effected in the rolling direction, the coefficient equals 0.354.

For hardness numerals above 175, when the impression is effected transversely to the rolling direction, the coefficient equals 0.344; when the impression is effected in the rolling direction, the coefficient equals 0.324.

If the hardness numerals are multiplied by these coefficients, the result obtained will be the ultimate tensile strength of the material in kilogrammes per square millimeter. It is evident that coefficients can easily be worked out so that if the hardness numerals be multiplied by these the strength could be obtained in pounds per square inch. Suppose for instance, that a test of an annealed steel bar by means of the Brinell ball test gave an impression of a diameter of 4.6 millimeters. Then the hardness numeral, according to our table, would be 170, and the ultimate tensile strength consequently 0.362 × 170 = 61.5 kilogrammes per square millimeter, provided the impression was effected transversely to the rolling direction.

In Fig. 1 are shown a number of diagrams which indicate the results obtained at the tests undertaken to ascertain the coefficients given. In these diagrams the full heavy line indicates the tensile strength of the material, as calculated from the ball tests in the rolling direction. The dotted lines indicate the strength as calculated from the ball tests in a transversal direction, and the "dash-dotted" lines show the actual tensile strength of the material as ascertained by ordinary methods for ascertaining this value. It is interesting to note how closely the three curves agree with one another, and considering the general uncertainty and variation met with when testing the same kind of material for tensile strength by the ordinary methods, it is safe to say that the ball test method comes nearly as close to the actual results as does any other method used. Especially within the range of the lower rates of carbon, or up to 0.5 per cent, or in other words, within the range of all ordinary construction materials, the coincidents are, in fact, so very nearly perfect as to be amply sufficient to satisfy all practical requirements.

In the case of any steel, whether it be annealed or not, that has been submitted to some further treatment of any other kind than annealing, such as cold working, etc., or in the case of any special steel, there would be other coefficients needed which would then also be ascertained by experiments. The same coefficient, however, will hold true for the same kind of material having been subjected to the same treatment. Thus, the ball testing method for strength is equally satisfactory, and far more convenient, in all cases where the rupture test would be applied. One of the greatest advantages of the Brinell method is that in the case of a large number of objects being required to be tested, each one of the objects can be tested without demolition, and without the trouble of preparing test bars.

Application of the Brinell Ball Test Method.

Summarizing what has been said in the previous discussion, and adding some other important points, we may state the various uses for which the Brinell ball test method may

be applied, outside of the direct test of the hardness of constructing materials and the calculation from this test of the ultimate strength of the materials, as follows:

1. Determining the carbon content in iron and steel.

2. Examining various manufactured goods and objects, such as rails, tires, projectiles, armor plates, guns, gun barrels, structural materials, etc., without damage to the object tested.

3. Ascertaining the quality of the material in finished pieces and fragments of machinery even in such cases when no specimen bars are obtainable for undertaking ordinary tensile tests.

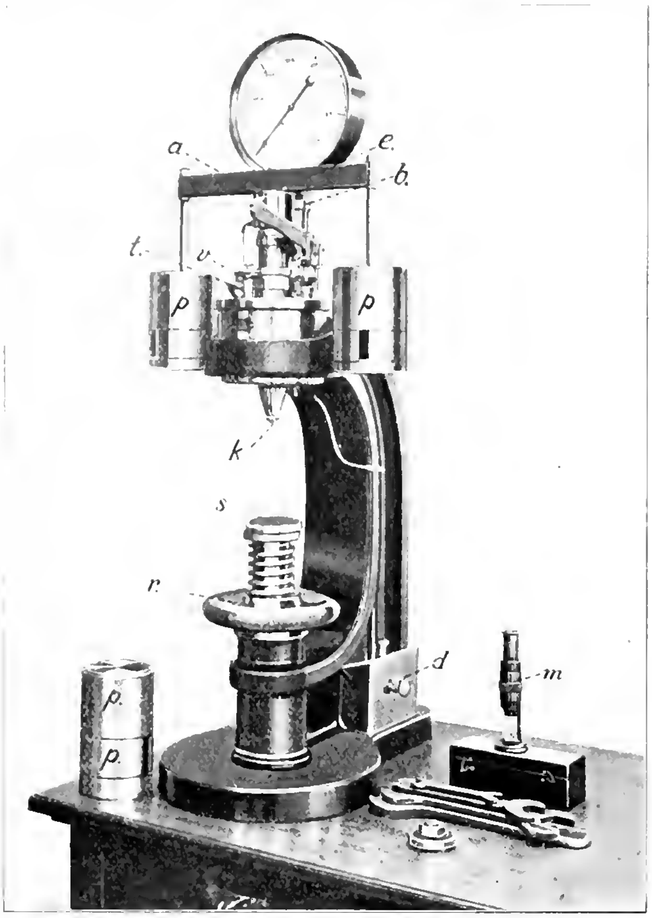

Fig. 2. Aktiebolaget Alpha's Machine for Testing Hardness of Materials.

4. Ascertaining the effects of annealing and hardening of steel.

5. Ascertaining the homogeneity of hardening in any manufactured articles of hardened steel.

6. Ascertaining the hardening power of various quenching liquids, and the influence of temperature of such liquids on the hardening results.

7. Ascertaining the effect of cold working on various materials.

Machines used for Testing the Hardness of Metals by the Brinell Method.

The method of applying the Brinell ball test was at first only possible in such establishments where a tensile testing machine was installed. As these machines are rather expensive, the use of the ball test method was limited. For this reason a Swedish firm, Aktiebolaget Alpha, Stockholm, Sweden, has designed and placed on the market a compact machine specially intended for making hardness tests. This machine, as shown in Fig. 2, consists of a hydraulic press acting downward, the lower part of the piston being fitted with a 10-millimeter steel ball *k* by means of which the impression is to be effected in the surface of the specimen or object to be tested. This object is placed on the support *s* which is vertically adjustable by means of the hand-wheel *r*, while at the same time it can be inclined sideways when this is needed on account of the irregular shape of the part tested. The whole apparatus is solidly mounted on a cast iron stand. The pressure is effected by means of a small hand pump, and the amount of pressure can be read off directly in kilogrammes on the pressure gage mounted at the top of the machine.

In order to insure against any eventual non-working of the manometer, this machine is fitted with a special contrivance purporting to control in a most infallible manner the indications of that apparatus, while at the same time serving to prevent any excess of pressure beyond the exact amount needed according to the case. This controlling apparatus consists of a smaller cylinder, *a*, directly communicating with the press-cylinder. On being loaded with weights corresponding to the amount of pressure required, the piston in this cylinder will be pushed upward by the pressure effected within the press-cylinder at the very moment when the requisite testing pressure is attained. Owing to this additional device, there can thus be no question whatever of any mistake or any errors as to the testing results, that might eventually be due to the manometer getting out of order.

Method of Performing the Ball Test.

The test specimen must be perfectly plane on the very spot where the impression is to be made. It is then placed on the support *s*, Fig. 2, which, as mentioned, is adjusted by means of the hand-wheel *r* so as to come into contact with the ball *k*. A few slow strokes of the hand pump will then cause the pressure needed to force the ball downward, and a slight impression will be obtained in the object tested, but as soon as the requisite amount of pressure has been attained, the upper piston is pushed with the controlling apparatus upward, as previously described. On testing specimens of iron and steel, the pressure is maintained on the specimen for 15 seconds, but in the case of softer materials for at least half a minute. After the elapse of this time, the pressure is released, and the contact between the ball and the sample will cease. A spiral spring fitted within the cylinder, and being just of sufficient strength to overcome the weight of the press piston, pulls the same upward into its former position, while forcing the liquid back into its cistern. The diameter of the impression effected by the ball is then measured by the microscope *m*, which is specially constructed for this purpose, the results obtained by this measurement being exact within 0.05 millimeter (0.002 inch). Fig. 3 shows a cross-section through the cylinder and piston part of the machine. Another type of machine is designed for special tests in which very high pressures are required. The ball in this machine is 19 millimeters (0.748 inch) in diameter, and the pressures employed vary from 3 to 50 tons. The construction and operation are otherwise exactly the same as that of the smaller machine in Fig. 2.

DROP FORGE WORK IN AN AUTOMOBILE SHOP.*

ETHAN VIALL.†

Ethan Viall.‡

Very little of value has been written on drop forging die work and shop practice as it actually exists in the modern drop forging shop. Here and there, a solitary die or device has been pictured and described, or a few sketches made of dies that may be entirely imaginary, so far as can be learned from any evidence offered, and which are of such a simple and elementary nature as to convey no adequate idea whatever of the magnitude or difficulty of the work, to anyone not familiar with it. This class of contributions covers the greater part of what has been published on a practice that has grown and developed from the hand forging process of the hammer and anvil, to one of the most important branches of modern machine industry.

Hundreds of parts that were formerly cast from malleable iron are now drop forged, the extra cost being more than made up by the uniformity, strength and reliability of the product; and no one has been quicker to realize this than the really live, up-to-date automobile manufacturer to whom the mechanical world is indebted for so many other valuable mechanical developments.

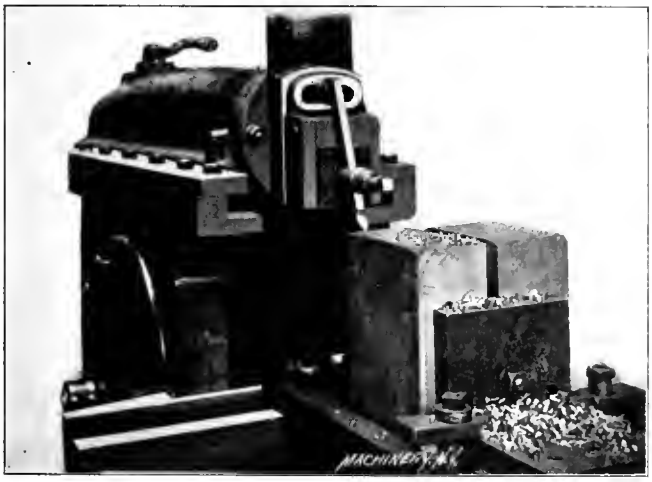

Fig. 1. Planing a Die-block on a Shaper.

The making of drop forging dies, together with the hardening process through which they are put and the methods of using them, is a trade in itself, though closely allied to tool and die making as understood in the big shops of to-day. Each branch of shop work presents its individual problems, and a tool- and die-maker, though skilled in other lines, cannot go into a forging shop and make drop forge dies without special instruction and training.

In drop forge die work, as in other kinds of tool work, there are various grades of accuracy and finish required. Some forgings must come from the hammer practically finished to size, while others are made large enough to allow considerable machining. Where only a few pieces of a rough nature are required, little skill is needed in the making or maintenance of the dies, but where small accurate parts are to be made in large quantities, special tools for both hand and machine use, and trained, skillful diemakers are needed, as well as a careful selection of the steel used

Materials for, and Life of, Drop Forging Dies

Steel, cast into blocks, is not suitable for this work, as flaws or blowholes are likely to develop where least expected or desired, so as a general rule, forged blocks of open hearth crucible steel are used. These blocks are either purchased ready forged, in various sizes, from the steel manufacturers, or are forged in the shop where they are used, the former plan being the usual one.

A rough estimate as to the average life of a drop forging die, used for medium sized work on Bessemer steel, was given by a foreman of long experience, as about forty thousand pieces. Some dies might be broken immediately when put in operation, while others might stand for a hundred thousand pieces or even more.

Automobile Shop Drop Forging Practice.

In preparing this article, the photographs and data were obtained in the factory of Thomas B. Jeffery & Co., Kenosha, Wisconsin, the manufacturers of the famous "Rambler" automobile. This company's drop forging department is far ahead of anything outside of the big concerns that make a specialty of drop forgings, and consists of a well-lighted, finely-equipped tool-room, used only for drop forge die work, a thoroughly up-to-date hardening plant, and a big building full of steam hammers, punch presses, heating furnaces and every appliance necessary for first-class work. This department is under the direct supervision of one of the best all-round drop forge men in the West.

The greater part of the drop forgings made here are of Bessemer bar steel, though some of the more particular automobile fittings are made of special grades of tool steel. All of the drop forging dies are of the highest class, calling for the best die-making skill, and necessitating a great deal of hand work in addition to the most accurate machining.

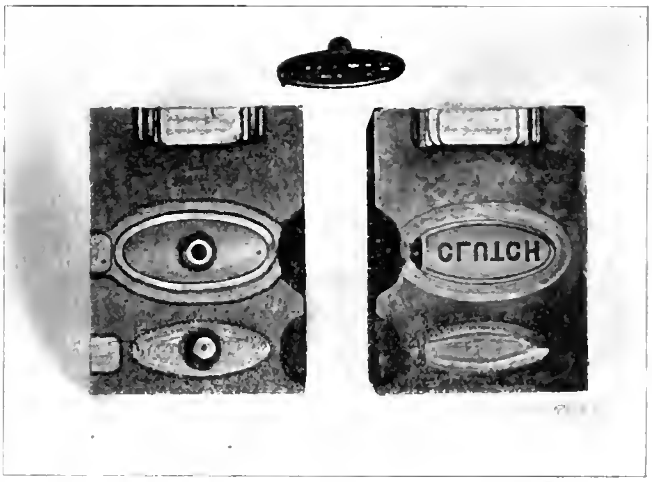

Fig. 2. A Pair of Typical Drop Forging Dies and Their Work

Making a Die.

In the original outlining of a set of drop forging dies, the measurements for the forming cavities may be taken from a blue-print supplied by the drafting-room, or they may be taken from a piece already made—possibly a forging or a lead casting obtained from some former set of dies, or perhaps a piece made up for a model. Sometimes a sheet metal templet is made to assist in obtaining the desired shape of the die cavities, while in other cases, only the outline scribed on the coppered surface, together with the necessary measurements, is needed. The size and outline of the forging to be made, as well as the accuracy required, govern the method of procedure.

The die blocks, which, as already stated, are forged of open hearth crucible steel, are first placed in a shaper and carefully surfaced off to the required dimensions, as shown in Fig. 1. These blocks are made over-size, so that enough of the surface can be machined off to insure good, sound metal to work on. The outlines for the breaking-down or roughing, the finishing, and sometimes the bending forms are then laid

‡ Ethan Viall was born in Kalamazoo, Mich., in 1873. He received a high school education, and took a course in mechanical engineering in a night school. He served an apprenticeship with E. T. Harris Co., Chicago, Ill., and has worked for the Pope Mfg. Co., Hartford, Conn.; Onward Mfg. Co., Williams-Lloyd Co., E. Goldman Co., Whelpley-Payson Co., all of Chicago; Ford Auto Co., Detroit, Mich.; and H. Mueller Mfg. Co., Decatur, Ill., with which concerns he has held positions of foreman of tool, machine and forge departments, and superintendent. His specialty is tool and die work.

off on the coppered faces, and the cavities roughed out on the drill press or lathe as the case may require, or on the profiling machine, as shown in Fig. 3.

The same set of dies shown in this engraving is shown still further roughed out in Fig. 2. The shape of the forging to be made in this set is shown at the top of the illustration, and it is a foot pedal for a clutch lever. The channel for the fin, or "flash," which is formed in the finishing operation, is plainly shown in the middle cavities.

The letters, C L U T C H, were first lightly stamped on the metal with special steel letters to get the outline; then they were chiseled out, and finally finished by driving in the steel letters to smooth up the roughness caused by chiseling.

Fig. 4 shows the final cuts being taken on the breaking-down part of this die, the rest of the work consisting of scraping, gouging and chiseling.

Tools Employed in Making Dies.

For the hand work, the die block is held in a special "ball vise" which is shown in Fig. 5. A vise of this type is the handiest device imaginable for heavy die work. This illustration also shows the breaking-down part of the die a little more plainly than the previous examples.

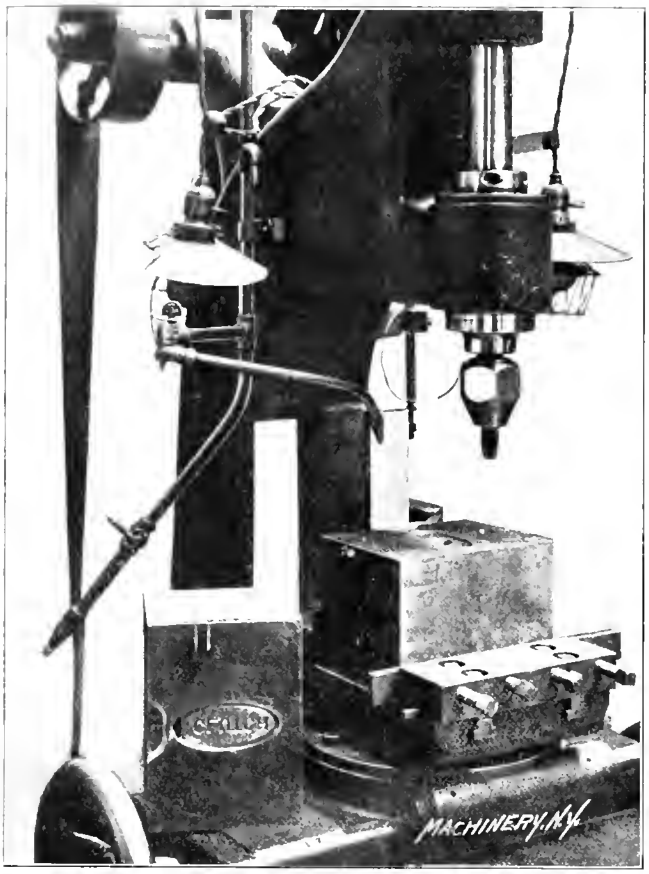

Fig. 3 Profiling Machine much Used in Die-sinking

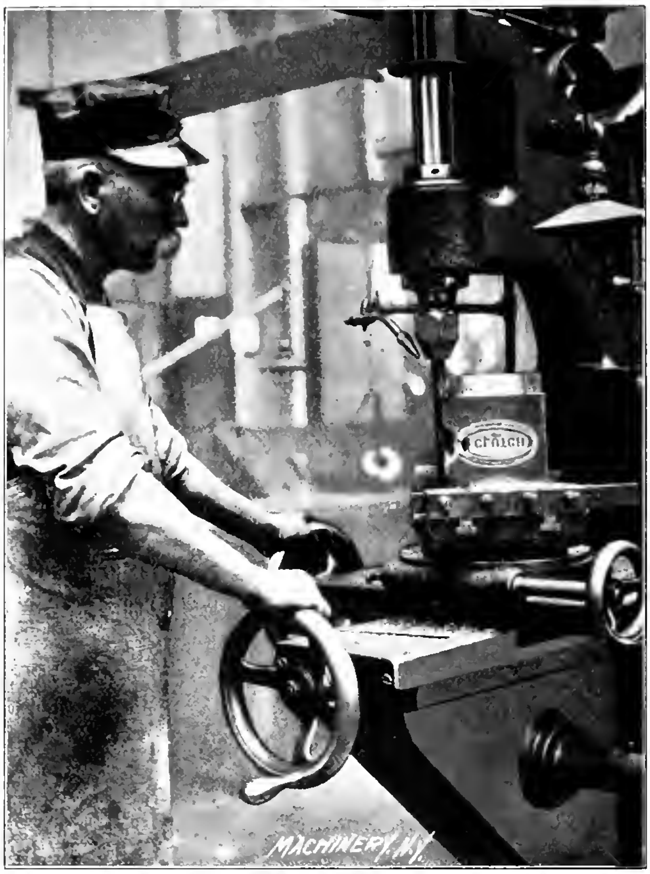

Fig. 4. Finishing the Die shown in Fig. 2 on the Profiling Machine.

Fig. 5 Special "Ball Vise" used in Sinking Drop Forging Dies.

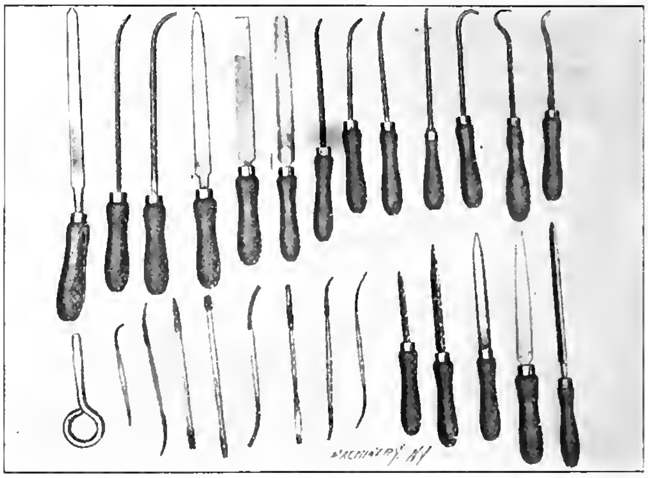

Fig. 6. Scrapers, Files, Rifflers and other Tools used by Die-sinkers.

Fig. 6 shows a few of the tools, scrapers, and rifflers used in the finishing work. These are mostly made of old files and are ground or bent to suit the needs of particular cases.

In Fig. 7 are some of the milling tools that have been made especially for this work. Only twenty-four of them are shown, though several hundred of all shapes and sizes are in stock. Another set of special cutters is shown in Fig. 8. Two of these have a single inserted blade or "fly-cutter" held in place by a set-screw, and are very useful tools for some kinds of work.

The tools shown in Fig. 9 are known as "types," and are used in scraping out cylindrical cavities to size. These types are turned to the proper size, and when used are smeared with lead and rocked back and forth in the partly finished cavity. The metal is then scraped away wherever the lead shows. For cylindrical work, these types are indispensable tools.

The tools shown in Fig. 10 were made by one of the expert die sinkers in the Jeffery shop. The tool shown at the right is used to scribe an outline from a forging. It consists of a hardened steel blade, with a point on one end, set into a flat steel block in such a way that it is free to move up and down to a limited extent. The rivet shown on the side passes

Fig. 14. Drop Forging Die showing both Edging and Flatting Breaking-down Dies.

through a short slot in the blade. When in use, a flat spring on the top edge of the tool presses the point down onto the coppered surface, causing a mark wherever moved. To use this tool, it is held on edge with the point down and the edge of the hardened blade in contact with the forging. The steel block keeps the blade perpendicular, and by keeping the edge of the blade in contact with the forging while scribing, a correct outline is obtained, which could not be done with an ordinary scriber on account of the working outline being considerably above the die face.

The middle tool shown in Fig. 10 is a one-inch inside micrometer, which was made by the die-sinker because he could not buy one small enough for the purpose. The other tool is a regular stock caliper square, to which has been added a depth gage. The gage is so made that the rod projects the same distance that the caliper jaws are apart. The usefulness and convenience of this tool are at once apparent to a toolmaker.

Examples of Drop Forging Dies.

One-half of a die set, showing the breaking-down and finishing forms, is illustrated in Fig. 13. In this illustration the method of leaving a ridge around the finishing form and cutting a channel for the fin is very plainly shown. This method is followed in all of the drop forge dies made in the Jeffery shop. Fig. 14 shows a more complicated die. In this, both edging and flatting breaking-down die forms are shown. In using this die, the hot bar from which the forging is being made, is alternately swung from one to the other form, it being held edgewise in one and flat in the other, and given a blow or two until sufficiently reduced for the finishing form, after which it is cut off from the bar by a shear fastened to the hammer at one side of the die block.

In Fig. 15 the roughing or breaking-down die is shown and also a bending form, the bar being roughed into shape, and then bent and finished. Of course, in these last two illustrations it is understood that the cuts show only one-half of the set, the other half corresponding in shape to the one shown in such a way as to produce the desired shape. To better illustrate this for the benefit of those not familiar with this class of work, both halves of a set of dies are shown in Figs. 16 and 17. These show the complete forging and bending parts for this particular piece. The end of the finishing form also shows a place where one of the types illustrated in Fig. 9 was used when first working out the cavity.

Fig. 15. Drop Forging Die showing Bending Form in Front.

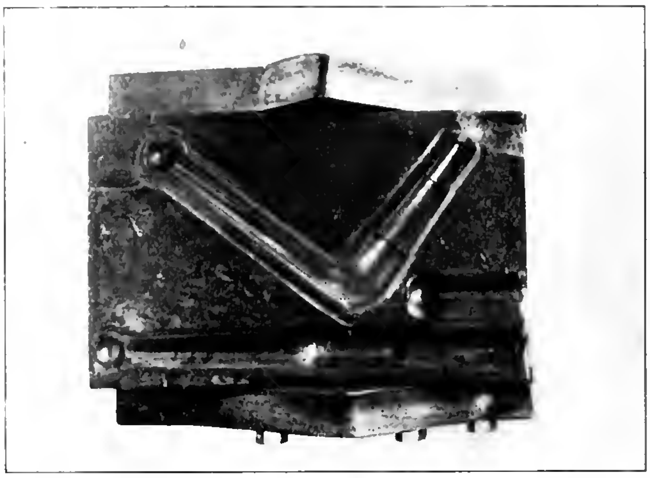

Fig. 16. Drop Forging Die and Bending Die for Steering Gear Part.

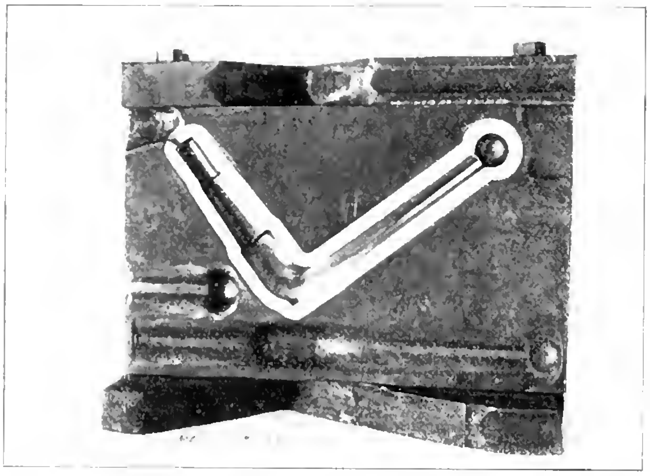

Fig. 17. Mating Die to Die in Fig. 16.

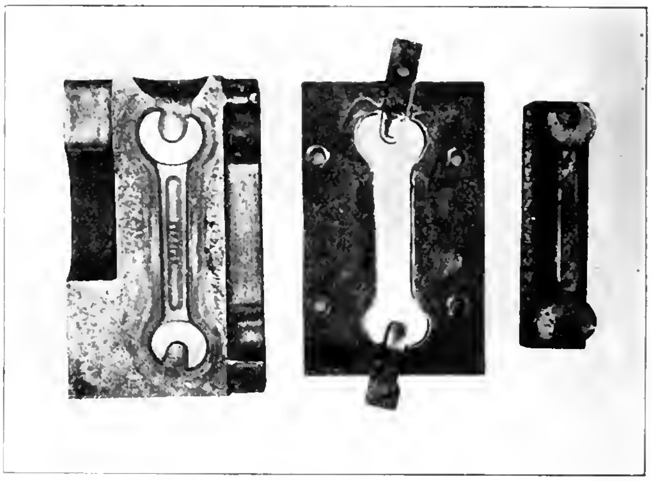

Fig. 18. Drop Forging Die for Wrench and Trimming Die for Same.

The Lead Casting or Proof.

After the mechanical work on a set of dies is done, a lead casting of the cavity is made and sent to the superintendent to be passed upon. If it is correct, the dies are hardened and sent to the forging shop, but if it is off size or shape, or for any reason not satisfactory, suitable changes are made, and another lead impression taken and passed upon as before. Fig. 11 shows a number of these lead castings which are kept in the tool-room for reference, and they often save considerable trouble when making duplicate dies.

Staking Tools used for Repairing Dies.

After a set of dies has been in use for some time, the dies are likely to develop cracks or drawing seams which cause ridges and [illegible] spots on the forgings. These cracks are closed up by hammering first on one side and then on the other with a hammer and what are called "staking" tools, which are simply specially shaped tempered steel punches made of chisel steel stock. Some of these staking tools are shown in Fig. 12.

Trimming Dies.

Some of the forgings are of such shape that the fin or flash formed is easily ground or machined off, while others are put through a trimming die. These trimming dies are about the same as the trimming dies used for other classes of work, and so need little comment. Fig. 18 shows a set of forging and trimming dies used for making "Rambler" wrenches. The breaking-down form is very plainly shown, as is also the finishing cavity. The trimming punch is at one side, while the trimming die in the middle is shown made up

of four separate parts. This is done because the die parts that shear out the wrench slots wear or break sooner than the rest of the die, and when made this way they are easily replaced without necessitating a wholly new die, which would be the case if made solid.

Fig. 19 shows a number of dies on the storage shelves, only one-half of each set being shown, the other half of each set being back of the one visible. The trimming dies which are in constant use are kept conveniently near the presses in the forge room. Both the trimming and forging dies are stored on heavy shelves close to where they are used, thus saving the unnecessary "toting" that is practiced in so many shops.

The keynote of the whole Jeffery factory is: "System without red tape," and the result is visible everywhere to the practiced observer, though a casual visitor would wonder how material traveled through as smoothly as it does.

Heating Furnaces.

The heating furnaces in a forging shop must be set near the hammers, and Fig. 20 shows how the oil furnaces are placed, so that little time is lost getting the heated metal to the hammers. Fig. 21 is an illustration of two of the big Brown & Sharpe furnaces in the hardening room. For small work several smaller furnaces are used, but those shown are used for large work, and are said to be the best obtainable.

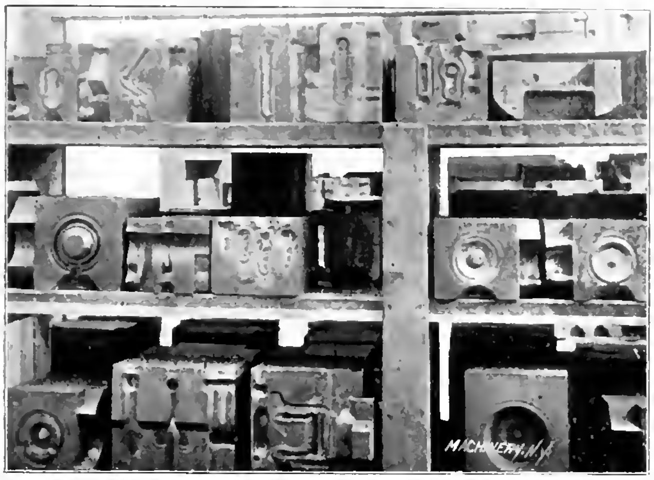

Fig. 19. A Few Examples of Drop Forging Dies in Storage.

Fig. 20. Oil Heating Furnaces and Drop Hammer

Fig 21. Brown & Sharpe Heating and Annealing Furnaces.

Fig. 22. Hardening the Face of a Drop Forging Die.

Hardening Drop Forging Dies.

In hardening drop forge dies only the face is hardened. The die is heated and placed face down in a tank of water on a sort of spider support, and a stream of water pours upward onto it. Fig. 22 shows how this is done. In the illustration a round piercing die is being hardened, so the water appears to be boiling up through the center, which would not be the case were it a solid block like a forging die. Large special shaped tongs make the handling of the heavy steel blocks of the drop forge dies comparatively easy.

Beware of the man who is going to do things to-morrow.—*The Silent Partner.*

JIGS AND FIXTURES 6.

EINAR MORIN *

EXAMPLES OF THE DESIGN OF OPEN JIGS

The present installment will be devoted to explaining and illustrating the application of the principles outlined in the previous issues, to the simplest and most common design of drill jig—the open jig. We will assume that the drill jig is to be designed for a piece of work, as shown in Fig. 61. Consideration must first be given to the size of the piece, to the finish given to the piece previous to the drilling operation, the accuracy required as regards the relation of one hole to the other, and in regard to the surfaces of the piece itself. The number of duplicate pieces to be drilled must also be considered, and, in some cases, the material.

The very simplest kind of drill jig that could be used for the case taken as an example would be the one illustrated in Fig. 62, which simply consists of a flat plate of uniform thickness of the same outline as the piece to be drilled, and provided with holes for guiding the drill. Such a jig would be termed a jig plate. For small pieces, the jig plate would be made of machine steel and case-hardened, or from tool steel and hardened. For larger work, a machine steel plate can also be used, but in order to avoid the difficulties which naturally would arise from hardening a large plate, the holes are simply bored larger than the required size of drill, and are provided with lining bushings to guide the drill, as shown in Fig. 63. It would not be necessary, however, to have the jig plate made out of steel for larger work, as a cast iron plate provided with tool steel or machine steel guiding bushings would answer the purpose just as well, and at the same time be much cheaper, and almost as durable. The thickness of the jig plate varies according to the size of the holes to be drilled and the size of the plate itself.

The holes in the jig in Fig. 62 and in the bushings in the

---

*Address: 833 W. Sixth St., Plainfield, N. J.

jig in Fig. 63, are made the same size as the size of the hole to be drilled in the work, with proper clearance for the cutting tools. If the size and location of the holes to be drilled are not very particular, it is sufficient to simply drill through the work with a full size drill guided by the jig plate, but when a nice smooth, standard size hole is required, the holes in the work must be reamed. The hole is first spotted by a spotting drill, which is of exactly the same size as the reamer used for finishing, and which fits the hole in the jig plate or bushing nicely. Then a so called reamer drill, which is 0.010 inch, or less, smaller in diameter than the reamer, is put through, leaving only a slight amount of stock for the reamer to remove, thereby obtaining a very satisfactory hole. Sometimes a separate loose bushing is used for each one of these operations, but this is expensive and also unnecessary, as the method described gives equally good results.

By using the rose reaming method very good results will also be obtained. In this case two loose bushings besides the lining bushing will be used. These bushings were described and tabulated in the second installment of this series, appearing in the May issue of MACHINERY. The drill preceding the rose chucking reamer is 1/16 inch under the size of the hole. This drill is first put through the work, a loose drill bushing made of steel being used for guiding the drill. Then the rose chucking reamer is employed, using, if the hole in the jig be large, a loose bushing made of cast iron.

When dimensioning the jig on the drawing, dimensions should always be given from two finished surfaces of the jig to the center of the holes, or at least to the more important ones. In regard to the holes, it is not sufficient to give only the right angle dimensions, *a*, *b*, *c*, and *d*, etc., Fig. 62, but the radii between the various holes must also be given. If there are more than two holes, the radii should always be given between the nearest holes and also between the holes standing in a certain relation to one another, for instance, between centers of shafts carrying meshing gears, sprockets, etc. This will prove a great help to the tool-maker. In the case under consideration, the dimensions ought to be given from two finished sides of the work to the centers of the holes, and also the dimension between the centers of the holes to be drilled.

When using a simple jig made as outlined in Figs. 62 and 63, this jig is simply laid down flat on the work and held against it by a C-clamp, a wooden clamp, or, if convenient, held right on the drill press table by means of a strap or clamp, as shown in Fig. 64. Here two pieces of the work are shown beneath the jig plate, both being drilled at one time.

Improving the Simple Form of Jig shown in Fig. 62.

The first improvement that could be made on the jig shown in Fig. 62 would be the placing of locating points in the jig plate in the form of pins, as shown in Fig. 65, in which the dotted lines represent the outline of the work. The plate need not necessarily have the shape shown in Fig. 65, but may have the appearance shown in Fig. 66, according to the conditions. As mentioned in the article last month, exact rules could not be given for the form and shape of jigs, but common sense together with the judgment obtained by long practice must be relied upon in determining the minor points of design.

The adding of the locating points will, of course, increase the cost of the jig somewhat, but the amount of time saved in using the jig will undoubtedly make up for the added expense of the jig, provided a fair number of pieces is to be drilled; besides, a great advantage is gained in that the holes can always be placed in the same relation to the two sides resting against the locating pins on all the pieces drilled.

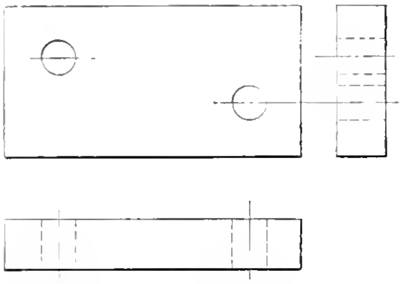

Fig. 61. Sketch of Piece to be Drilled.

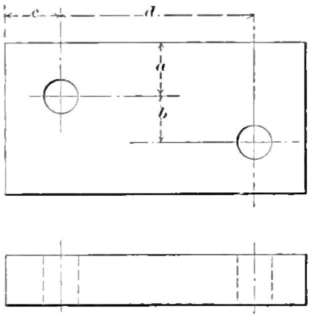

Fig. 62. Simplest Form of Jig for Piece shown in Fig. 61.

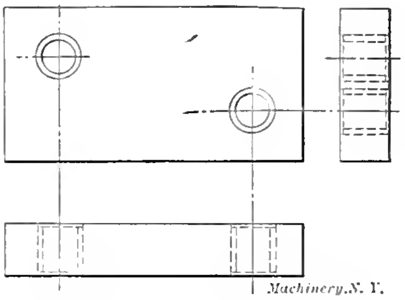

Fig. 63. Plate Jig with Inserted Guide Bushings.

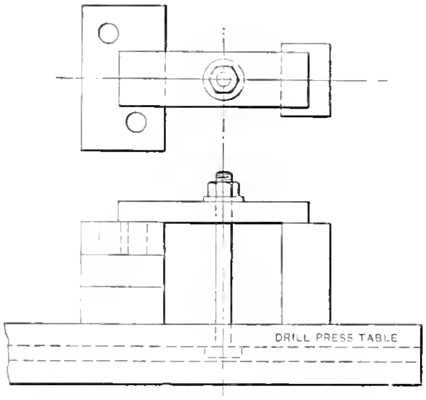

Fig. 64. Holding Jig and Work on Drill Press Table. Two Pieces drilled at Once.

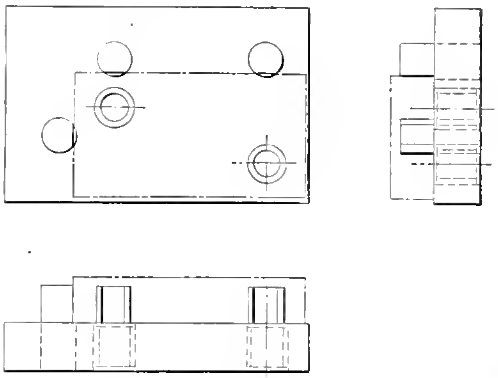

Fig. 65. First Improvement of Plate Jig Locating Pins Inserted.

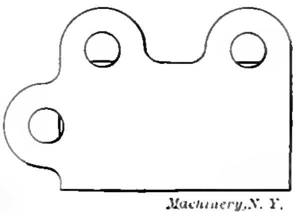

Fig. 66. Variation in Shape of Plate Jig.

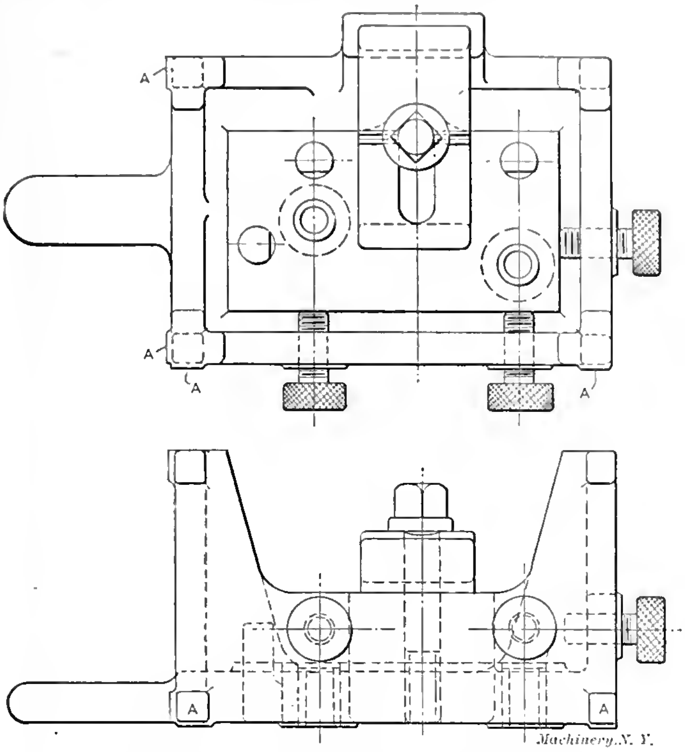
The locating pins are flattened off to a depth of 1/16 inch from the outside circumference, and dimensions should be given from the flat to the center of the pin holes and to the center of the nearest or the most important of the holes to be drilled in the jig. The same strapping or clamping arrangements for the jig and work, as mentioned for the simpler form of jig, may be employed.

Improving the Jig by adding Locating Screws.

The next step toward improving the jig under consideration would be to provide the jig with locating screws, as shown in Fig. 68. By the addition of these, the locating arrangements of the jig become complete, and the piece of work will be prevented from shifting or moving sideways. These locating screws should be placed in accordance with Rule 10 laid down in the summary of the principles of jig design in the first installment of this series, in the April issue of MACHINERY, saying that all clamping points should be located as nearly opposite to some bearing points of the work as possible. In order to provide for locating set-screws in our present jig, three lugs or projections *A* are added which hold the set-screws. If possible the set-screw lugs should not reach above the surface of the piece of work, which should rest on the drill press table when drilling the holes.

The present case illustrates the difficulty of giving exact rules for jig design and indicates the necessity of individual judgment. It is perfectly proper to have two set-screws on the long side of the work, but in a case like this where the piece is comparatively short and stiff, one lug and set-screw, as indicated by the dotted lines at *B* in Fig. 68, would be fully sufficient. The strain of the set-screw placed right between the two locating pins will not be great enough to spring the piece out of shape. When the work is long and narrow two set-screws are required on the long side, but whenever a saving in cost can be accomplished without sacrificing efficiency, as in the case illustrated, two lugs would be considered a wasteful design.



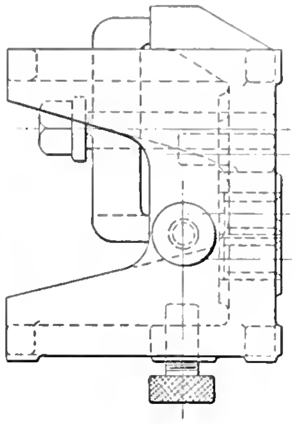


Fig. 67. Complete Jig for Rapid Duplicate Work.

Providing Clamps and Feet for the Jig.

The means by which we have so far clamped or strapped the work to the jig when drilling in the drill press (see Fig. 64) have not been integral parts of the jig. If we wish to add clamping arrangements that are integral parts of the jig, the next improvement would be to add four legs in order to raise the jig plate above the surface of the drill press table enough to get the required space for such clamping arrangements. The completed jig of the best design for rapid manipulation and duplicate work would then have the appearance shown in Fig. 67. The jig here is provided with a handle cast integral with the jig body, and with a clamping strap which can be pulled back for removing and inserting the work. Instead of having the legs solid with the jig, as shown in Fig. 68, loose legs, screwed in place, are sometimes used, as shown in Fig. 70.

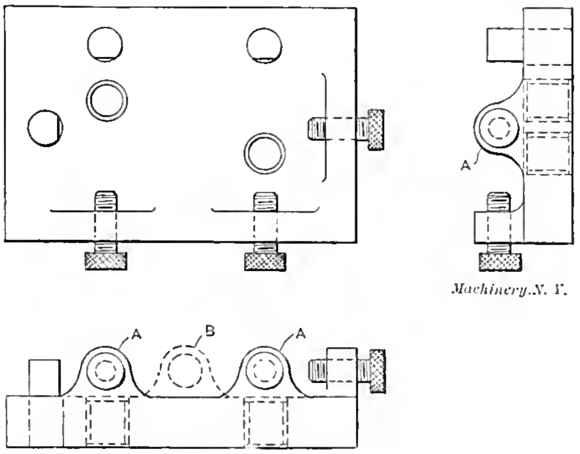

Fig. 68. Second Improvement: Locating Screws Holding Work in Place.

These legs are round, and provided with a shoulder *A*, preventing them from screwing into the jig plate. A headless screw or pin through the edge of the circumference of the threads at the top may prevent the studs from becoming loose. These loose legs are usually made of machine steel or tool steel, the bottom end being hardened and then ground and lapped, so that all the four legs are of the same length. It is the practice of many tool-makers not to thread the legs into the jig body, but to simply provide a plain surface on the end of the leg, which enters into the jig plate, and is driven into place. This is much easier, and there is no reason why for almost all kinds of work, jigs provided with legs attached in this manner should not be equally durable.

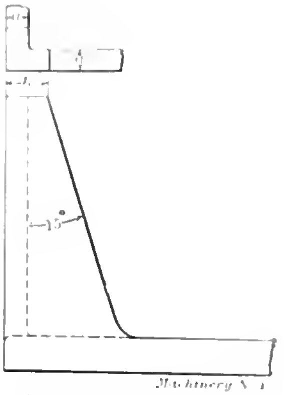

Fig 69 Design of Legs for Cast Iron Jig Bodies.

Of course, when jigs are made of machine or tool steel, and legs are required, the only way to provide them is to insert loose legs. In the case of cast iron jigs, however, solid legs cast in place are preferable. The solid legs cast in place generally have the appearance shown in Fig. 69. The two webs of the leg form a right angle, which, for all practical purposes, makes the leg fully as strong as if it were made solid, as indicated by the dotted line in the upper view. The side of the leg is tapered 15 degrees, as a rule, as shown in the engraving, but this may be varied according to conditions.

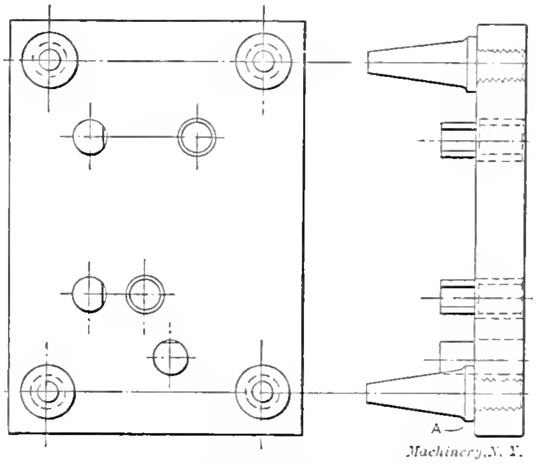

Fig. 70. Legs Screwed into Jig Body.

The thickness of the leg varies according to the size of the jig, the weight of the work, and the pressure of the cutting tools, and depends also upon the length of the leg. The length *b* on top is generally made 1½ times *a*. As an indication of the size of the legs required, it may be said that for smaller jigs, up to jigs with a face area of 6 square inches, the dimension *a* may be made from 5/16 to 3/8 inch; for medium sized jigs, ½ to ⅝ inch; for larger sized jigs, ¾ to 1½ inch; but of course, these dimensions are simply indications of the required dimensions. As to the length of the legs, the governing condition, evidently, is that they must be long enough to reach below the lowest part of the work and the clamping arrangement.

If a drill jig is to be used in a multiple spindle drill, it should be designed a great deal stronger than it is ordinarily designed when used for drilling one hole at a time. This is especially true if there is a large number of holes to drill

simultaneously. The writer has had sad experiences with drill jigs which would give excellent service in common drill presses for years, but which, when put on a multiple spindle drill, immediately broke to pieces as if subjected to a hammer blow. It is evident that the pressure upon the jig in a multiple spindle drill is as many times greater than the pressure in a common drill press as the number of drills in operation at once.

Referring again to Fig. 67, attention should be called to the small lugs *A* on the sides of the jig body which are cast in place for laying out and planing purposes. The handle should be made about 4 inches long, which permits a fairly good grip by the hand. The design of the jig shown in Fig. 67 is simple, and fills all requirements necessary for producing work quickly and accurately. At the same time, it is strongly and rigidly designed. Locating points of a different kind from those shown can, of course, be used; and the requirements may be such that adjustable locating points, as described in the June issue may be required. A more quick acting, but at the same time, a far more complicated clamping arrangement might be used, but the question is whether the expense of making is warranted by the added increase in the rapidity of manipulation.

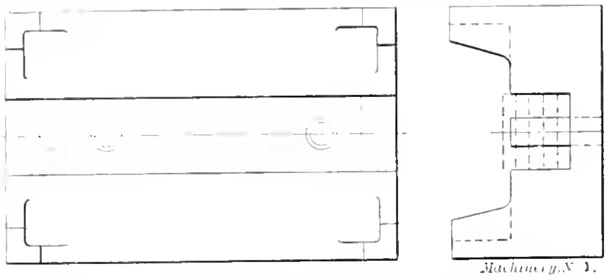

Fig. 71. Form of Jig which may be used for drilling a Number of Pieces Simultaneously.

Another improvement which should not be overlooked, and which in a case like this probably could be made, and which it is always wise to look into at any rate, is: Can more than one piece be drilled at one time? In the present case, the locating pins can be made longer, or, if there is a locating wall, it can be made higher, the legs of the jig can be made longer, the screw holding the clamp can also be increased in length, and if the pieces of work are thick enough, set-screws for holding the work against the locating pins can be placed in a vertical line, or if the pieces be narrow, they can be placed diagonally, so as to gain space. If the pieces are very thin, the locating might be a more difficult proposition. If they are made of a uniform width, they could simply be put in the slot in the bottom of the jig, as shown in Fig. 71, or if a jig on the principles of the one shown in Fig. 67 is used, they must be located sideways by a wedge, as shown in Fig. 72. A couple of lugs *A* would then be added to hold the wedge in place, and take the thrust. In both cases the pieces must be pushed up in place endways by hand. If the pieces are not of exactly uniform size, and it is desired to drill a number at a time, they must be pushed up against the locating pins by hand from two sides, and the clamping strap must be depended upon to clamp them down against the pressure of the cut and at the same time prevent them from moving side or endwise. If the accuracy of the location of the holes is particular the pieces should not be piled up on one another to be drilled.

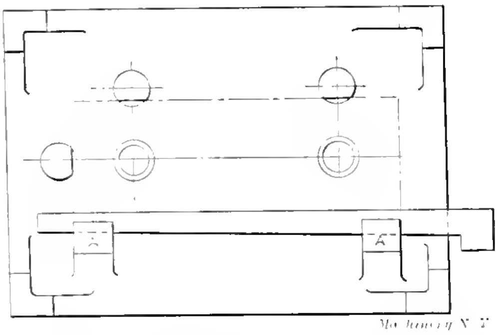

Fig. 72. Jig with Wedge for Holding the Work

TOOLS FOR THE BLACKSMITH SHOP.*

JAMES CRAN†

Among mechanics, the blacksmith holds a unique position, he being practically the only one who makes his own tools. This he often does without any apparent aim at economy, beauty, or usefulness, if judged by the chunks of steel on the ends of handles to be found in the odd corners of a great many blacksmith shops. It would not be fair to put the whole blame on the blacksmith, as he is usually allowed but very little time either to keep his tools in repair or to make new ones; the result is that if ever blacksmiths' tools have had a high standard of efficiency, they soon depreciate. Too much reliance seems to be put on the old saying: "A good workman can do a good job with any kind of tools." But when it comes to saving time, which is one of the most important points in modern manufacturing, the good workman with good tools comes out ahead.

Tools used by blacksmiths do not have to be so accurate to size, or made with the same precision as those used by machinists or tool-makers. Still, some of the points most essential to doing good work seem to have been overlooked. It would be to the advantage of all concerned to have one smith in every shop do the tool-making. He would soon become an expert, and would make better tools in less time than the smith who makes a tool occasionally. It would also insure every man employed having equally good tools and equal chances of doing good work. Tools made by a good blacksmith are preferable to those upon the market for several reasons, the principal of which is the poor quality of the material of which the article on the market is made. Besides, the blacksmith's tools on the market are often poorly constructed and are mostly used in small or country shops where there is no steam hammer.

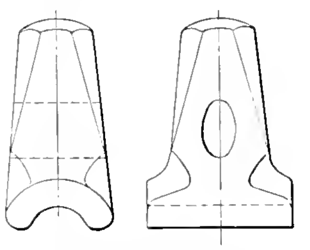

Fig. 1. Correct Form of Top Part of Blacksmith's Swage.

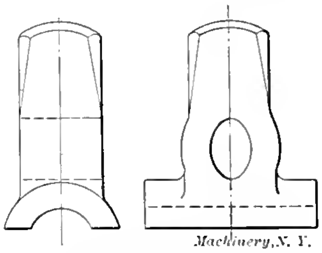

Fig. 2. Incorrect Form of Blacksmith's Swage, Top Part.

Tools such as swages are usually made with the impression or hollow part too deep, the corners too sharp, and the face too long for the best results. Swages, being tools used for finishing round or semi-round work at the anvil after it has been drawn nearly to size at steam or trip hammers, should be constructed so that finishing can be done in the best and quickest manner possible. They should be made in pairs consisting of one top and one bottom piece. The depth of the impression ought to be about one-third the diameter of the piece the swages are intended to finish. The edges or lips of the impression should be well backed off, and all corners rounded to prevent cold shuts and unsightly marks being left upon the work. The swages may be slightly crowned from end to end, which will give them a tendency to draw the stock, should it be a trifle over size, and if the crowning is not overdone, it will help to leave the work smooth.

The bottom swage should be made to come flush with one side of the anvil, and to reach about half way across it. The swages can then be used for finishing hubs, bosses, forgings with large heads or arms, at right angles to the hub of the work. The bottom swage can also be reversed and used from the other side of the anvil when necessary. Bottom swages should preferably be a little longer on the face than the top swages. For small sizes they might be from 2¼ inches to 2½ inches from end to end of the impression, while the corresponding top swages might be about 1¾ inch. For larger sizes the bottom swage could be from 4 inches to 4½ inches

---

* See MACHINERY, June, 1908; Reasons Why so Little is Heard from Forge Shops; and August, 1908; System for the Blacksmith Shop.

† Address: 916 West Third St., Plainfield, N. J.

long and the top swage from 2¼ inches to 2½ inches. The number and sizes to constitute a set for one forge would have to be determined by the size and class of work for which the swages would be used. The following list would cover the average range of machine blacksmithing: Top and bottom from 3/16 inch to 1/2 inch, inclusive, advancing by 1/16 inch; from ⅝ inch to 2¼ inches, inclusive, advancing by ⅛ inch; larger sizes up to the limit to advance by ¼ inch. Fig. 1 shows the correct style of top swage, and Fig. 2 an objectionable style. Fig. 3 shows the correct style of bottom swage, and Fig. 4 the incorrect style.

The shape and style of fullers is not so important from the fact that there can be no sharp corners to come in contact with the work. Care should be taken to make them in pairs which match each other perfectly. With bottom fullers it is well to have a large shoulder to rest on the anvil. The shank should be a snug fit to keep it from wobbling.

Flatters as a rule are too large and too level on the face for doing good work, and like swages are usually too sharp and square on the corners and edges. More and better work can be done with a flatter 2½ inches square on the face than can be done with one 3 inches square face. When a large level flatter is used, the edges come in contact with the work and leave a mark every time it is struck with a sledge. With a small flatter with crowning center and rounded edges a blow with the sledge will have more effect, and it will be almost impossible to leave a mark upon the work. The same principle applies to sets. The style best suited for machine blacksmithing should be from 2¼ inches to 2½ inches long, and from 1⅜ inch to 1½ inch wide on the face. It would be of advantage to have one with the edges well rounded to use around fillets, and one with sharp square edges to finish corners which must be sharp.

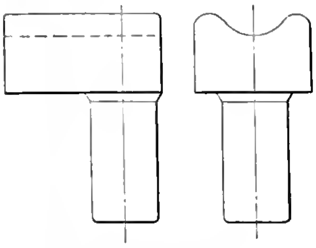

Fig. 3. Correct Form of Bottom Part of Swages.

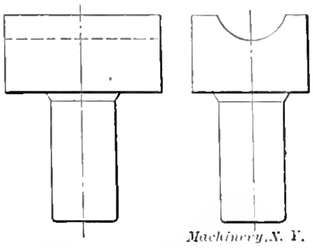

Fig. 4. Incorrect Form of Bottom Part of Swages.

Breaking-down tools should be made with the edge rounded, which will prevent the leaving of a cold shut where the shank joins the body of a forging. Fig. 5 shows the correct style in full lines; the dotted lines show the incorrect style. When square work is being drawn at the steam or trip hammer, it will sometimes become diamond shaped, and it is very hard to work it back to the square form without flattening two of the corners, unless a pair of V swages are used. These ought to have a place in every set of tools, the impression in both top and bottom to be 90 degrees, with the edges well rounded so that they would have their greatest bearing at the apex of the V. This forces out the other two corners of the work until it is perfectly square, without marking it. Chisels, punches, and gouges must be made to suit the work. The tools previously mentioned, with the exception of chisels punches, and gouges, could be made of steel of about 0.60 carbon. All tools intended for cutting should be made of steel not less than 0.75 carbon.

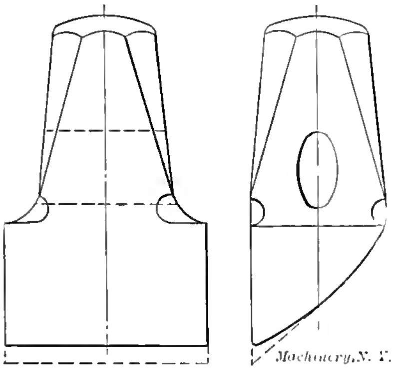

Fig. 5. Correct and Incorrect Shape of Blacksmith's Breaking-down Tool.

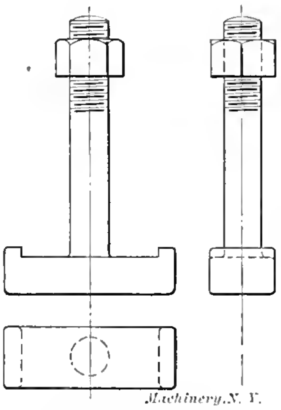

Fig. 6 Clamping Screw used with Clamp in Fig. 10.

Tools will give better service and satisfaction if hardened on both ends. The writer appreciates the fact that in recommending the hardening of the heads of tools he is laying himself open to criticism, as it is departing from all general rules and practice. Nevertheless, if the head of a tool is properly hardened, the tool will give at least five times more service than a tool with a soft head. In hardening the working end of such tools as swages, flatters, etc., the face, after being heated to the proper temperature, should be cooled in a stream of water rising straight from the bottom of the quenching tub. Care should be taken to hold the tool so that the stream will strike its center, which will insure the center being hard. After the tool is cold enough to carry water on the face, polish, and draw the temper in a hot fire until the edges are a light blue, leaving the center as hard as possible. If hardened in a bath without a stream, the edges are liable to be extremely hard and the center soft.

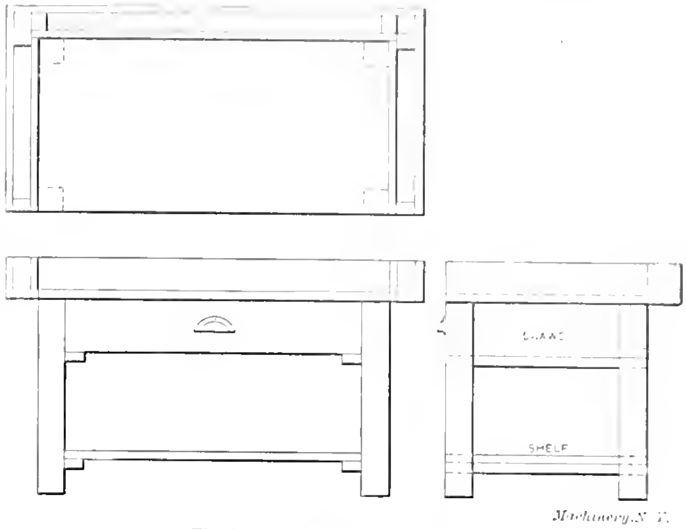

Fig. 7. Blacksmith's Tool Bench

When hardening the heads of tools, they should be heated to a cherry red about 1 inch of their length, dipped to a depth of about ⅝ inch in water until fairly cooled, and then the head polished and the temper drawn with back heat until the color just runs out. If much heat is left, dip slightly to check it, and leave the tool to cool off gradually in the air. Heads treated in this manner will neither chip off, nor crack, nor batter down.

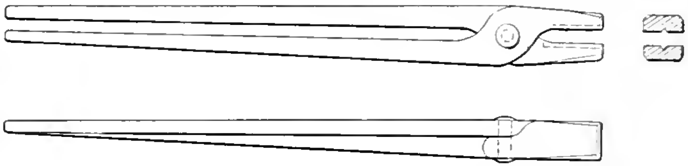

Fig. 8. Approved Type of Tongs with Flat Jaws.

Fig. 7 shows a tool bench which is of a suitable style for the blacksmith's tools. The rack around the top holds tools with handles; the shelf at the bottom accommodates bottom or anvil tools, and the drawer is used to hold such tools as are usually the personal property of the blacksmith, as well as orders, drawings, etc., which ought to be kept clean and out of the range of sparks. A bench of this style made of wood will give good service if the top edges of the rack are covered with light band-iron attached with screws. Every tool ought to have its own place on the bench, swages, fullers, etc., in consecutive arrangement, so that the blacksmith can put his hand on any tool at any time. It takes but very little time to put away a tool immediately after it has been used. If this is done every time, it will save confusion and lots of expressive language when it is wanted again.

The next tools to be considered are tongs. These are by no means the least important of the blacksmith's tools. In

order to do good work, it is of the utmost importance to have tongs which will hold the work firmly. In a great many cases tongs are poorly proportioned. For light work they are too heavy, and for heavy work they are too light. In making tongs, several things should be taken into consideration, such as the shape of the stock they are intended to hold, where to leave the most material to resist strain, and the parts most liable to wear out. For flat tongs the jaws should be heaviest near the joint, and taper toward the point. The point should be about half the thickness of the width of the jaw. The reins should be round on the edges and taper gradually from the joint to the tip, which will give them elasticity, and afford a comfortable grip for the hand. Care should be taken to leave no sharp corners around the joint, as it is there that the tongs are most liable to break. Flat tongs should have a small V shaped impression the full length of he jaw, so that they can be used to hold square stock cornerwise, or round stock. Fig. 8 shows a pair of flat jawed tongs of about the proper proportion for holding ½-inch flat, ½-inch square or ⅝-inch round stock. Barring accidents this style ought to give the maximum of service. This type of tongues can be used for stock of the smallest sizes up to two inches. For larger sizes of flat stock the tongs ought to have one box jaw, or a jaw with a cross section on the point with lips turned up, to prevent the work from moving edgeways. The tongs shown in Fig. 9 are the most convenient style for holding round or square stock, the V shaped jaws giving them a perfect grip on square work, and a bearing on four points of round work. This gives them an advantage over the circular jawed tongs commonly used for round stock, as these only have two bearings. The goose neck section between the jaw and the joint is also an advantage, as it will accommodate a burr or irregularity on the end of a piece of iron or steel which is usually found after it has been cut with shears or with a saw, while the bar is hot. Tongs of this shape can be used up to 5 inches capacity. For holding them upon the work, the style of link shown in Fig. 9 in enlarged scale in proportion to the tongs should be used. Being made narrow at the ends, it has the advantage of hugging the reins tightly, and having two bearings on each rein makes it less liable to fly off than the link with circular ends.

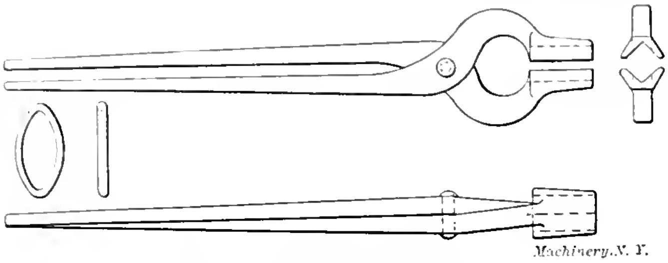

Fig 9 Tongs with V-shaped Jaws.

For work over 5 inches, the style of clamp shown in Fig. 10 should be used. This clamp can be bolted firmly to the work whether it be round or square, and can be operated with the small clamps with handles attached to the shank in the same manner as would a porter bar. For heavy work, clamps are a great deal safer than tongs, and can be made to handle flat or irregular shaped pieces. For fastening the clamp to the work, the bolt shown in Fig. 6 is the most suitable, it having a cross head with lugs to keep it from turning, and it can therefore be tightened or unscrewed with one wrench.

In nearly every blacksmith shop there is work to be done which can only be accomplished with special tools about which it would be impossible to give any intelligent information without seeing the pieces to be made; but whenever the quantity is such that it will justify the making of special tools, it should be done. A former or a fixture will not only reduce labor and cost, but makes the work more uniform. It is no exaggeration to say that at the present time very few blacksmith shops give more than 75 per cent of their possible efficiency, and others not more than 50 per cent, simply for lack of tools, system, and good executive guidance. A little consideration and a little outlay of capital would be a good investment, as in the majority of cases it would raise the blacksmith shop from being a "drag" to one of the most remunerative departments in a manufacturing plant.

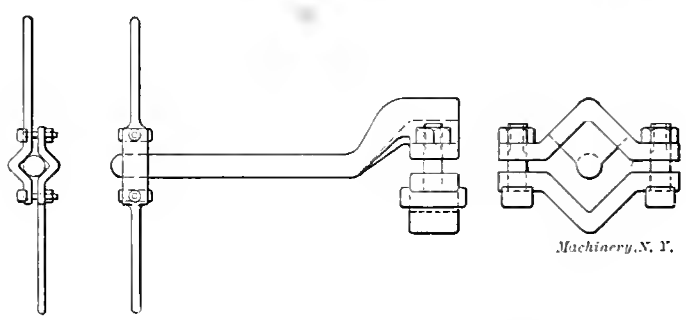

Fig. 10. Clamp for Handling Large Work in the Blacksmith Shop.

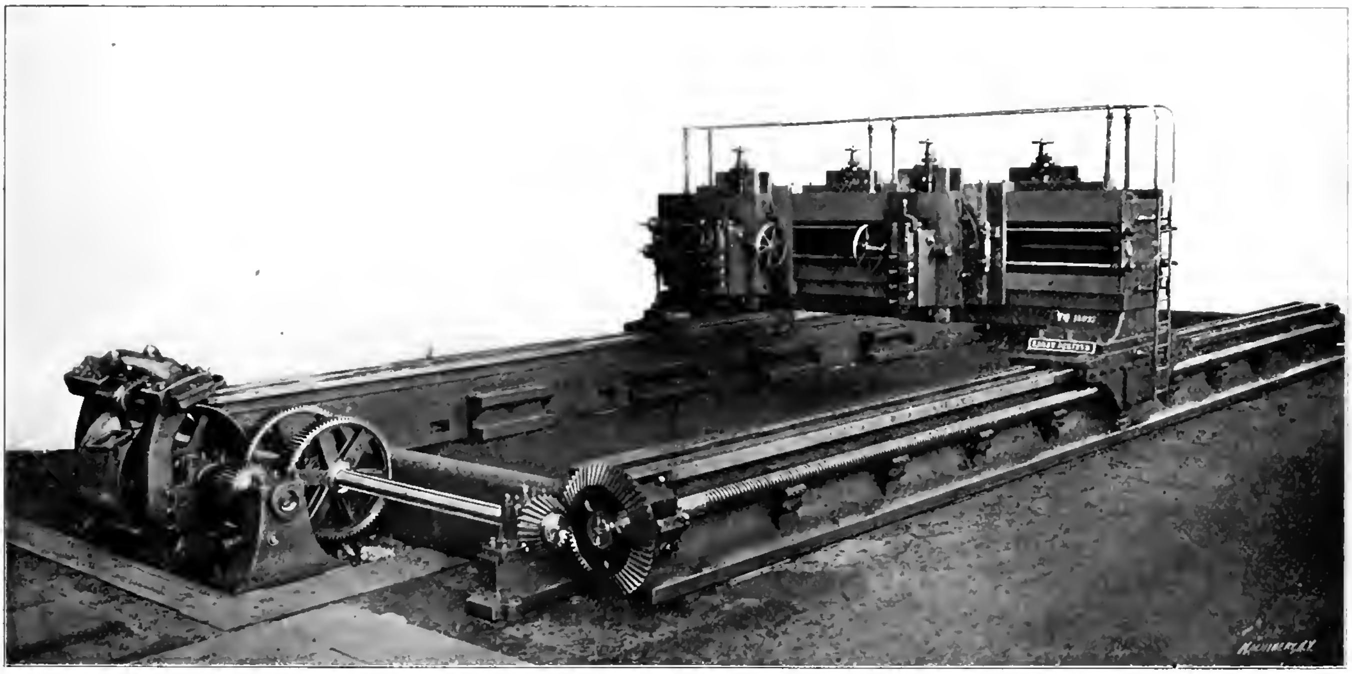
ERNST SCHIESS PIT PLANER.

We read with much interest your communication "An Alternative Planer Type Suggested" in your June issue, and your comments thereon. We would like to point out that the Société Anonyme des Etablissements Fetu-Defize, Liége, Belgium, is not, as might be inferred, the only firm building this sort of pit planer. We are building pit planers and have delivered machines built for similar purposes of 10 meters (32 feet 9¾ inches) length and 4 meters (13 feet 1½ inch) width, among others to Messrs. Schneider & Co. in Le Creuzot (three); Krupp, in Essen (two); Dillingen Hüttenwerke, Dillingen (two).

The accompanying illustration shows our machine which planes 8,000 millimeters (26 feet 3 inches) long, and 4,000 millimeters (13 feet 1½ inch) wide, and which is provided with four tool-posts. The side beds of the machine, each consisting of two pieces coupled together and bound at the ends by heavy cross ties, are made with flat guides for the cross-slide. The cross-slide is fitted with side strips on the inside edges for taking up the wear. The outside strips are to prevent side slipping of the cross-slide.

The drive is obtained through open and cross belts and steel spur and bevel gears connecting the two long heavy screws lying outside of the beds. These screws run in phosphor bronze bearings, and are provided with nuts filled with white hard anti-friction metal for driving the cross-slide. Two transmission shafts also run in phosphor bronze bearings. The length of the bed is 13,700 millimeters (45 feet, about).



Large German Pit Planer.

The machine is arranged to plane both forward and backward, and the cutting speed in both directions is 2 meters (6.56 feet) per minute for very hard material and 4 meters (13.12 feet) per minute for medium hard metals. The tool slides are self-acting and may be operated independently, either horizontally or vertically. The feed for each carriage is operated by means of a crank disk and movable connecting-rods. The horizontal feed motion of the main slides is so arranged that both slides can be operated together or independently in the same direction or in opposite directions, and the tool boxes can be set at any angle.

ERNST SCHIESS WERKZEUGMASCHINENFABRIK AKTIEN-
Düsseldorf, Germany. GESELLSCHAFT.

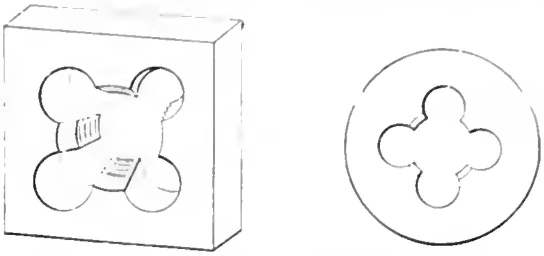
* * *

A new aluminum alloy has been patented in Germany by Walther Gosman, of the Krupp's Steel Works, of Essen-on-the-Ruhr, Germany. This alloy is composed of 87 per cent of aluminum, 8 per cent of copper and 5 per cent of tin. It is stated that the alloy casts better than the common aluminum and zinc mixtures, that it machines well, is homogeneous, and has a relatively higher ultimate strength.

THREADING DIES.

ERIK OBERG *

Threading dies may be divided into four general classes Solid dies, which may be either square or round, as shown in Figs. 1 and 2; adjustable split dies, which usually are round; spring screw threading dies; and inserted chaser dies, where the blades, provided with cutting teeth, are inserted in the body, and secured in some suitable manner.



Figs. 1 and 2. Square and Round Solid Dies

Solid Dies.

The solid die is used to a great extent on general work, either in cases where a correct size is not essential, or for roughing a thread before taking a finishing cut with an adjustable die. The solid die is not preferable to use when threads are to be cut requiring a high degree of accuracy. In the first place, the size when the die is hardened, cannot be depended upon to be exactly the size wanted, as dies are very apt to "go" more or less in hardening, and on account of their construction, apt to "go" in an irregular manner, one land closing up or departing more from the true axis of the thread than the others. In the second place, even if the die were correct from the beginning, there are no provisions for adjusting it to size when worn.

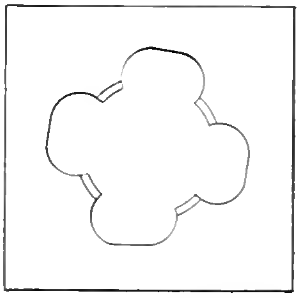


Fig 3 Large Size Square Solid Die, showing Form of Clearance Holes.

Solid Square Dies.

The solid die, as a rule, is of a square form. It is used principally for threading in bolt cutters, and for work of this kind answers its purpose well. It is also used for pipe dies, in which case the thread evidently must be tapered. As a tapered thread, in order to cut a thread smoothly and correctly, requires to be relieved in the angle, and, as the difficulties for relieving an internal thread like that of a pipe die, are very great, and it is not customary to

---

* Associate Editor of MACHINERY.

do so, pipe dies and, of course, also all other taper dies, cannot be used for cutting the threads of taps, but can only be used for rough work on pipes and similar soft metal where a perfect thread is not essential.

Lands and Clearance Holes.

Solid square dies are always provided with four lands, excepting if very large, when five lands may be preferable. The width of the land should be about 1/12 of the circumference of the screw to be cut with the die, or approximately 1/4 of the diameter of this screw. The clearance holes should be laid out so as to provide for this width of land. The center of the clearance holes should be located a trifle outside of the circle which measures the diameter of the screw to be cut. Some makers of dies locate the center of the clearance holes exactly on this circle, but the clearance holes then become rather small, and are easily clogged with chips which may tear the threads of the screw being cut, and occasionally break the teeth of the threads in the die. In very large dies it is not possible to make circular clearance holes, as these would be required to be of too large a diameter in order to make the lands of the correct width. In such cases, two clearance holes are drilled between each two of the lands and connected with a straight surface, as shown in Fig. 3.

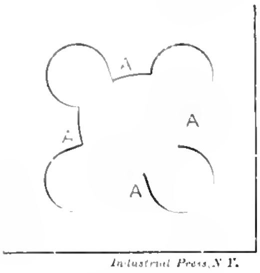

Fig. 4. Cutting Edges as Ordinarily Made.

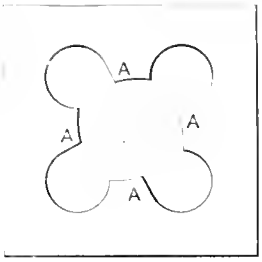

Fig. 5. Cutting Edges with Negative Rake.

TABLE I. DIMENSIONS OF SOLID SQUARE BOLT DIES.

Diameter of Thread.	Size of Square.	Thickness.	Diameter of Thread	Size of Square.	Thickness.
1/4	2 1/2	1/2	7/8	2 1/2	3/4
5/16	2 1/2	1/2	1	2 1/2	1
3/8	2 1/2	1/2	1 1/8	2 1/2	1
7/16	2 1/2	1/2	1 1/4	2 1/2	1
1/2	2 1/2	3/4	1 3/8	2 1/2	1
9/16	2 1/2	3/4	1 1/2	3	1
5/8	2 1/2	3/4	1 5/8	3	1
11/16	2 1/2	3/4	1 3/4	3	1 1/4
3/4	2 1/2	3/4	1 7/8	3 1/2	1 1/2
13/16	2 1/2	3/4	2	3 3/4	2

The chamfer on the top of the thread should extend for about three to four threads. It is necessary to relieve the dies on the top of the thread of the chamfered teeth, in order to make the die cut. If the die should be expected to cut a thread close up to a shoulder, the chamfer, of course, would have to be made proportionally shorter.

TABLE II. DIMENSIONS OF SOLID SQUARE PIPE DIES.

Nominal Pipe Size.	Size of Square.	Thickness.	Nominal Pipe Size.	Size of Square.	Thickness.
1/8	2	1/2	1	3	3/4
1/4	2	1/2	1 1/4	3	3/4
3/8	2	1/2	1 1/4	4	1
1/2	2 1/2	3/4	1 1/2	4	1
[illegible]	2 1/2	3/4	2	4	1
3/4	2 1/2	3/4	2 1/2	5	1 1/4
[illegible]	3	3/4	3	5	1 1/4

As the clearance holes when drilled do not produce a desirable cutting edge on the face of the teeth, the front face must be filed after the holes are drilled. They are, as a rule, filed radial, as shown in Fig. 4. When the dies are used wholly for threading brass castings, and various other alloys of copper, it is common in many shops to give the face of the cutting edges a negative rake, as shown in Fig. 5. However, opinions differ widely as to the proper rake to give to the lands of threading dies, and it is probably as well to make the faces radial in all cases. As a matter of fact, the dies will cut all metals ordinarily used in a machine shop to full satisfaction if made in this manner.

Dimensions of Solid Square Dies.

In regard to the sizes to which solid square dies should be made, the outside dimensions evidently depend upon the sizes of the holders in which the dies are used. The thickness of the die should preferably not be made less than one and one-quarter times the diameter of the screw to be cut with the die, but manufacturers of dies do not, as a rule, make their dies fully as thick. The average rule is to make the thickness about equal to the diameter, at least for sizes of screws larger than 3/4 inch diameter. In Tables I and II are given the general dimensions of dies as commonly manufactured, both for regular sizes and pipe sizes. These dimensions are, of course, only given as a guidance, there being no particular reason for making the dies in these certain sizes excepting that the outside dimensions being standardized, the number of holders necessary to use with the dies are reduced to a minimum.

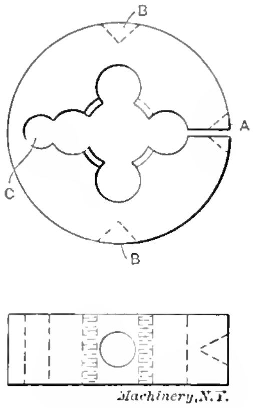

Fig. 6. Round Split Adjustable Die.

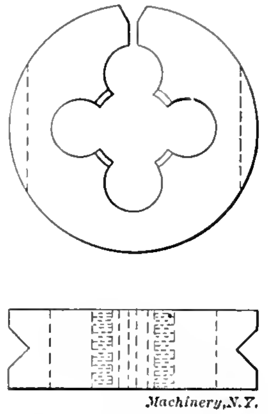

Fig. 7. Round Split Adjustable Die with Grooves for Adjusting Screws.

It is, however, necessary to call attention to the fact that, on account of the clearance holes, the size of the outside square must have some minimum relation to the diameter of the thread to be cut, so that the metal where the clearance holes are drilled does not become too thin. Even if strong enough to stand the strain incident to the thread cutting operation, a die with too thin metal at the clearance holes will spring badly out of shape in hardening and will become a very poor tool for its purpose. The outside size of the square ought not to be less than double the diameter of the thread to be cut.

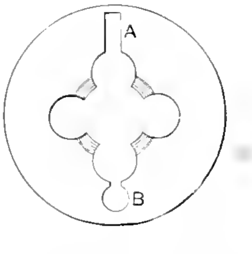

Fig. 8. Manner of Splitting Round Adjustable Die before Hardening.

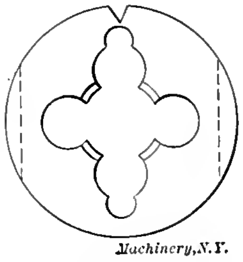

Fig. 9. Round Adjustable Die before Hardening.

Number of Lands.

While four cutting edges or lands are sufficient, at least for all dies up to four inches diameter which cut a full thread, it is necessary to provide more than four cutting edges in a die used for threading work in which part of the circumference is cut away. A greater number of cutting edges are here needed in order to steady and guide the die, and prevent the work from crowding into the side where the metal is cut away. When more than one-sixth of the circumference is cut away, it is not advisable to try to use dies for cutting the thread. The number of cutting edges should be in relation to the amount of the circumference of the work cut away as follows:

Fraction of Circumference Cut Away.	Number of Cutting Edges.
1/24	5
1/12	6
1/8	7

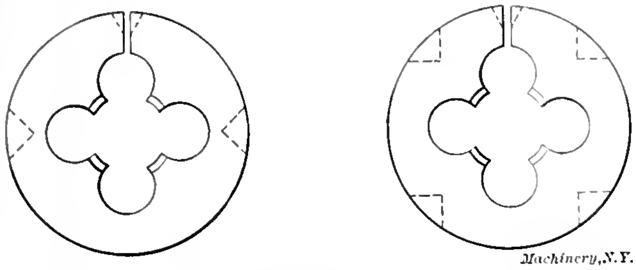
Split Adjustable Dies.

Split adjustable dies, as said before, are usually round, as shown in Fig. 6. The split permits the die to be opened, or closed up, for adjustment. The countersink *A* at the split is for the point of the adjusting screw. The countersinks *B* are for the binding screws, which close up the die to bear upon the point of the adjusting screw. Instead of countersinking at *A* and *B*, as shown in Fig. 6, it is cheaper, when making these dies in quantities, to mill grooves, as shown in Fig. 7. The grooves, as well as the countersinks, for the adjusting screws, are usually made 60 degrees inclusive angle, and those for the binding screws 90 degrees.

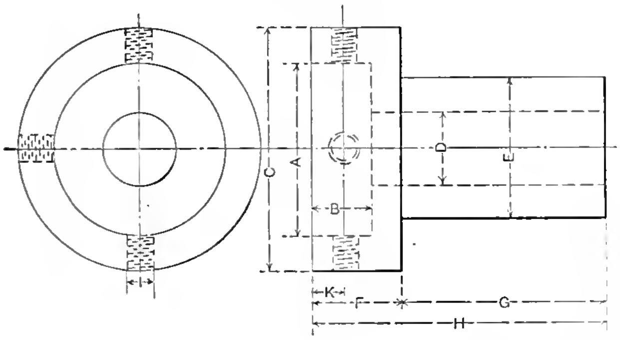


Machinery,N.Y.

Fig. 10. Comparison between Common Ways used for Locating Adjusting Screws.

In order to make the dies more easily adjustable, a small hole is often drilled outside of the clearance hole opposite the split, as shown at *C* in Fig. 6. If the dies made are few, they may be split before hardening, as shown at *A* in Fig. 8, with a saw or narrow file, but should not be split all the way through until after hardening, in order to prevent springing due to this process. When made in large quantities, a hole may be drilled outside of the clearance hole, where the split is to come, and the groove for the adjusting screw milled so as to leave a narrow bridge of metal between the hole and the bottom of the groove, as shown in Fig. 9. This bridge of metal is then removed after hardening by means of grinding with a thin emery wheel, or a bevel wheel with an acute angle.

TABLE III. DIMENSIONS OF DIE HOLDERS FOR USE IN ORDINARY LATHE.



Machinery,N.Y.

Fig. 11.

Diameter of Recess.	Depth of Recess.	Outside Diameter.	Diameter of Hole in Shank.	Diameter of Shank.	Length of Body.	Length of Shank.	Total Length.	Size of Screws.	Location of Screws.
A	B	C	D	E	F	G	H	I	K
0.632	1/4	1	3/16	1/2	3/8	3/4	1 1/8	5/32	0.135
0.821	1/4	1 1/4	7/16	5/8	3/8	3/4	1 1/8	3/16	0.135
1.009	3/8	1 1/2	9/16	1	9/16	1 1/8	1 11/16	7/32	0.197
1.511	1/2	2 3/16	13/16	1 3/8	3/4	1 1/2	2 1/4	1/4	0.260
2.013	5/8	2 5/8	1 1/16	1 3/4	15/16	1 7/8	2 13/16	5/16	0.322
2.515	11/16	3 9/16	1 3/8	2 1/4	1	2 1/16	3 1/16	3/8	0.354

Round split dies for sizes up to and including 3/16 inch are given only three lands. All other sizes are provided with four lands. When hardening these dies, draw to a blue in back of the clearance holes, in order to insure a good spring temper.

About three threads should be chamfered and relieved on the top of the chamfer, on the leading side of the die. Such dies as are intended for use in die stocks should be chamfered on both sides or ends, in order to permit the turning of the die and its cutting close up to a shoulder. In such cases the chamfer on the leading side should be about three threads as before, and on the back side from one to one and one-half thread. The thread which is to be cut close to a shoulder should, however, always be started with the leading side of the die, both because this side is provided with a longer chamfer and consequently possesses better cutting qualities, and because of the guide with which the die stock is provided on the leading side which is necessary to insure a straight thread.

There is some difference of opinion as to the best manner of arranging the binding screws for adjustable split dies. The common arrangement with two screws has been referred to, but an arrangement for four screws, as shown in Fig. 10, evidently will close up the various lands more uniformly, and the die will cut more freely. If adjusted so that the lands do not come at a uniform distance from the true axis of the die, all the lands will not cut, or, if they cut, will produce a thread that will be out of true.

TABLE IV. DIMENSIONS OF ROUND SPLIT ADJUSTABLE DIES.

Diameter of Thread.	Outside Diameter of Die.	Thickness	Diameter of Thread.	Outside Diameter of Die.	Thickness.
1/16	13/16	1/4	1/2	2	5/8
1/8	13/16	1/4	9/16	2	5/8
3/16	13/16	1/4	5/8	2	5/8
1/4	13/16	1/4	11/16	2	5/8
3/16	1	3/8	3/4	2	5/8
1/4	1	3/8	11/16	2 1/2	11/16
5/16	1	3/8	3/4	2 1/2	11/16
3/8	1	3/8	13/16	2 1/2	11/16
7/16	1	3/8	7/8	2 1/2	11/16
3/8	1 1/2	1/2	1	2 1/2	11/16
7/16	1 1/2	1/2	1 1/8	2 1/2	11/16
1/2	1 1/2	1/2	1 1/4	2 1/2	11/16

The outside dimensions of round split dies are usually made of certain standards to fit a few holders. Dimensions commonly used are stated in Table IV.

Die-holders.

An ordinary lathe die-holder is shown in Fig. 11, and dimensions for holders of this design for the dies in Table IV are given in Table III. A holder for a smaller size is also specified, as dies for small machine screw sizes are often made with an outside diameter of 5/8 inch and a thickness of ¼ inch. The dimensions cannot, perhaps, always be adhered to, but they will be of value as guidance when proportioning holders of this or similar kinds.

It will be noticed that the center line of the binding screws does not fully coincide with the center of the die in the longitudinal direction, but that the screws apparently are located 0.010 inch too far in. This is for the purpose of forcing the dies solidly toward the bottom of the recess, the screws exerting a wedge action on the dies in the countersinks or milled grooves provided for the point of the screws.

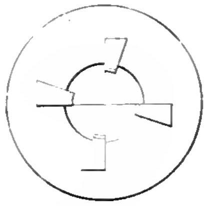


Fig. 12. Solid Inserted Blade Die.

Approximate formulas may be given from which well-proportioned holders for other sizes than those given in the table may be made. In the formulas:

d = the outside diameter of die,
A = diameter of recess,
B = depth of recess = thickness of die,
C = outside diameter of holder,
D = diameter of hole in shank,
E = diameter of shank,
F = length of body,
G = length of shank,
H = total length,
I = size of adjusting and binding screws, and
K = distance from end of holder to center of screws.

The following formulas give results, approximately, as stated in Table III:

$$A = 1.004\,d + 0.005 \text{ inch}$$

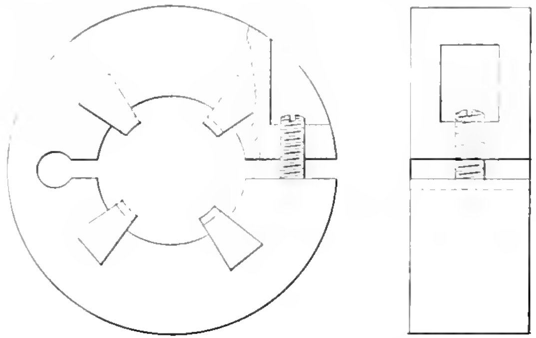
$$C = \frac{11\,d + 1}{8}; \qquad D = \frac{9\,d}{16}; \qquad E = \frac{3\,d + 1}{4};$$

$$F = \frac{3\,B}{2}; \qquad G = 3\,B; \qquad H = \frac{9\,B}{2};$$

$$I = \frac{d}{8} + \frac{3}{32}; \qquad K = \frac{B}{2} + 0.010.$$

Inserted Chaser Dies.

Inserted chaser dies may be of two kinds, such as have the chasers driven solidly in place, and such as have chasers which are easily removable, and can be replaced without difficulty. It is evident that the latter form is superior, but it is also the more complicated and expensive form.

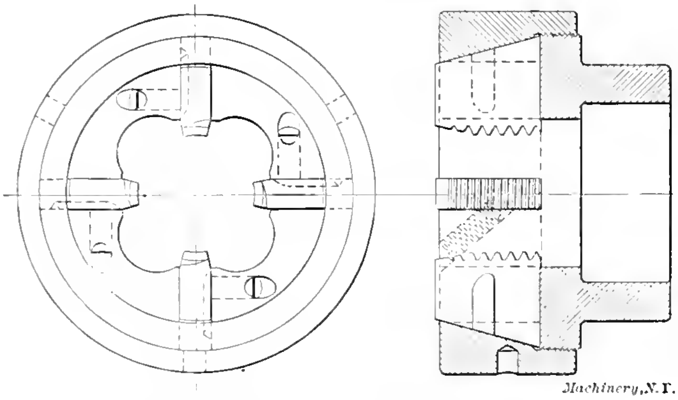


Industrial Press, N.Y.

Fig. 13. Adjustable Inserted Blade Die.

Inserted Chaser Dies with Fixed Chasers.

If we first consider the case of the dies with the blades solidly in place, we may safely say that it is not advisable to attempt to make very small dies with inserted blades, but for dies which are two inches in diameter, or possibly 1¾ inch, a ring of machine steel, having slots in which are inserted blades made of tool steel, is the simplest construction of an inserted blade die. The slots receiving the blade are made so that the front edge will be radial, as shown in Fig. 12. In this way there will be no difference in the cutting action of the inserted blade die, and a solid die having its cutting edges on the radial line. The slots should be of the dovetail type, that is, wider at the bottom than at the top, so that the blade is drawn into its seating surface, and prevented from being pulled out when in use. The first cost of a die made in this manner may not be any less than the first cost of a solid die, but the cost of new blades is less than the cost of a new solid die, and therefore, in the long run, this type of die should be cheaper. Besides, there is no risk of spoiling the dies in hardening, because only the blades are hardened, and these, of course, would not crack, at least not under any ordinary circumstances. The inserted blade dies are made either solid or adjustable. When made of the former type, they are threaded with a hob of exactly the same size as the screw to be cut with the die. When made adjustable, they should be tapped with a hob about 0.005 inch over size for a 20-pitch thread to about 0.015 over size for a screw having from 4 to 5 threads per inch. There are several methods for adjusting inserted blade dies, one of the simplest, and at the same time one of the best, is shown in Fig. 13, but it is claimed by many mechanics that better results are obtained if this class of die is provided with the same adjustment as has been previously described under the head of adjustable dies in the previous portion of this article.



Machinery,N.Y.

Fig. 14. Inserted Chaser Die with Removable Blades.

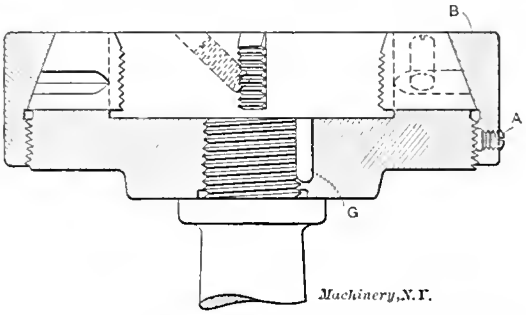
Inserted Chaser Die with Removable Blades.

A typical construction of inserted chaser die with easily removable blades is shown in Fig. 14. This die consists of four chasers or blades inserted in radial slots in a body or collet, the chasers as well as the collet being enclosed in a die-ring. This ring is beveled on the inside to fit a corresponding bevel on the back of the chasers. It can be screwed up or down on the collet, thus pushing the chasers in toward, or permitting them to recede from, the center. Screws are provided bearing in slots of the chasers for holding the latter in place after they have been adjusted by means of the ring.

TABLE V. OVER-SIZE OF TAPS FOR HOBBING SPRING SCREW DIES WHEN CUT STRAIGHT.

No of Threads per inch.	Over-size.	No of Threads per inch.	Over-size.	No. of Threads per inch.	Over-size.
4½	0.015	12	0.006	28	0.004
5	0.013	13	0.006	30	0.004
5½	0.012	14	0.005	32	0.004
6	0.010	16	0.005	36	0.004
7	0.008	18	0.005	40	0.003
8	0.007	20	0.005	48	0.003
9	0.007	22	0.005	56	0.0025
10	0.006	24	0.004	64	0.002
11	0.006	26	0.004	72	0.002

The chasers must, of course, be made in sets so that each is, so to speak, one-quarter of a thread ahead of the following one, or in other words, the teeth on the chasers must all form one continuous thread around the die. The die shown in Fig. 14 is known as the Woodbridge adjustable die. The shank is in one solid piece with the body. Another form of inserted chaser die is shown in Fig. 15. Here the shank is screwed into the body and secured to it by means of a pin *G*. The screw *A* serves the purpose of locking the die ring *B* to the body as soon as the chasers are properly adjusted; the chasers are secured the same as in the die previously described.



Machinery,N.Y.

Fig. 15. Another Type of Inserted Chaser Die with Removable Blades.

The object of inserted chaser dies is the adjustment possible, and the saving caused by being able to use the same body and ring for an indefinite period, the chasers only being replaced when worn. The chasers only are made from tool steel, the remaining parts being machine steel. As there is a considerable element of waste in being obliged to throw away a solid or adjustable die made from expensive steel whenever the cutting edges are worn away, the economy of replacing the cutting edges only is obvious.

Spring Screw Threading Dies.

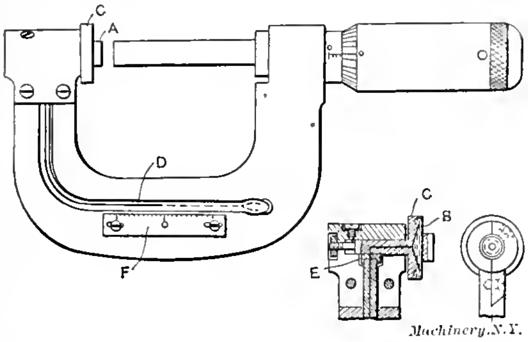
In the August, October, and November, 1906, issues of MACHINERY, three articles appeared dealing with the design and making of spring screw threading dies. In these articles, the commonly employed methods of making these dies were outlined, and some suggestions given in regard to possible improvements. In Table V is given the amount of over-size which the die tap is required to be when hobbing out spring screw dies, when threaded straight from the front of the die.

An article giving the method of determining the relative sizes of roughing and finishing spring screw dies was published in MACHINERY, March, 1907.

ITEMS OF MECHANICAL INTEREST.

SENSITIVE INDICATING MICROMETER.

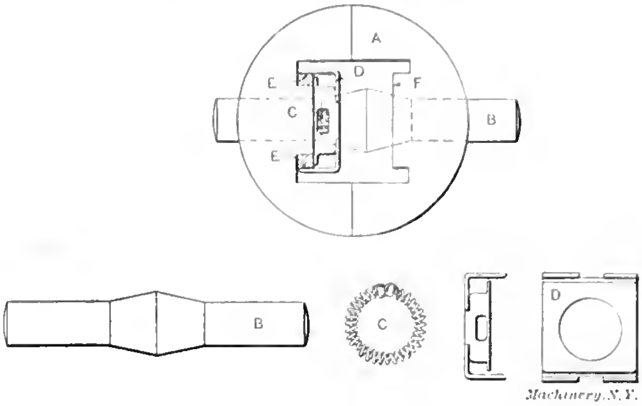
The accompanying illustration shows a micrometer which has been patented by the General Electric Company, of Schenectady, N. Y. The object of this tool is to avoid dependence on the sense of touch of the person handling the measuring tool. In the instrument shown, the accuracy of the reading is independent of the sense of touch or experience of the operator, and a correct reading can be easily detected by the eye by means of an indicator. The principle of the device is simply this: The stationary member or anvil *A* is attached to a circular diaphragm *B*, which is supported on its circumference in the head *C*. This head is cut away, so as to form a cone-shaped depression, which, in connection with the diaphragm forms a receptacle for mercury. The head *C* is provided with a stem, which fits into a bearing in the micrometer frame, and is slightly adjustable. A capillary tube *D* is partially imbedded in the frame, and has one end screwed to the stem of *C*, by means of a collar *E*. An adjustable scale *F* is arranged at the center of the frame. When measuring, the object to be measured will be pressed against the anvil *A*, until the mercury in the tube reaches the zero graduation on the scale *F*. For every piece measured the micrometer screw will be screwed down until the pressure on the anvil equals the standard pressure required for the mercury to indicate at zero on the scale. The tube, of course, must be made of glass, so as to make the mercury column inside visible to the eye. It is evident that very close measurements can be obtained in this way. One objection to the instrument may be that it must be held in a vertical, or nearly vertical, position when in use. The principle involved, however, may possibly be used for other micrometer measuring instruments, where the dependence on the sense of touch is objectionable.



Sensitive Indicating Micrometer.

INGENIOUS ELECTRIC SWITCH MECHANISM.

The accompanying line engraving shows an electric switch mechanism, the interesting feature of which is the simplicity of its action. In the top view the mechanism is shown assembled, and below are shown the three main details, the casing *A* not being shown here. Disregarding the casing, the switch mechanism consists practically of only three parts: first, a push bar *B* extending clear through the switch, having its largest diameter in the center, and shaped conically from the center for some distance towards each end, as clearly shown in the illustration; second, a coil spring *C* which encircles the bar previously mentioned in such a manner that the axis of the spring forms a circle around the bar; third, a moving contact piece *D*, forming a casing over the spring. When this contact piece is in the position shown in the upper view, it is in contact and forms a circuit at *E*, the contact pieces in the casing *A* being shown cross-sectioned for the sake of clearness. The action of the device is simply this: when the bar is pushed forward, the coil spring rides up on the conical surface until it reaches the center of the bar, all the time preventing the contact piece from releasing from contact at *E* until the spring has reached the central and highest part of the bar. At this moment it suddenly contracts and moves swiftly along the conical shape on the other side of the highest point of the bar, carrying with it the moving contact piece *B* and releasing it from its contact at *E*, bringing it against the other side of the casing at *F*. It is not possible to move the contact piece part way and let it slip back again, drawing an arc which burns the contacts and eventually destroys them. The contact piece must be either positively in contact at *E* or out of contact, resting against *F*. The simplicity of the mechanism makes it particularly interesting, and no doubt devices using the principle employed would be successful in automatic machinery for positive and instantaneous "knock-outs" and stops of various descriptions. The switch mechanism as shown is made by the Cutler-Hammer Mfg. Co., Milwaukee, Wisconsin.



Simple Electric Switch Mechanism.

CRANK TURNING DEVICE.

Patents have been applied for in Great Britain for the device working on the principle shown in the line-engraving herewith, intended for turning crank-pins, and pieces rotating around a central shaft in a similar manner. In the upper part of the figure, the general principle of the device is indicated, the lower part being a plan view showing diagrammatically its connection with the lathe to which it is applied. The principle of the device is easily seen from the illustration. The crank-shaft is mounted on its own centers in the lathe, and the working tools are given a reciprocating motion, vertically and horizontally, so as to coincide with, or follow, the motion of the work being turned. The motion of the tool is positive, and interdependent of the motion of the crank or shaft. In the lower part of the engraving, the device is shown in two positions, first when operating on one and then when operating on the other crank-pin of a crank-shaft having two pins. While not shown in the engraving, the two disks to which the tool holder arm is connected must be positively geared together, as otherwise difficulties are sure to be encountered. To what extent a device of this kind will prove practical for the purpose for which it is intended it is difficult to say.

The receipt of a subscription is acknowledged by sending the current issue. Checks and money orders should be made to THE INDUSTRIAL PRESS. Money enclosed in letters is at the risk of the sender. Changes of address must reach us by the 15th to take effect on the following month; give old address as well as new. Single copies can be obtained through any newsdealer.

We solicit communications from practical men on subjects pertaining to machinery, for which the necessary illustrations will be made at our expense. All copy must reach us by the 5th of the month preceding publication.

SEPTEMBER, 1908.

PAID CIRCULATION FOR AUGUST, 1908, 20,577 COPIES.

MACHINERY is published in four editions. The practical work of the shop is thoroughly covered in the Shop Edition—$1.00 a year, comprising more than 430 reading pages and 36 Shop Operation Sheets, containing step-by-step illustrated directions for performing 36 different shop operations. The Engineering Edition—$2.00 a year, coated paper $2.50—contains all the matter in the Shop Edition, including Shop Operation Sheets, and about 250 pages a year of additional matter, which includes a review of mechanical literature, and forty-eight 6 x 9 data sheets filled with condensed data on machine design, engineering practice and shop work. The Foreign Edition, $3.00 a year, comprises the same matter as the Engineering. RAILWAY MACHINERY, $2.00 a year, is a special edition, including a variety of matter for railway shop work—same size as Engineering and same number of data sheets.

The fourteenth volume of MACHINERY, regular edition, was completed with the August issue, and the yearly indexes for the Engineering, Shop and Railway Editions will be ready in September. The reader who binds an index with his issues for the year will have a volume of mechanical knowledge without a parallel in smallness of cost and comprehensiveness of contents. Copies of the index are sent free; specify the edition wanted.

* * *

THE VALUE OF PUBLICITY TO INDIVIDUALS.

Once in a while some contributor who has sent us a valuable article, and to whom we think is due all the publicity resulting from its publication, objects to having his portrait and biography, and sometimes even his name, used in connection with his contribution. His objection usually arises from modesty and the lack of appreciation of the value to him personally of the kind of publicity afforded by a mechanical journal of large circulation. There are hundreds of able men in as many different shops in the country who are working for far less compensation, or at least under far less favorable circumstances, than they might, did some other employer (or, in fact, in many cases, even their own employer) know of their ability, and thereby feel warranted in offering them places of responsibility which they cannot now reach, simply because they lack the requisite advertising.

It is not enough that a man is an able man, that he does his work carefully and conscientiously, and that he is able to carry out the tasks given to him. To be really successful, it is also necessary that other people know of this ability and appreciate it; and one of the simplest and easiest ways for a person to become known among mechanical men is by presenting his work and his experience in the pages of trade journals. In this manner he reaches mechanical men all over the country, he develops his ability to think and write clearly and logically; and in some cases, too, he finds out his limitations, and thereby is given an opportunity to improve.

A manufacturer's product may be the most perfect in his line and still his sales may be far less than his competitor's, who, perhaps, turns out inferior work. The reason for the difference is simply that the former manufacturer does not advertise his goods adequately, or in a proper manner. In the same way, an individual may possess great ability, fitting him for authoritative positions, but nobody knows of him, simply because he lacks the requisite publicity. There are three stages, one might say, in a man's success; the first, to "make good"; the second, to let others know that he can make good; and the third, to continue to make good.

* * *

PRACTICAL KNOWLEDGE OF SALESMEN.

The practical knowledge possessed by salesmen of the construction and use of the machines which they represent and sell, is a factor that is not so fully appreciated as it ought to be. When a salesman does not possess any practical or technical knowledge regarding his machines, but is merely a good talker, he may be successful as long as he deals with people interested merely in the selling end of the business; but nearly always he will have to deal also with men who are mechanics in the first place, and who soon find out the shortcomings of the salesman, and realize that most of what he says is not the result of his own knowledge, or matters which he could himself verify, but is simply said because others have told him so. The practical man is at once prejudiced against dealing with a man of this type, and although the salesman may be both honest and able in his particular line, and represent the very best machines, his lack of mechanical knowledge may prove to be his undoing. It is therefore important, in order that the salesman may make a good impression upon his customers, that he should know in detail the mechanical construction and use of the machine he is trying to sell, and be able to point out, from his own experience, the reasons why it is superior to competing machines. Salesmen of this type are able to convince practical men, and they create a good impression. The firm employing such salesmen has in them one of its greatest assets.

THE ADVANCE OF ENGINEERING EDUCATION.

The new departure in engineering education, inaugurated two years ago at the University of Cincinnati, in the form of a cooperative course in engineering, appears so far to have proved an unqualified success. It is natural that it should be so, considering that the factors required in the training of an engineer have been taken care of by this course in a far better manner than by engineering schools in general. It should be remembered, however, that a cooperative course of this kind cannot be instituted by every technical school or college. The fundamental requirements are that the college be located in a city with a highly developed machine industry, and that the men in charge of these industries be favorably inclined towards the proposition, and willing to accept students for training purposes. But wherever the technical school is so located, there is little doubt that such a school will turn out a product superior to the average, and that it will receive applications from young men wanting a practical engineering training, in such abundance as to make possible a judicious selection of the raw material that is offered. This, at least, has been the experience of the Cincinnati school.

The advantages of the cooperative course, from a technical and mechanical point of view, can hardly be overestimated. This system of educating engineers is also likely to have far-reaching sociological results. It brings those men who in the future are to guide and superintend the work of others, in close contact with the very men they are to lead later on. It gives the students a clear conception of the conditions under which these men work, and should enable them as leaders to avoid a great deal of the friction that is often due simply to misunderstanding. This departure in engineering education should therefore be productive of results more far-reaching than even its inaugurators have anticipated. It has proved embarrassing in some cases to the old school of professors and teachers. They have found themselves out of place when confronted by young men who one week work in the shop, and the next week in the class-room, and who come there full of practical ideas. This experience will naturally force some instructors either to assume a different attitude toward practical education, or to make way for another class of instructors able to meet the demands of the times. The cooperative engineering courses are likely to be a regenerative force in our engineering education.

INCREASED USE OF HIGH-SPEED STEEL.

The main disadvantage under which high-speed steel has labored during the last few years, as regards its employment universally in the metal trades, has been its high cost. With the steel used merely as a cutting tool, this high cost would not be prohibitive, inasmuch as the increased production would well warrant the use of high-speed steel; but a large portion of every tool is used not as a cutting tool, but merely as a holding device, shank, etc., and it is rather expensive, particularly in large tools, to have these parts of the tool made of so expensive a material. Tool-holders of various shapes and kinds have been used, but for many purposes they are not as satisfactory as a solid tool. For this reason, attempts have been made to weld high-speed steel to shanks of cheaper materials, but in the past these attempts have been unsuccessful, the high-speed steel having refused to comply with any welding process intended to combine it by cohesion to either carbon steel or machine steel. An abstract of an article in an English contemporary in our Engineering Review this month gives a short review of a welding process which has been developed in England, and which is claimed to give satisfaction. Should it prove that this welding process is all that has been claimed for it, it is likely to revolutionize the use of high-speed steel, and in cases where now the expense of this material has been looked upon as prohibitive, it is likely to become universally used. It is to be hoped that the welding process, as outlined, is not merely a process developed for company promoting and stock jobbing purposes, but that it will prove to be of actual importance to the metal trades.

THE INCONSISTENCY OF SOME MANUFACTURERS.

JOHN B. SPERRY.*

Other manufacturers, besides machine tool builders, would do well to follow the suggestions offered in the editorial on "Obsolete Tools in Machine Tool Shops" in the July number of MACHINERY. The writer can call to mind several instances where manufacturers show their inconsistency in this respect. This can be best illustrated by a specific case, referring to a concern capitalized at $300,000, and manufacturing steam engines, air compressors, water in-takes operated by compressed air, air-lift systems, centrifugal pumps of all sizes, and several other kinds of machines for pumping purposes. This firm has a machine shop, foundry, wood shop, pattern shop, blacksmith shop, and ware-house—all modern buildings. These shops all receive their power from a central power plant equipped with a Corliss engine and a direct current generator. The machine shop is equipped with an electric traveling crane, while the foundry and blacksmith shop have jib cranes operated by hand. The concern has spent thousands of dollars for jigs in order to lower the cost of production. The shops are lighted by electricity, and the clock system of time keeping has been installed. Besides this, there is an excellently arranged stock department.

Contrasted with this is the equipment of the foundry. Since this firm manufactures air compressors, one would naturally expect to see some pneumatic tools in operation, especially in the foundry; but no, all the riddling and chipping is done by hand. Pieces that are too large to put in the rattler are brushed and cleaned up by hand. And to cap the climax, instead of using one of the firm's own air-lift pumps for the water system, there is an old power pump jack that keeps the water well oiled, and breaks down regularly once every two weeks.

Now this firm's trade in air compressors has fallen off considerably in the last two years, due, it is claimed, to the competition in that line. It is the writer's opinion that if this firm would practice what it preaches, it would be able to get in on the ground floor with the other fellow. The use of air hammers, air chisels, air brushes, sand blasts, emery wheels operated by air, air drills, riddles operated by air, and air lifts, would not only cheapen the labor cost, but the practical application of compressed air to the work of the machine shop, foundry, blacksmith shop, etc., would be an object lesson to the intending purchaser that would tend to hasten his decision.

This shop is not the only one that seems to be trying to make and sell something that the firm's officers do not seem to believe in themselves; there are others, and one does not have to travel far to find them. Without citing any more cases one might add that if the manufacturer would be consistent and make it a point to have practical applications of the machines or appliances that he manufactures, where they can be seen by a buyer, he will find it easier to convince the public of the utility and advantages offered by his product.

[In connection with the foregoing it may be interesting to relate an occurrence which took place at the works of a well-known machine tool building firm a few years ago. A Japanese, traveling in the United States for the purpose of selecting and buying some new machinery for a Japanese ordnance works, was taken through the shops by one of the members of the firm, and shown a new lathe brought out by the company. This guide, having a mental vision of a large contract from the Japanese government, became more and more enthusiastic as he explained the merits of the new machine, and, in particular, pointed out that no machine shop could afford to keep their old machines, when installing this new lathe would double the production, or nearly so. He explained to the Japanese that in America it was very common for manufacturers to throw out the whole of their old equipment, and install new machinery when its superiority had been proved. This particular machine, he said, was a machine of the type that would justify such action. The Japanese listened with a pleasant smile, and, according to the Japanese code of politeness, agreed with everything said. After having been taken all through the shops, and on return to the office, when the question of "making a deal" was brought up, the little Japanese quietly and pleasantly asked: "Now, if this machine that you have shown me, and the merits of which are so great as to warrant throwing out old equipment and installing a new set of machines, actually possesses all the merits you claim for it, how is it that you have only three of these new lathes installed in your own shop?" The reply is not recorded, nor is the sale of the machines.—EDITOR.]

SPECIFIC ADVERTISING.

The great advance in machine tool construction which has taken place during the last decade is strikingly demonstrated by a comparison of the advertising pages of a technical journal ten years ago and to-day; and such a comparison will show not only that there has been an advance in the building of machines, but also in the method of presenting the advantages of the machines to prospective customers. The same holds true of all catalogues and advertising literature of to-day. Years ago it was common for the maker merely to state that he had such and such machines to sell, that they were of accurate workmanship, built of the best materials, and in all ways the most perfect on the market, etc. To-day, while of course these generalities may still be included, we see a large amount of what we may call *specific* advertising telling exactly what the machine will do and in how short a time it will do it, and what tools are required to perform the operation. Samples of work carried out on the machine are shown, and complete details about turning out the work, the material from which it is made, and so forth, are given. This is the kind of advertising that appeals to mechanical men. To speak in generalities does not appeal to them, because judging only by general terms, one machine is as good as another; but when the actual facts are given, provided they are given honestly and correctly, a mechanic can judge for himself without hesitation about the merits of the machine. He has some definite data to deal with when making his comparisons. It appears that manufacturers are commencing to appreciate the value of this kind af advertising, because it is becoming more and more common both in catalogues and in trade journal advertisements, to show the work performed, and to give the exact information regarding the performance. It is likely that in the future this class of advertising will be even more common than now, and the mechanical trades will undoubtedly gain by it.

ENGINEERING REVIEW.

CURRENT MECHANICAL EVENTS—LEADING ARTICLES OF THE TECHNICAL PRESS.

It is reported that a measure will be introduced at Ottawa for the reconstruction of the collapsed Quebec bridge. The construction work will be in the hands of a board of prominent engineers, and the Canadian government, it appears, is going to undertake the work as a government project.

According to *Indian Industry and Power*, a system of automatic signaling worked entirely by electricity is being installed on the Metropolitan railway in London. The new system provides for applying the brakes to the train automatically if the engineer should pass a signal set at danger.

Superheated steam locomotives appear to be so favorably considered by European railroads that at the present time hardly any express locomotives are ordered without superheaters. Recently 24 express locomotives for the Italian State Railways, built in Germany, were completed, all being furnished with Schmidt superheaters.

Beginning August 3, the last section of the Philadelphia subway was opened for traffic. This subway, which is run in connection with the new Market Street elevated railroad, gives an entire length of rapid transit through the city of about seven miles. The subway construction is of the very highest type, and the approximate cost of the subway portion alone is $20,000,000.

It appears that the authorities of the German State railways have concluded that incandescent gas lighting is superior to electric light in railway cars. No more cars are equipped with electric light, and the engineers, after long and exhaustive tests, have satisfied themselves of the value of the former system of car lighting, and are now changing over the equipment at the rate of 500 to 600 lights a day.

The British Admiralty has decided that in the future all small naval craft shall be constructed to use both coal and oil fuel. The oil-burning system has been used for a considerable time, and many of the destroyers and torpedo boats are designed exclusively for the oil-burning system. All the modern battleships and cruisers of the navy are also constructed to use either coal or oil.

During the year ending June 30, 1908, 1,506 vessels, with an aggregate tonnage of 588,627 gross tons were built in the United States. This is, so far, the largest annual output of the ship building yards in this country. The steel vessels built numbered 142, representing 417,167 gross tons, of which 75 were built for the Great Lakes, with an aggregate tonnage of 304,379 tons. The largest steamer on the lakes built during the year was very nearly 8,000 tons.

After several years of thorough testing and experimenting, the officials of the Burlington railroad have come to the conclusion that concrete ties are not satisfactory, and that the best solution of the railroad tie problem at present is to treat wood so that it will not deteriorate as rapidly as when in its natural state. According to the *Scientific American* it has been decided to construct a large plant for treating ties, bridge timbers, etc., with creosote.

In the May issue of MACHINERY, we mentioned that Professor Kamerlingh-Onnes, a Dutch scientist, had succeeded in solidifying helium. This statement, however, as we mentioned in a later issue, depended on a mistake made by Professor Onnes, he having been deceived by impurities in the helium. He has now, however, announced that he has been able to produce helium in a liquid state, boiling at a temperature of 7.75 degrees F. above absolute zero. He was not able, however, to solidify the liquid.

In a recent issue of the *English Mechanic and World of Science*, it is stated that at the June 15 meeting of the Academy of Science, Mr. Devaux Charbonnel gave particulars of a method of photographing sounds of the human voice, in such a manner that the photographic record could be read. Vowels and consonants are combined by means of the Blondel oscillograph. This extremely sensitive instrument impresses the sounds upon a photographic plate in the form of curves, which can, with a little practice, be easily deciphered.

According to the *Far Eastern Review*, a Chinese gentleman named Hu Chuen has obtained a patent on an improved method of wireless telegraphy, simplifying the methods hitherto in use. The system has been recommended by Chinese authorities for the reason that it makes use only of domestic Chinese materials of lower cost than imported articles, and it is also simpler to operate. At the test of the equipment at Canton it was pronounced a success. Detailed information as to the workings of the new system, however, are not as yet at hand.

The Society of German Engineers, at its annual convention held in Dresden June 29 and 30, and July 1, empowered its officers to negotiate with representatives of the Prussian State government, as well as the government of the German Federation, to make arrangements for the bringing out of the Technolexikon, which, as we have mentioned before in MACHINERY, the society found itself forced to give up about a year ago, on account of the great scope of the work, involving expenditures greater than the society considered that it could consistently make.

The much-advertised New York-Paris automobile race, which started from New York, over a route across the United States, Siberia, Russia, and Germany, to Paris on February 12, this year, was practically concluded by the arrival of the Thomas car in Paris on July 30. This race marks one of the most interesting events in the automobile history, and the fact that it was carried to a conclusion indicates the present state of the endurance of the automobile, and rather reverses the general opinion that the automobile is fit only for good and smooth roads in a country where the repair shop is near at hand.

It is interesting to note that the slide rule, which but lately has become universally used for calculations, was invented nearly 300 years ago. An article in *Zeitschrift für Vermessungswesen* calls attention to the fact that Gunter, shortly after his bringing out the trigonometric logarithm tables in 1620, placed logarithmic scales on wooden rules, and used a pair of dividers to add or subtract the logarithms. In 1627 these logarithmic scales were drawn by Wingate on two separate wooden rules, sliding against each other, so as to render the use of dividers unnecessary, and in 1657, or over 250 years ago, Partridge brought out the slide rule in its present form.

In view of the present agitation for the preservation of the natural resources of the United States, the methods employed by the Swedish government for the preservation of forest reserves as well as ore deposits are of special interest, and we have previously referred to the replanting of forests, the limitation of export shipments of iron ore, and the taking over of some iron ore deposits by the government. It is now reported that the Swedish government is still further pursuing the policy of actual ownership of ore deposits, the present parliament having passed a bill providing for the state purchase of the important Svappavaara ore fields in the northern part of the country.

In an editorial in *Teknisk Tidskrift*, attention is called to the mistaken idea of economy which manifests itself in the

use of cheap materials and cheap labor, rather than in a proper systematizing for using the given opportunities in the most economical way. Many a man thinks that when he can buy some belting for a few dollars less than he has been used to do, by selecting a secondary quality, he has accomplished a great saving, but loses sight of the fact that this mere temporary saving may be lost many times over, through frequency of repairs, faster wear, and disturbances in the running of the shop machinery. Still more serious, however, is the case when the "saver" selects the living material as the proper territory for his exploitation. The expression "cheap labor" is not clear, and it often is the cause of serious mistakes. It is self-evident, says the editorial referred to, that a poorly paid employe, as a rule, does not develop full energy, and that an efficient draftsman, for instance, if he is paid less than the common standard of wages for his class, will constantly give greater interest to the question, "How can I get out of here?" than to the problems which he is supposed to solve.

In an article in the *Engineer*, London, Mr. P. V. Vernon states that a good rule for the horse-power required to drive machine tools is to assume one horse-power for each 10,000 square inches of belt delivered to the machine per minute. This rule is based on a working belt pull of 39.6 pounds per inch of width tending to rotate the pulley, a rule which, it is stated, is justified by the author's experience, and which may be demonstrated as follows: 10,000 square inches of belt per minute = 10,000 linear inches of belt one inch wide per minute = 10,000 ÷ 12 linear feet of belt one inch wide per minute. As each inch of width of belt is assumed to carry 39.6 pounds of effective tension, the power transmitted will be:

$$\frac{10,000}{12} \times 39.6 \text{ foot-pounds} = 33,000 \text{ foot-pounds},$$

$$\text{or H.P.} = \frac{\pi DWn}{10,000},$$

in which formula, D = diameter of pulley in inches,

W = width of belt in inches, and

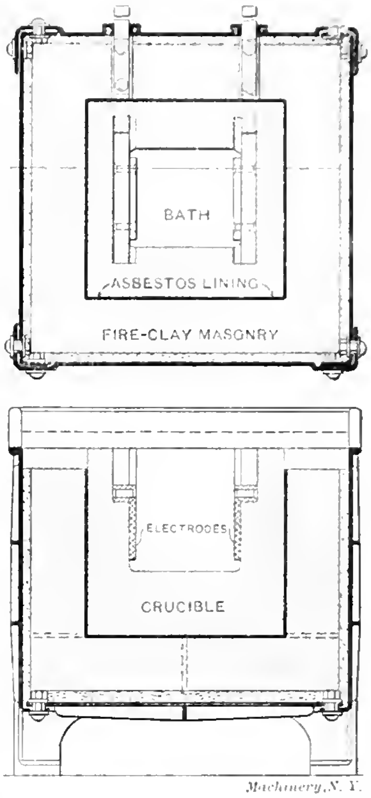
n = revolutions of pulley per minute.

A tight double belt may transmit twice the amount of power given by the above rule; but although the machine must be strong enough to resist the extra pull, yet it is not wise to provide for double the motive power where a separate motor is used, as most motors will stand as much temporary overload as a belt, and no belt will work well with a permanent overload.

A method for surface-hardening structural steel and steel rails is described in the *Mechanical Engineer*. The principle whereby this is accomplished is as follows: The steel ingot, when stripped from the mold, is enclosed in a receptacle lined with brick, the receptacle being about eight or ten inches larger than the ingot placed in it. Space is left between the ingot and the sides of the chamber, and when the ingot has been lowered centrally into the receptacle, the intervening space between the hot ingot and the sides of the receptacle is filled as rapidly as possible with dry powdered carbon or other carbonaceous material. This material is rammed in between the ingot and the walls, and when the receptacle is completely filled, the ingot is allowed to remain covered for a length of time depending on the amount of carbon to be absorbed by the surface. Several hours, as a rule, is necessary for obtaining the required results. The carbon penetrates into the surface of the steel ingot, and the whole process may be compared with the case-hardening of mild steel parts. The carburized ingot, when removed from the receptacle, is again heated and rolled into a structural shape, the finished article now presenting a hardened surface. It is stated that if it is desirable that only a part of the outer surface of the ingot should be hardened, so that when rolled down, the harder part may form the head of a steel rail, for instance, the part forming a web or flange still remaining soft, the hot ingot may be put into a receptacle, and suitable division pieces inserted so that carbon may be brought into contact only with the part required to be hardened. This process has been developed by Mr. Benjamin Talbot, formerly of Phoenixville, Pa., who is now living in England.

ELECTRICALLY HEATED HARDENING BATHS

In an article in *Page's Weekly*, the method of hardening small cutting tools adopted by the firm of Ludwig Loewe & Co., in their Berlin works, is referred to. The hardening process is carried on by means of electrically heated barium salt baths, the arrangement of the crucible and the electrodes being as shown in the accompanying engraving. By means of this process, it has been possible to harden large milling cutters in about half an hour, including the time for pre-heating, which takes the greatest part of the time. To bring the cutters up to a temperature of 750 degrees F. constitutes this pre-heating. After that, it takes only about a minute to bring an average-sized cutter to 1,400 or 1,500 degrees F., and then another minute to bring it up to about 2,370 degrees F., which is, by this firm, considered the right hardening temperature. The time stated above refers to average-sized and heavy milling cutters, whereas it only takes from 6 to 10 minutes to bring a small milling cutter to the right temperature in the electrically heated salt bath.



Machinery, N. Y.

Arrangement of Crucible and Electrodes for Electrically Heated Hardening Baths.

The advantage of electrically heated salt baths is stated as being the total absence of any scale on the tool thus hardened, and that the tools are not distorted in the hardening process. The bright appearance is retained by the hardened tool, so that it is sometimes difficult to tell from the appearance whether a tool has been hardened or not.

In regard to cooling the cutters, the firm of Ludwig Loewe has found that when high-speed steel tools are cooled in an air blast, any moisture coming in contact with the hot tool has a tendency to crack it, so that it becomes necessary to dry the air before it enters into the nozzles. It has also been found that it is absolutely impossible to cool a cutter which has a very heavy body and fine teeth in the air blast, as the heat from the central portion is not extracted fast enough, and therefore does not permit a sufficiently rapid cooling of the teeth to insure proper hardening. For this reason, the firm has adopted a method of cooling the cutters from the hardening heat of 2,370 degrees F. to a temperature of about 1,100 degrees F. by quenching in an electrically heated salt bath. After having been cooled to about 1,100 degrees F. in the bath, the cutters are allowed to cool down slowly in the air, and the whole process has the advantage of being cheap and reliable, as well as effecting a considerable saving in time.

It must, however, be understood that electrically heated barium salt baths are advantageous to use only when a large quantity of tools is to be hardened, because this method will otherwise prove expensive. It has also been remarked that the electrically heated bath is more advantageous for heavy than for small tools but it is not clear why the process should be thus limited to the former class of tools.

A NEW SYSTEM OF WELDING.

Engineering, June 19, 1908.

On account of the high price of high-speed steel, its use, particularly for heavy tools, has been rather limited in the past. All kinds of devices in the form of tool-holders have been adopted whereby a small tool made of high-speed steel performs the cutting, while the remainder of the tool, or the holder, is of cheaper material. Many attempts have been

made to weld high-speed steel onto mild steel, as well as onto high carbon steel, in order that a superior cutting edge may be presented to the work, while the cost of the tool is still kept down to a reasonable figure, the required size and stiffness of the tool being provided for by the body of cheaper material. All attempts to weld high-speed steel onto high carbon steel or machine steel have, however, until quite recently, proved futile. This is apparently due to the different coefficients of expansion of the different steels, high-speed steel having a low coefficient of expansion.

Lately a welding process, however, has been invented which is controlled by the Fusion Welded Metals Co., Ltd., 56 Victoria St., Westminster, London, by means of which it is possible to weld high-speed steel onto other steels. The operations are very simple. The welding of the two steels is performed by means of a thin film of copper. The copper is placed in the form of a feeder along the line of the joint. The parts to be welded are then surrounded by a reducing compound and are placed in a furnace where the temperature is raised to about 2,200 degrees F. The gas which is formed by the burning of the compound seems to affect the copper in such a way that the latter is reduced to a fluid as thin as spirits of wine, and in this condition it penetrates the molecular surfaces of the two classes of steel and produces actual cohesion and not merely adhesion. In fact, the weld becomes stronger than the remainder of the metal, so that if the two pieces being welded are forced apart, the line of fracture will follow the course of a new break rather than pass through the joint. The weld is so close that in some cases it is hardly possible to find a trace of the copper. A wide field of usefulness is predicted for this process. One application which has already been suggested, and where the process most likely will be most commonly used, is that of welding high-speed steel to carbon or machine steel bodies for the production of high-speed cutting tools at a moderate price.

A YEAR'S EXPERIENCE WITH A SUCTION GAS POWER PLANT.

J. C. Miller, in *Power and the Engineer*, May 26, 1908.

The author, in this article, presents the results of a year's operation of a suction gas power plant, stating the fixed charges in a way that will satisfy men who are prone to think of interest, depreciation, etc., as important elements in power cost. The engine under consideration was a single cylinder, horizontal 50 brake-horse-power, regulated on the hit-and-miss principle, and belted to the line-shaft. The gas was drawn from a suction producer, using anthracite pea coal. The plant was of English manufacture, and was well designed and constructed. The producer was equipped with the usual vaporizing apparatus for supplying steam to the blast, and with the usual coke scrubber and expansion box. The cost of the installation of the plant was $3,300. The table below gives the fixed and operating charges:

FIXED CHARGES	
Interest at 6 per cent	$198.00
Depreciation, repairs, taxes, insurance, 12 per cent	396.00
	$594.00

OPERATING CHARGES.	
Engineer at $2 daily, 300 days	$600.00
67¾ tons coal at $4.50	304.87
Oil and waste	48.00
Scrubber water	12.00
	$964.87
Total yearly charge	$1,558.87
Cost per horse-power-year of 3,000 hours, assuming an average rate of 50 horse-power	$31.17

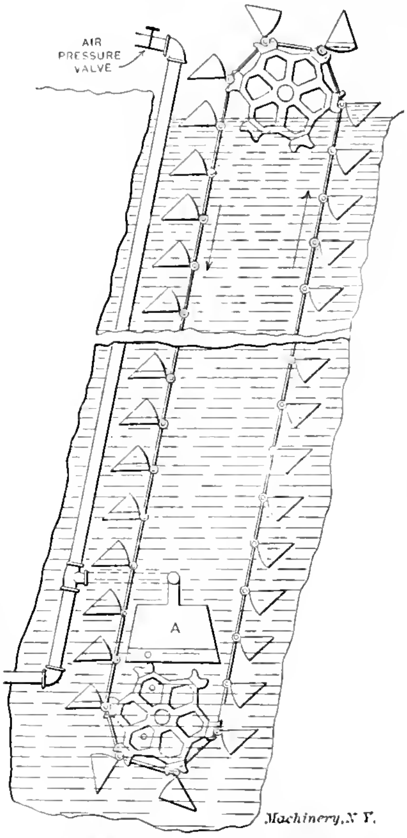
The repairs of the year were relatively small, consisting of new grate-bars in the producer, new coke in the scrubber, and small repairs to the connecting-rod and ignition equipment. The total cost of the repairs, in fact, was less than $10. In the fixed charges given above, 12 per cent has been allowed for depreciation, repairs, insurance and taxes, which was more than ample for the year in question. The cooling water was used over and over and therefore no charge is made for this item. In the item of attendance, the entire salary of the engineer is charged up against the plant, although he had ample time for other work, but little of his time being needed with the producer and engine after the plant was in operation. The coal used came from the Scranton district and cost $4.50 per ton, delivered. The coal consumed averaged 441 pounds per working day, so that it can safely be said that the consumption was only one pound per brake-horse-power.

The writer sums up by stating his conviction that only hydraulic power can surpass the present showing for economy. The cost as shown, corresponds with electric power delivered to the consumers at 1 1/3 cent per K. W., much below the lowest commercial rate to consumers using an equal amount of power.

NEW IDEA IN AIR COMPRESSION.

Joseph H. Hart, in *The Mining World*, July 25 1908.

The accompanying illustration shows a system of air compression which may become useful under certain circumstances. In the engraving merely the principle is shown, some mechanical improvements being possible of introduction in a commercial apparatus not being indicated. The construction of this device is very simple. It consists of an endless chain of buckets moving over two cog-wheels, the apparatus being almost entirely sunk under water. The buckets on the left-hand side turn their openings downward when moving in the downward direction, and are thus filled with air when they strike the surface of the water. During the downward movement of the buckets the air inside of them is compressed, as indicated by the double lines on the lower buckets on the left-hand side, the pressure on the air depending simply on the depth of the buckets below the surface of the water. When the bucket comes to the lower cog-wheel, it is turned around and the air escapes, being then collected into a hood *A* where it will be under pressure corresponding to the hydrostatic pressure of the water at the point at this depth below the surface. At the top of the mechanism the water is carried from the surface to the upper level of the wheel, and when the buckets are reversed, the water is dumped, and the buckets again filled with air. The raising of the water from the surface to the place where it leaves the buckets represents one of the losses of the mechanism. This loss remains approximately constant for all conditions, and expressed as a percentage of the total power required, it decreases as the depth of the device, and in consequence the compression, increases.



New Idea in Air Compression.

EDISON MONOLITHIC CONCRETE HOUSES.

Several months ago Mr. Thomas A. Edison aroused considerable interest in a proposed monolithic concrete construction for dwelling houses, the details of which he has worked out. The idea briefly is to mold a house complete, the same as an iron casting is made in sand, with the difference that in the Edison house scheme the mold is constructed of cast-iron forms, which are set up to make the house complete, even including the roof, porches, steps and everything required to complete a dwelling house. Mr. Edison had calculated that a workingman's two-family dwelling house of one-piece

concrete could be made in this manner for about $1,200; but, like many other schemes that appear promising on the face, this one does not appear as promising upon investigation.

In the first place, the cost of the cast-iron molds for a two-family house would be not less than $25,000, according to Mr Edison's own estimate, and the weight would be not less than 280,000 pounds. This, of course, means a very large initial investment and costly transportation of the molds from one building site to another. The size of the dwelling proposed to be built in this manner is 21 feet by 49 feet, with a height of 35 feet, not including the cellar. The walls will be 12 inches thick, decreasing to 8 inches on the second story. The roof is to be 6 inches thick, and the floors and partitions are 4 inches in thickness throughout. The structure will be reinforced with $\frac{1}{2}$-inch and $\frac{5}{8}$-inch steel rods. Water pipes, gas pipes, plumbing, ducts for wiring, and lining for chimney flues are set in position before pouring the concrete.

The concrete mixture proposed is one part cement, three parts fine sand, and five parts stone or gravel, fine enough to pass through a one-half inch sieve. In order to prevent segregation of the materials before reaching their destined position in the molds, it is proposed to add colloids, which, in common language, are certain clays that promote fluidity of the concrete and non-segregation of the constituents.

The scheme undoubtedly would prove unprofitable except where large numbers of houses were built on one plot and where the materials could be obtained at low cost. The investigation made by a disinterested expert appears to indicate that Mr. Edison's estimate of the weight of the molds and the cost of houses built in this way is too low. The cost of a house, with the present prices of labor and material, would be nearly twice the figure quoted, according to the *Cement Age*, and the weight of the molds would be considerably greater than 280,000 pounds.

The future of monolithic concrete construction for houses, factories and other structures depends very largely on the means developed for holding the materials in place during the setting period. It appears that the Edison plan is crude and very costly. The ultimate development of cheap concrete construction of the monolithic type would appear to require a combination of wooden forms and cast-iron molds made up so that a large variety of shapes can be produced with comparatively few forms.

CALCULATIONS FOR MAGNETIC CLUTCHES.

Engineering Digest, June, 1908.

The author of the article here abstracted presents the following formula for calculating the number of ampere turns of excitation required for an ordinary magnetic clutch, consisting of a thick disk with an annular space machined out of one face for the magnetizing coil, and provided with a flat-faced disk armature of the same diameter.

$$\text{Ampere turns} = \frac{9{,}500{,}000\ LBD\ \sqrt{H.P.}}{A\mu\ \sqrt{BN(D^2 + 8\ RB)}}$$

In this equation,

L = mean length of the magnetic circuit,
B = radial width of the annular pole face,
D = diameter of central pole face or hub of clutch,
$H.P.$ = brake-horse-power to be transmitted.
A = mean cross-sectional area of the path of the lines of force,
μ = permeability of metal, say 2,500 for wrought iron,
N = revolutions per minute,
R = mean radius of annular pole face, which, in turn,

$$= \frac{\text{outside diameter of clutch} - B}{2}$$

All dimensions are in inches.

As an example, assuming that $R = 4$ inches, $D = 2\frac{1}{2}$ inches, $B = 1$ inch, $L = 10$ inches, $A = 9$ square inches, $H.P. = 4$, $N = 100$, and $\mu = 2{,}500$, then the ampere turns equal

$$\frac{9{,}500{,}000 \times 10 \times 1 \times 2.5 \times \sqrt{4}}{9 \times 2{,}500 \times \sqrt{1 \times 100(2.5^2 + 8 \times 4 \times 1)}} = 340$$

To allow for the reluctance of the joint, this should be increased to, say, 400.

CASTING PIPES IN PERMANENT MOLDS

Paper read by Edgar A. Custer before the Franklin Institute
March 26, 1908.

A great deal of experimenting has been undertaken in the past in order to determine the requirements for permanent molds for making castings, that is, molds which could be used over and over again for producing the same parts. The purpose of the present discussion is to describe a method and apparatus using permanent molds which are not destroyed through the action of the hot iron, and in which cast iron pipe can be produced in which the supposed evils of unequal heating and cooling due to the use of permanent molds do not appear.

So-called permanent molds are not new. For many years, small iron castings have been successfully made in iron molds without great detriment to either casting or mold. These castings, however, have invariably been very small, and the process chilled them to extreme hardness, so that it was not possible to machine them. This limited the use of such molds very materially. Extensive experiments, however, have been undertaken by the Tacony Iron Co., Philadelphia, Pa., for producing cast iron water and gas pipe in permanent molds.

The ordinary process for casting such pipe is as follows: Iron flasks, a cope and drag, are rammed with sand over a metal pattern; a green sand core is introduced, and the cope and drag are clamped together. The pipe is then poured, with the pipe in a horizontal position, and after cooling, the pipe is removed from the flask and carried to the end of the floor where the cores are removed. Then it is carried to the cleaning room where the sand is rattled off, the gates and fins are removed, and after inspection it is ready for shipment. Altogether the pipe has to be handled ten times. In this process the loss is great, often reaching 12 to 15 per cent. In fact, with very few improvements, and these relating mainly to cores, soil pipe is made in precisely the same manner and with just as much labor per pipe as was the practice fifty years ago.

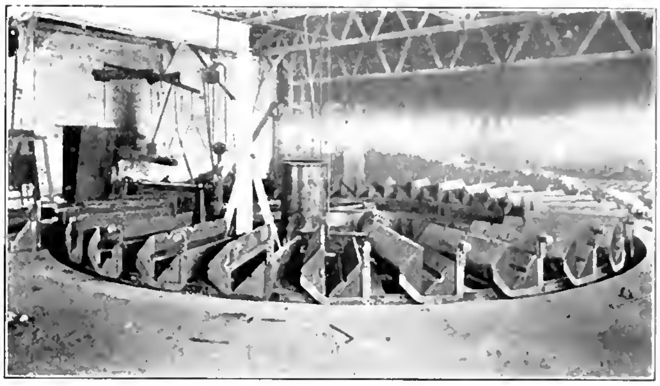


Fig. 1. General View of Machine for Casting Pipe in Permanent Molds.

Any process that would save the use of sand for the mold, and would produce pipe that could be easily cut, would naturally be very desirable. In addition, if it would be possible to produce a machine so that the work could be carried on continuously day and night, it would evidently be of great advantage for economical production. The experiments undertaken by the firm previously referred to made it possible to design a machine which would operate continuously, using permanent molds. These experiments showed that when pipes were cast in a mold every eight minutes, the temperature of the mold never raised above 450 degrees F., even if the operations were continued for hours. If, however, pipes were poured every two minutes, the temperature of the mold would rise rapidly, and at 900 degrees F. it would begin to warp. In order to comply with the requirements thus determined, the machine as described in the following was designed.

Machine for Continuous Casting of Pipes.

The machine consists of an angular table or ring approximately 40 feet in diameter, which carries 30 molds arranged at equal intervals. The table is constructed of two concentric rings of channel beams connected with 30 cross pieces or trucks, each of which has two wheels with roller bearings to

support the frame. The wheels run on concentric circular tracks laid in concrete foundations. The tracks are arranged on an inclining conical surface, and by this means the table will resist any movement other than rotating about its center.

Each truck or cross bar of the table carries a steel pin working loosely in a vertical hole and of such length as to allow about two inches of the pin to project below the bottom line of the truck, but admitting it of being pushed up until flush with the bottom of the truck. Under the table or ring, at two diametrically opposite points, are arranged two hydraulic cylinders which slide in ways similar to those of a planer, the pistons within the cylinders being held stationary, and the cylinders moved back and forth by the operation of a four-way valve controlling the admission of water alternately to each end of the cylinders. The stroke of the cylinders is of such length as to be slightly more than the spacing of the molds carried by the table. Projecting from the top of the cylinder is an inclined plane surface designed to lift the truck-pins, previously referred to, when the cylinders move in a direction opposite to the required motion of the table, and to allow a pin on each side to fall, after the inclined surface has passed. This occurs at or near the end of the backward stroke of the cylinders; and when the controlling valve is so moved as to cause the cylinders to move forward, the pins which have been lifted and allowed to fall are brought in contact with the projections on the cylinders, and hence the table is carried forward by the motion of the cylinders a distance equal to the spacing of the molds, and the cylinders are ready for another return or back stroke to engage the next pins, thus intermittently moving the table ahead one space at each cycle of the cylinders.

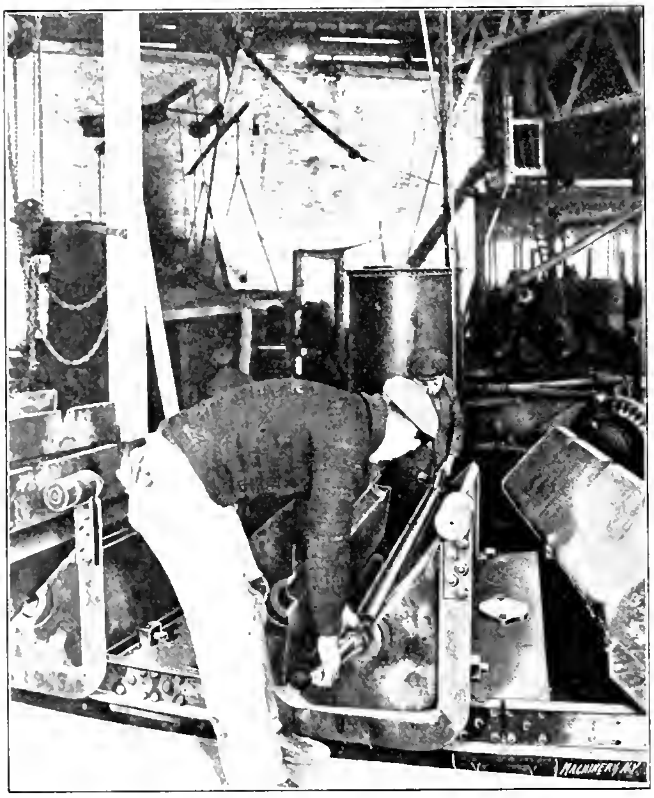

Fig. 2. Setting the Core

The center of the table is left open for the location of hydraulic pumps, operating valve reservoirs, etc., required in imparting motion to the table. The table makes one complete revolution every seven and one-half minutes, and consequently produces thirty pipes in that time, or two hundred and forty pipes an hour.

At certain points about the table are arranged closing and opening devices which are designed to close the mold, or bring the cope swing down to its place on the drag side, without shock, after the cores are set in place, and to open the mold or lift the cope after the pipe has been poured.

Between the closing device and the opening device is located a pouring device adapted to receive the molten metal from the cupola and pour it into the molds.

Description of Mold.

Each mold consists of a rectangular block of cast iron, approximately 18 inches wide and 18 inches high, by 6 feet long, parted on a diagonal line across the corners, and provided with hinges at the lower edge of the parting so as to allow the upper portion or cope to be swung up and back from the lower portion or drag. These molds weigh about 6,500 pounds complete. At the center of the mold is the cavity into which the metal is to be poured to form the pipe. Thus one-half of the pipe is formed in the upper and one-half in the lower portion of the mold.

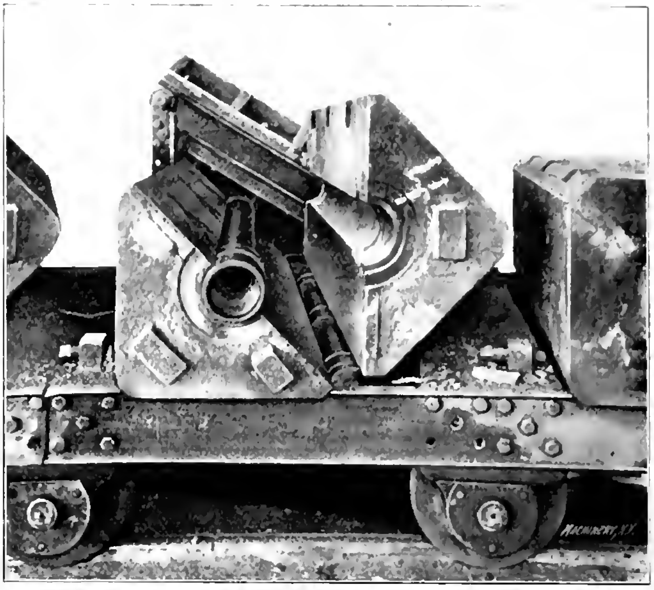

Fig. 3. Mold entering Closing Device.

Gates are cut in the face portion of the lower part or drag, of such size and shape as to receive the molten metal from the ladle and guide it into the mold. Three such gates are used, each dividing into two portions. Thus the cavity of the mold is entered at six points. The gates are so shaped as to receive the shock of the falling stream of molten metal at a point outside of the mold cavity, and convey it into the mold quickly but gently, so that the core is not damaged by a rush of molten metal against it. At the highest point of the barrel of the mold, a small groove is cut, extending throughout the entire length of the barrel. This groove, which is quite small, being only one-eighth of an inch wide and deep, is intended to receive any gases or air which may be trapped in the mold, and so avoid the formation of flat spots at the top of the pipe. The resultant ridge not being prominent is not an objection, but rather adds to the strength of the structure.

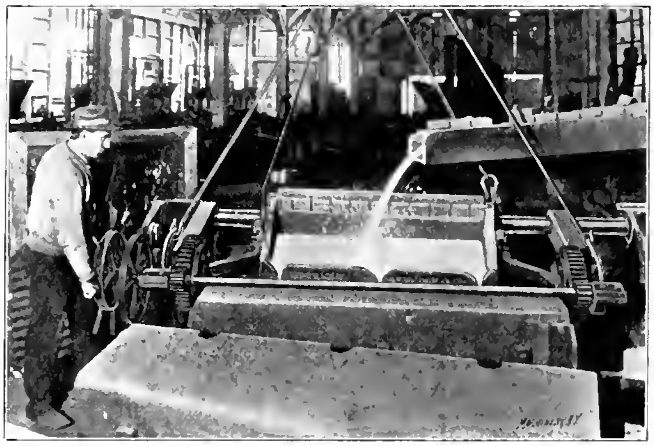

Fig. 4. Pouring the Metal.

On one end of each mold is carried an arm rigidly attached to the upper or movable half. This arm extends under the mold, and is of such form that when the mold is open it forms a rest for the movable half, holding it in such position as to allow of any work, such as setting cores, removing finished pipes, cleaning, etc. On the end of this arm is a steel roller

which is caused to travel down an inclined plane by the rotation of a table carrying the mold. This inclined plane is arranged to receive the roller at its higher position when the mold is open, and to guide it smoothly to its lower position, by this means closing the mold without shock or jar to disturb the core. This inclined plane constitutes the closing device. Each end of the mold is provided with rings or bushings which are used to support the core arbor in a precisely central position in the cavity of the mold, so that the pipe when finished shall have uniform thickness of metal at every point.

The core arbor consists of a cast iron hollow cylinder somewhat longer than the pipe to be cast and about three-quarters of an inch less in diameter than the inside diameter of the pipe. It is perforated throughout most of its length by small holes to allow any gases formed by contact with the molten metal to pass into the arbor and so have free vent to the air through the ends.

The core is made by placing the core arbor in the core machine, which consists of a support for the ends of the arbor, semicircular in form, and of a diameter to fit the arbor ends a shaking screen arranged to sift sand, and a guide to drop it upon the arbor, and a knife, so shaped as to form the sand to the outline of the inside of the pipe.

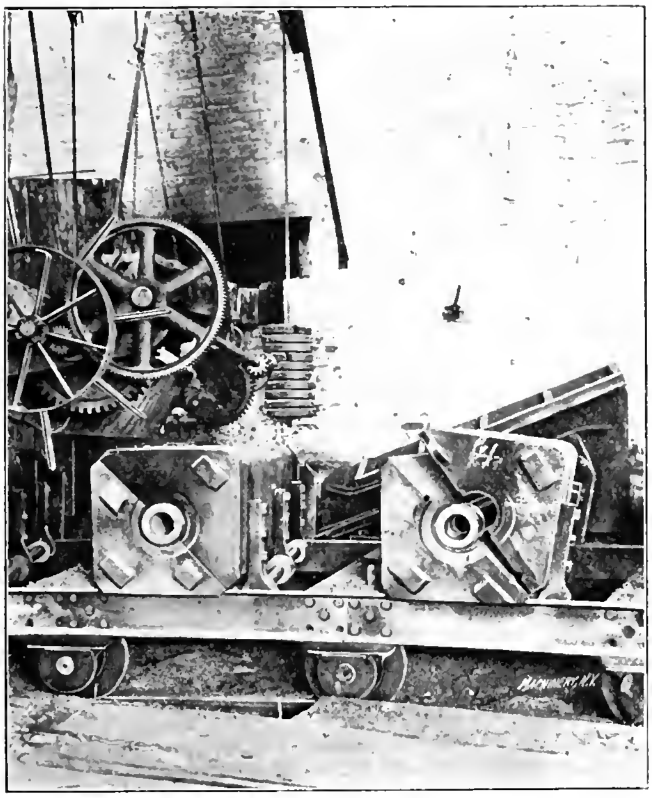

Fig. 5. Immediately after Pouring. Mold, entering Opening Device, partially opened.

The core arbor, after being thoroughly wet, is placed in the end supports and rotated by a crank-shaped piece of iron held loosely in one end by an operator. At the same time another operator shakes a sieve suspended over the arbor and previously filled with sand, saturated to the proper degree with water. This sieved sand is caused to fall directly upon the wet, rotating arbor and clings to it. The surplus sand is scraped away by a steel knife held at the proper distance from the arbor to make the finished core of the diameter and shape required. When sufficient sand is on the arbor to make a full and complete core (which requires about five seconds), the core is lifted from its supports and is ready for use. No further treatment of any kind is needed, and the core is placed in position in the mold, which is then caused to pass the closing device, bringing the upper portion down in place, and the mold is ready to receive the metal.

A ladle is provided to receive the metal as it flows from the cupola. As the table rotates and brings a mold, which has passed the closing device, into pouring position, the ladle automatically drops into position with the lips close to the pouring holes. The ladle is then tilted to pour by the operator, but in tilting it rotates around a center line which passes through the pouring lips, and hence the points of pouring do not move; and the streams of metal are guided directly from the pouring holes through the various gates into the mold, and fill it completely, compressing any air or gas which may be trapped into the groove provided at the highest point for that purpose. If no gases are trapped, which, strange as it may seem, is usually the case this groove is also filled with metal and forms a slight rib running the length of the pipe. When the pouring operation is complete and the operator tilts the ladle back, it automatically rises to a higher position, so that the next mold may pass under it and assume the pouring position.

Fig. 6. Mold open. Pipe Cast in Place.

The mold being now filled with metal, is held long enough to allow the metal to set, and is then opened by passing the opening device, which is just the reverse of the closing device, the roller on the end of the arm or mold being guided up an inclined plane, thereby lifting the upper half or cope side, and swinging it away from the lower or drag side. The pipe, which is still a bright orange color, is lifted from the mold and placed, after removal of the gates, with those previously cast, in piles, to cool slowly, when the core arbor is withdrawn and returned to the core machines to be used again. After removal of the finished pipe from the mold, the loose sand which falls from the core during the handling of the pipe, and any other dirt, loose gates, etc., which may be left in the mold are swept out by air blasts or hand brushes, and the mold is ready for another core and another filling with metal.

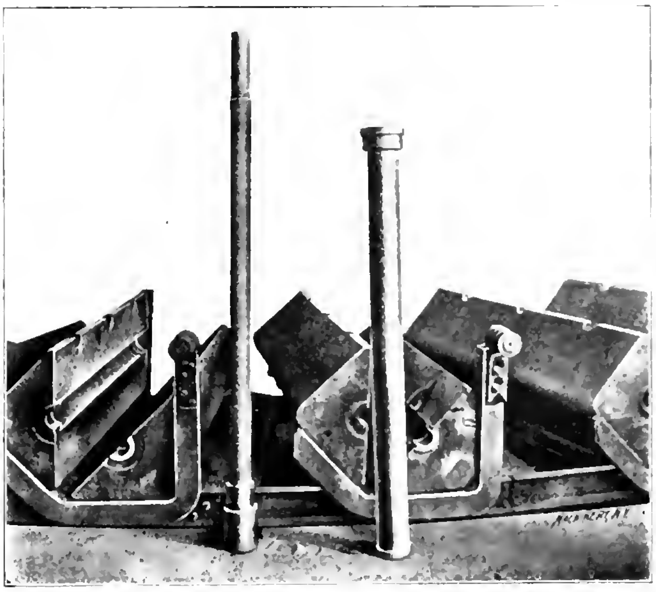

Fig. 7 Finished Pipe and Arbor Molds Open.

LOCK NUTS USED IN ENGINEERING PRACTICE.

R. B. LITTLE*

A great variety of different means have been devised for locking a nut in place, so as to prevent accidental loosening of the parts being held together by the tightening of a nut on its bolt. In the accompanying Supplement are shown twenty-seven different styles of locking arrangements, care having been taken to select those that are most commonly found in engineering practice. It is not necessary to explain all of the methods indicated at length; a few words relating to each type will suffice. Referring to the Supplement, Fig. 1 shows a locking device where the nut is locked to the bolt by means of a set-screw. A small plug of steel or brass is placed in front of the screw point, to prevent the screw from injuring the thread of the bolt.

Fig. 2 represents the U. S. Navy standard form of lock nut. It will be noticed that the first shoulder below the nut proper fits in the stock, while the second one is smaller and acts as a face for the set-screw to engage with. Also note that the set-screw is "dog-pointed," and that the nut proper never should come down flush against the stock; 1/32 inch clearance is allowed here for all sizes of nuts.

Fig. 3 shows a very good form. A shoulder is turned down on the lower side of the nut to the diameter across flats, and a groove is turned in this shoulder for the point of the set-screw. A collar fitting this shoulder is fastened by a pin as shown. A set-screw is then passed through this collar and engages in the groove of the nut. The thickness of the collar and shoulder should be about one-quarter the diameter of the nut plus $\frac{1}{4}$ inch, in good practice, and the pin which holds the collar should be one-eighth the diameter of the bolt plus 1/16 inch.

In the method shown in Fig. 4, a special nut with a slotted flange is required. This flange has six slots, and the dog which acts as a check is provided with an oblong slot. This arrangement gives a positive lock, and the nut can be locked at any position required. The thickness of the dog and the slotted flange should be about one-quarter the diameter of the bolt.

Fig. 5 is an excellent form. It is a combination of the spring and double nut arrangements shown in Figs. 10 and 11. The double nut may work loose under constant rattle and jar, but the split ring below has a tendency to absorb the jar. This form is used extensively in automobile frame construction.

In the method shown in Fig. 6, a small taper pin is put half in the nut and half in the bolt, one half-hole being put in the nut and six, or as many as desired, in the bolt. This allows of finer adjustment than one hole only. The taper pin should never be driven in too tight to prevent its being pulled out without difficulty when required.

Fig. 7 requires a specially made nut. It is made of stock one-half the thickness of the nut, which is doubled over on itself, as shown, and afterwards tapped. After this nut is screwed down tight in place, a little extra twist on the top half locks it very securely.

Fig. 8 shows an inner nut which is tapered and split. This inner nut fits in an outer shell which has a tapered hole. When the nut is assembled in place, the screwing down of the outer shell pulls the inner nut down in the taper hole, which closes the split in the side. This clamps the inner nut to the bolt. This form is highly recommended.

Fig. 9 shows the regular slotted or castle nut. When the nut is screwed down in place, a small hole is drilled through the bolt at the bottom of one of the slots, and a cotter pin is inserted.

Fig. 10 shows the old reliable form of nut and check nut, or double nut. The check nut is commonly made one-half the thickness of the nut proper, and should be placed on the under side as shown. This arrangement puts the stress on the thicker nut, as it should be because of the greater number of threads engaging it.

Fig. 11 shows what is known as Grover's spring. When the nut is screwed down tight, the spring is flattened, and its resistance keeps the nut tight on the bolt.

Fig. 12 shows the ear washer. After the nut is screwed down in place, the ear on the washer is bent up tight against a flat side of the nut, and a small pin keeps it from turning. This washer should be about one-sixth of the diameter of the bolt in thickness.

Fig. 13 shows a right-hand nut below, with a smaller left-hand nut above it, both screwing on the same bolt. All tendency of the larger right-hand nut to unscrew is counteracted by the smaller left-hand nut, which screws on tighter if the larger nut turns.

Fig. 14 shows a regular hexagon nut with a slot sawed a little past the center and about three threads from the top. After this nut is screwed down in place, give the part above the slot a little extra twist, the same as in Fig. 7, or hit it a light tap with a hammer, and spring the shelving part down a trifle. When the nut is to be removed, the top part may be sprung back again to place, and it is then easily unscrewed.

In Fig. 15 the same sawed nut is used as in Fig. 14, and a small screw is placed as shown. After the nut is screwed down, the small screw is tightened. This increases the friction between the threads of the bolt and nut by springing down the upper and thinner part.

Fig. 16 represents the lip washer. This washer has a small lip on the inside which slides in a groove in the side of the bolt. All tendency of the work below the nut to move is spent on the washer which cannot move because of the lip. This is a very good form, and is extensively used.

Fig. 17 shows a small lock fastened down by a cap screw, the flat side of the lock coming against the flat of the nut. In Fig. 18 the principle of locking is practically the same as in Fig. 17, except that the nut may be locked at every one-twelfth turn instead of one-sixth turn. This allows of much finer adjustment. The principle of the form shown in Fig. 19 is the same as in Figs. 17 and 18, except that the lock fits the corner of the nut. The method shown at Fig. 20 is exceptionally good where a circle or long row of nuts are to be locked. Fig. 21 quite closely resembles Fig. 18, except that the nut is locked on all sides. This form also admits of a one-twelfth revolution in locking. The locks shown at Figs. 17, 18, 19, 20, and 21 are known as stop plates.

In Fig. 22 an ordinary bolt and nut are used. The bolt is allowed to stick through the nut a short distance. The end of the bolt is sawed before the nut is screwed on. After the nut is screwed home, the end of the bolt is wedged out a trifle with a dull cold chisel. This locks the nut very securely, but by screwing the nut off, the sawed end of the bolt will be brought back to its original shape.

In Fig. 23 a small cap screw is screwed down so that its head is tangent to a flat side of the bolt. In Fig. 24 a taper pin is driven in firmly as shown, so that it enters partly in a groove in the side of the nut.

Fig. 25 shows an excellent method, but a special nut is required. The nut must have a slotted flange as shown. The small pin shown has a shoulder which comes up under the bottom of the nut, and behind the pin is a coil spring. By pushing this pin down flush with the surface of the work, the nut may be turned to any position desired, and the pin will spring back into place, thus locking the nut.

In Fig. 26 a small hole is drilled through the bolt, flush with the top of the nut. A piece of soft wire is run through the hole and wound around the bolt, as shown, to insure against its coming out. This form also answers very nicely where more than one nut is to be locked. The wire may be passed on through any number of bolts and its ends fastened.

In Fig. 27 a slotted nut is required. A groove is cut down the side of the bolt deep enough to contain a wire. The nut is screwed down with the wire in place in the slot in the bolt, and the wire is then bent over in one of the slots.

* [illegible] Lansing, Mich.

* * *

It is alleged that freight shipped from Cincinnati to Toledo, *via* the Erie and Miami Canal often is received in a shorter time than when sent by rail. This, if true, confirms the statistical average of railway freight movement of only about 25 miles per day, a rate of progress considerably less than that achieved by the canaller traveling by daylight only. A canal boat hauled both day and night can easily make 60 miles per 24 hours.

GAGE FOR TESTING THE PLANING OF A TURRET MACHINE BED.

The large bed casting shown machined and mounted on its supports in Fig. 1, is that of the Libby turret lathe, built by the International Machine Tool Co., of Indianapolis, Ind.* In this machine the head-stock and bed are one solid casting, so that particular care has to be taken in planing and boring to have all parts come to the right dimensions, as the machine is built on the interchangeable plan, and no alterations from the drawings are allowed for the sake of making a faulty casting "finish out." One of the special tools used to place the making of the bed on an interchangeable basis, is the gage shown in place on the ways in Fig. 1. This gage is used for testing the planing of all the sliding surfaces of the casting, in their relation to each other and to the center line of the spindle.

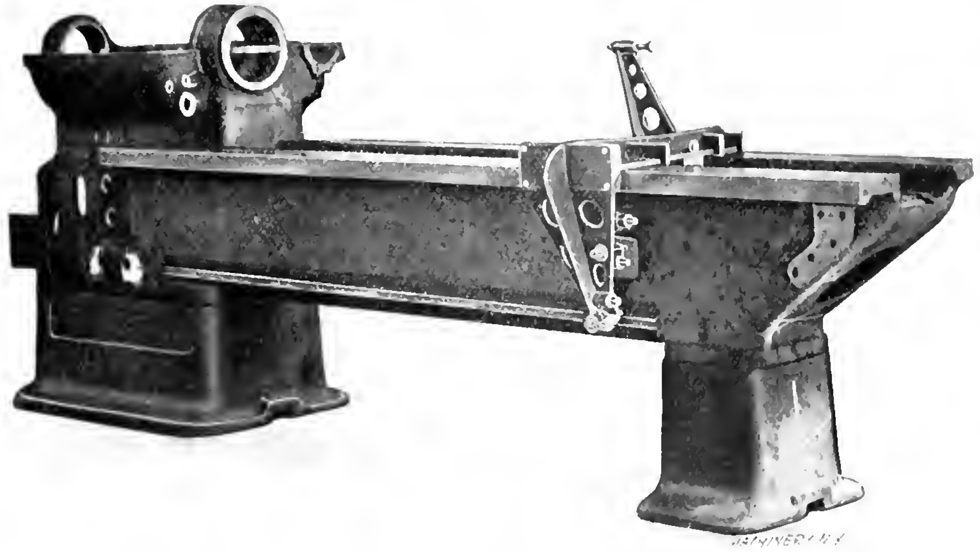

Fig. 1. A One-piece Turret Lathe Head-stock and Bed, with the Gage by which the Planing is Tested; the Center in the Vertical Arm must coincide with the Center Line of the Spindle.

After the casting has been cleaned and made ready for machining, the first operation is naturally that of "laying out." The reference line is the center line of the spindle. It is located in the usual way, by prick-punch marks in cross pieces inserted in the spindle boxes. This center line is so located that the spindle boxes will clean out, the ways finish to the right horizontal and vertical distances from the center line, and all other planed surfaces and bored holes come to the proper dimensions. When this laying out is completed, the bed is placed on the planer table right side up, with the axis of the spindle carefully lined so that it is parallel with the ways of the planer. Roughing cuts are then taken over the top and front edge of the casting at the points marked *A* and *B* in Fig. 2, which shows a cross section of the bed. This operation determines the lay-out of the bed, and if there are any surfaces or holes which do not finish out to dimensions in the subsequent operations, the piece is spoiled.

The casting is next turned over on the planer and mounted on parallels so that the head-stock clears the bed, being clamped on surfaces *B* and *B*, and lined up with surface *A* parallel to the ways of the planer. The base *C* is now planed to the finished dimension. The casting is then again reversed and clamped to the planer platen on this finished surface *C*, with edge *A* lined up with the ways of the table; all subsequent planing operations are completed without further shifting of the work.

The next finishing operation is the surfacing of *A* and *B*. To test this operation, the gage shown on the bed in Fig. 1 is used. The general form of the gage is perhaps more readily seen in the succeeding illustrations, Figs. 3 to 7. It will be seen that it rests on surface *B*, and when in use is aligned by its bearing on the vertical surface *A*, against which it is held by a clamp screw (best seen in Fig. 7) which bears on surface *D*. When these surfaces *A* and *B* are properly finished, and the gage is aligned as described, the center mounted in the upper arm must coincide with the prick-punch mark in the cross piece of the front spindle box, from which the primary lay-out was made.

These gaging surfaces, *A* and *B*, having thus been finished, the next operation is the laying-out of the succeeding cuts. Vertical surfaces *D*, *E* and *F* are located by scribing on the top surface of the bed lines gaged by the corresponding surfaces *D*, *E* and *F* in Fig. 3, these surfaces being carefully machined to the dimensions given on the drawing of the work. *D*, *E* and *F* may now be roughed and finished, the final testing of the accuracy of the work being effected by clamping the gage on the bed in its proper position, and testing the surfaces completed to see if they match up with the corresponding surfaces on the gage.

At *G* in Fig. 2 is the surface to which is fastened, by means of a clamp entering the dove-tail *H*, the casting which carries the series of stops used for limiting the movement of the turret slide. At *G* in Fig. 3 will be seen a hardened plunger, carried by a steel bushing mounted in the gage, and provided with a cross pin, projecting through an L-shaped opening in the bushing. This plunger, which is forced downward by a spring, may be released so that the lower end rests on the surface *G* of Fig. 2. If this surface is properly located, the upper end of the plunger and the upper end of the bushing in which it is contained will be flush with each other, both having ground surfaces. By this means, the accuracy of location of surface *G* is tested. When the plunger is not in use, the operator's finger on the cross pin raises it, and swings it into the horizontal portion of the slot, thus holding it into its upper position. For locating the dove-tail slot, block *H* in Fig. 3 is provided. It may be slipped into a slot on the under side of the gage, and used for scribing the lines used for locating the rectangular groove, which is first planed to the proper depth in the casting. This rectangular groove is then finished out to the desired angle on each side by tools held in the swivel head of the planer. The accuracy of the finishing of each side of the slot is gaged by block *H'* in Fig. 3, which, when placed in the dove-tail groove, with the bevel on either side, must accurately enter the same slot in the gage in which block *H* is shown in the figure.

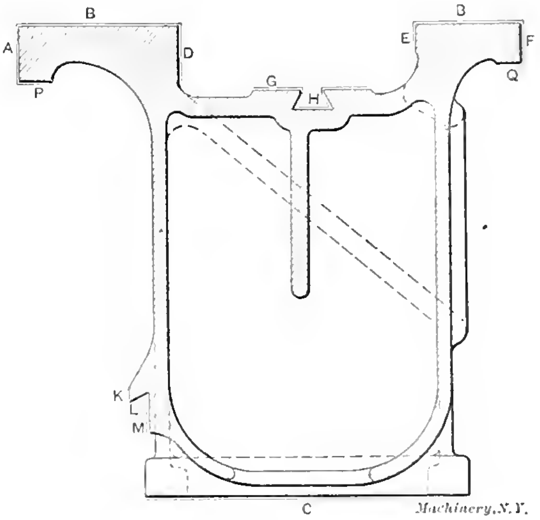

Fig 2. Cross-section of the Bed, the Surfaces to be Finished are Indicated by Double Lines.

As may be seen in the various illustrations (see Fig 4, for instance) the gage is provided on the front side with an arm which projects downward, and carries the various reference surfaces, gage pins, etc., required for properly testing the

---

* See the New Machinery and Tools section of the March, 1908, issue of MACHINERY.

machining on the front side of the bed. In the cross and turret slide carriages of this machine, there are three revolving parts which only just clear the rough surface of the bed. These clearances are made small, to reduce the overhang of the carriage as much as possible, so that the operator may get close up to his work. The gage is provided with pivots *I*, *I* and *I*, on which may be mounted cast iron disks *J* and *J* (see Fig. 4). When mounted on these pivots, these disks exactly correspond in position and diameter with the revolving parts which have to clear the bed, and if the operator slides the gage from one end of the ways to the other, and these disks clear, he may be sure that in the finished machine the carriage parts will also clear. If they interfere, the casting must be trimmed in the planer. The lower and smaller of the two disks *J*, after being tested in the position shown, is tried again on the middle pin *I*.

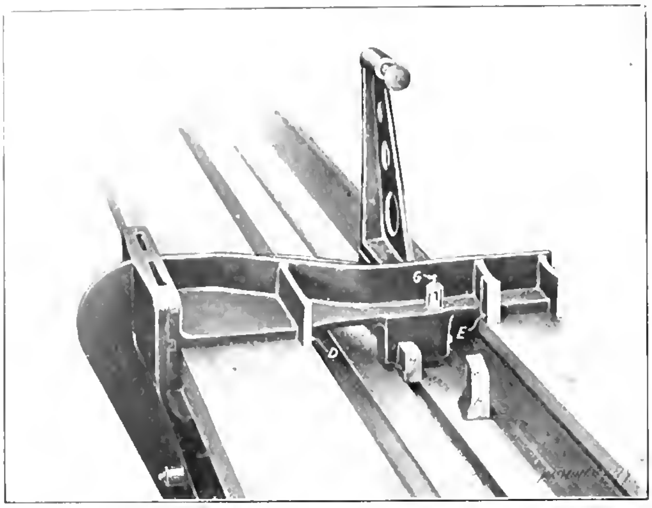

Fig 3. Block and Gages for Laying Out and Testing the Dove-tail Slot.

As those of our readers who are familiar with this machine know, the cross-slide carriage is mounted on the bed in a very peculiar way, being supported entirely by surfaces *D*, *B*, *A*, *L* and *M*, in Fig. 2. It does not extend across to the ways on the rear side of the machine. This construction allows the cross slide to clear practically the full diameter of the work capable of being swung over the ways, so that while the work is in place, the slide may be moved clear back past it and the chuck by which it is held, allowing the turret slide to be brought close to the work. It is evident, then, that surfaces *L* and *M* must be finished with reference to surfaces *A*, *B* and *B*. They are gaged as shown in Fig. 5, where a spring plunger *M* is shown, exactly identical in construction with *G* in Fig. 3, which is released from its locked position and forced down by a spring against the surface in question. If this surface is right, the ground end of the plunger and of the bushing contained in it will be flush with each other. To measure surface *L*, an angular face is provided at the lower extremity of the arm, as shown, on which the straightedge *L* in Fig. 5 may be laid. If this accurately lines up with the corresponding surface of the casting, the planing is right in this respect.

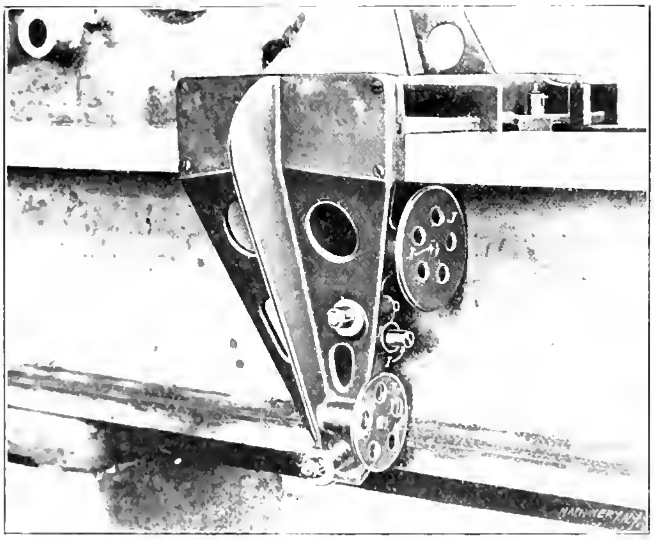

Fig 4. Testing the Bed for Clearance for Revolving Parts in the Apron.

There are finished pads on both the front and back sides of the bed, not shown in Fig. 2, which support the various feed and rapid-traverse shafts. These must also be machined to the proper distance horizontally from reference surface *A*. The spring plunger *N*, identical in construction with *M* and *G*, is used for the front surface. This is shown applied to this surface in Fig. 1. For the pads on the rear, a gage *O*, Fig. 6, is used, which, when held as shown against the finished face of the bed, must just make contact with a plug set into the rear end of the fixture.

When all the tests described have thus been made, it may be assumed that the work is correct, so far as the planing is concerned. Surfaces *K*, *P* and *Q* are good enough if made to careful scale measurements.

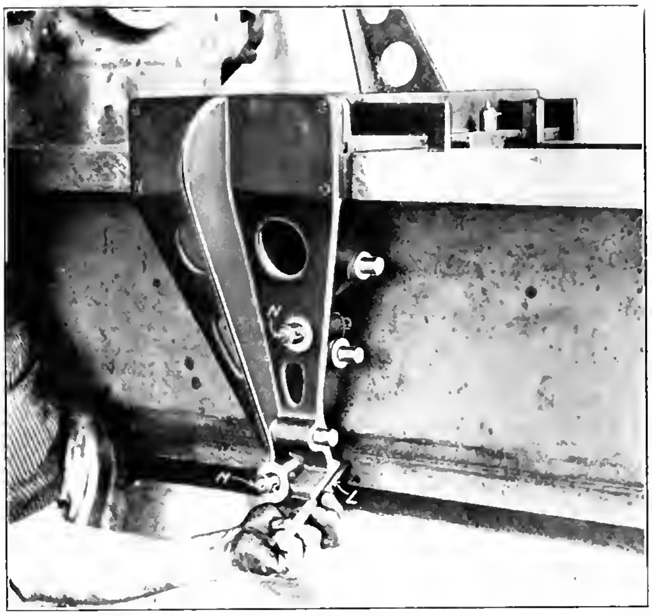

Fig. 5. Testing the Bevel Bearing Surface for the Cross-slide Carriage Support.

It will be seen that this gage simplifies to a remarkable degree the inspection, the laying out, and machining of these castings. The foreman, for instance, if there is a question about the accuracy of the workmanship in a particular case, can put the gage in place and take all the measurements inside of a very few minutes. It can be imagined that the device under these conditions is a great incentive to accurate work.

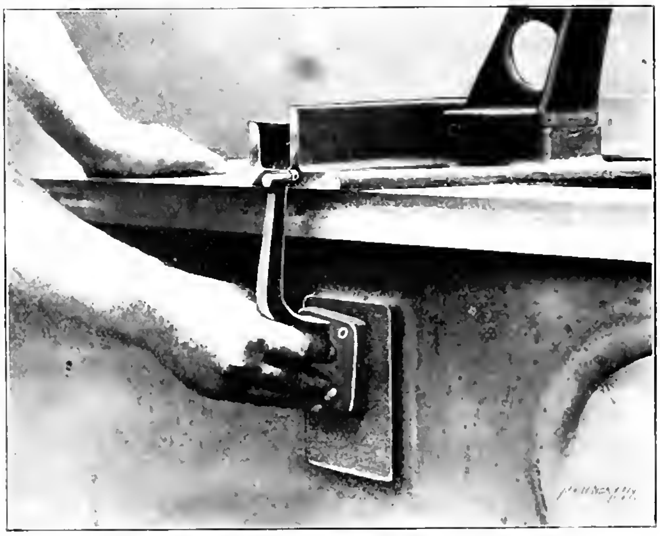

Fig. 6. Testing the Planing of the Pad for the Bracket of the Quick-motion Shaft.

A practical man will readily understand that the advantage of working so closely to figures as is required by a gage of this kind, does not consist in cheapening the actual

cost of the planing or inspection. The cost of planing, in fact, is doubtless increased by its use, owing to the higher grade of workmanship which it requires. The advantage is seen when it comes to assembling and fitting up the machine. The main casting is always the part that is most difficult to build on an interchangeable basis. With the aid of such devices as the one we describe, carrying throughout the whole casting the system of close working to figures, the time of assembling and fitting is greatly reduced. This is what counts, as it saves a large share of the most costly work that goes into the building of a high-grade machine tool.

Fig. 7. The Gage mounted on its Truck, by which it is carried where needed.

The possibility of saving a lot of time in the assembling, at the expense of a comparatively small loss of time in the manufacturing, is one that is not always appreciated.

A tool that is as useful as the one we have just described merits the best of treatment. In Fig. 7 we show the gage as it looks when at home. As may be seen, it is comfortably mounted on a special truck, which may be wheeled from point to point in the shop, as the case may require. The various supplementary devices shown in the preceding illustrations are carried in the box body of the truck. It is certainly encouraging to see a faithful servant so well looked after.

THE SELF-RELIANCE OF JIM WEST.

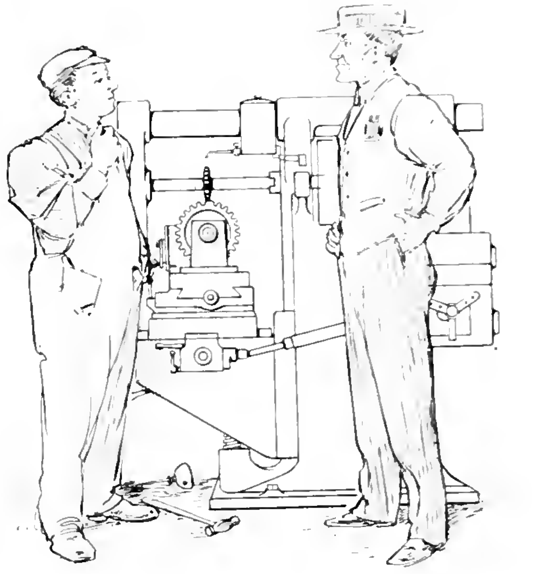
GREBO.

A modicum of self-reliance and self-esteem is a pretty good thing for any man to have, but in the days when a man is very hard up for a job, it has occurred that his estimate of his own ability has been somewhat above par with results disastrous to his self-esteem and reputation.

Some years ago Jim West concluded that the only way to get a job was to put up what is commonly called a big bluff, and start in as a machinist. Now Jim had not worked in a machine shop except for about two weeks in a little shop somewhere in Indiana seven years before. He had tried the job in the belief that he wanted to learn a trade, but he soon tired of shop work because a clerking job seemed more suitable to a young gentleman of his refined tastes and lady-like manners. He had not prospered in the clerking business, and being out of a job and hard up, he remembered that the machine shop did not seem so bad after all. Stranded in a city where there were many shops and a scarcity of machinists, he concluded to take a chance and hire out as a machinist—on the strength of his two-weeks' shop experience! Now the city where Jim found himself stranded was the Queen City of the West, the center of machine tool building where a machinist usually can get a job if he can anywhere. He applied to the superintendent of one of the large shops, and upon being asked if he was an experienced man he replied without hesitation in the affirmative. The "super" quickly let him understand that the shop really did not need any more help, this information being conveyed to properly cool off the applicant's expectancy of a bulky weekly pay envelope, but finally admitted that if Jim had any experience in cutting spur gears on a milling machine, he might employ him. Jim saw that his expected job would go "glimmering" if he did not convince the "old man" that gear cutting was his specialty, and he did not hesitate to state his qualification in very emphatic and convincing language. The "super" was given to understand that no gear-cutting job existed that he could not do in proper form.

Now in justice to Jim we must say that it was not his intention "to draw a long bow," but when a man is hard up and he feels quite uncertain where the money for the next week's board bill is coming from, a slight stretching of the truth may seem excusable that under ordinary circumstances would not be approved of.

Jim was told to go to work the next morning, and was placed in charge of the foreman of the milling department. A lot of gear blanks were turned over to him, together with a drawing and a few verbal instructions. Jim did not understand the situation very clearly, but he started to work. He busied himself for some time with the drawing, first scratching his head behind the right ear and then behind the left, and then finally concluded that he had better make friends with the man operating the next machine. He frankly confided how matters stood, and the man taking pity on him, showed Jim in as unostentatious a way as possible how to set up the work, start the machine, manipulate the feed and work the index head. Jim started to work, taking great pains with the first gear. He indexed tooth after tooth carefully, and about noon he found that he had a space left that did not seem quite big enough for two teeth, but that clearly was too large for one tooth. He realized that here was a case where judgment meant more than experience(?), and in order to show that he knew what he was talking about, he called on the foreman, showed him the situation, and said: "What would you think to be best—to put in two small teeth or one big one in the space that I have left here? Personally, I would say that two small teeth would work the best." The foreman looked at Jim steadily for what seemed like a long time, swelling up as though he were about to explode, but he was a wise foreman and did not cuss. He simply said, "I wish, Jim, that you had given me your opinion about the two small teeth before you commenced to cut this gear. It would likely have saved you and me a lot of trouble. The next time that you hire out as an all-around machinist, be careful about giving your personal opinions unless you know what you are talking about. Perhaps you might be able to hold your job down a little longer than five hours if you do" That ended Jim's experience as a machinist in that shop.



"Two small teeth or one big one?"

MACHINE SHOP PRACTICE.*

PLANING AND LAYING OUT A BLANKING DIE.

When constructing a die, the degree of accuracy with which it is made, and the general finish, will depend somewhat upon the amount of work that it will be required to do, or the number of pieces to be produced. When this number is comparatively small, the most inexpensive die that will do the work properly should be made. Dies of this class are known as "emergency dies," as they are quickly made, and are not constructed to withstand long and continuous usage. When, however, a die is to be used incessantly for a long period, or, perhaps, until it is worn out through use, the materials used, and the quality of the workmanship, should be of the highest possible grade, and every detail brought as near perfection as possible. If the design of the die is at all complicated, it should be so constructed that the parts subjected to the greatest wear can be replaced, thus avoiding the necessity of making a new die.

The selection of a high grade of steel for dies is of paramount importance, and though such steel may be somewhat expensive, the increased efficiency of the die will more than compensate for this expenditure. In the Shop Operation Sheets accompanying this number, a simple form of blanking die is shown. This die, when in use, is held in place in a bolster, or die-bed, by the dove-tailed sides of the bolster, and by a key which is driven in between one side of the die and the bolster. The latter is bolted to the table of the power press. It is not necessary to have a bolster for each die, for by making the die-fitting standard, a number of dies of nearly the same size may be used in the same bolster. In order that this may be done, the beveled sides of the die blanks are planed to an angle of 10 degrees, this being the standard angle to which the dove-tailed seats of the bolster are planed.

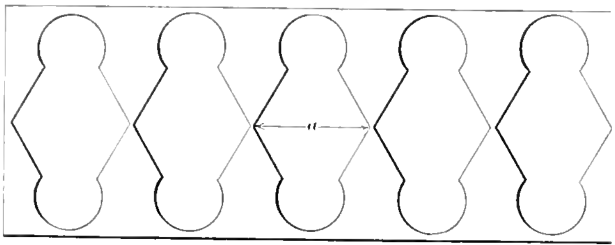


Fig. 1

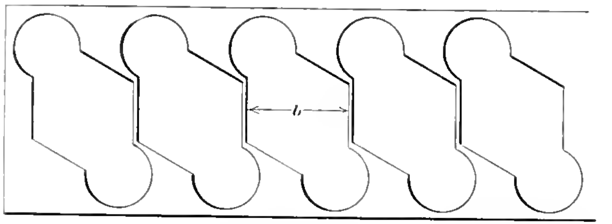

Fig. 2 *Machinery,N.Y.*

Figs. 1 and 2. Illustration of the Saving of Metal Effected by cutting the Blanks diagonally from the Stock.

The Shop Operation Sheet explains the various steps in connection with planing and laying out a blanking die. The die proper should be finished before the punch-plate or stripper, as these are laid out from the die itself. A piece of high-grade, annealed steel, long enough to make several dies, should be selected, and cuts taken on both the top and bottom surfaces, the top surface being finished smooth. The piece is then set up on the planer as shown, with the finished, or top side held against a beveled parallel strip, which, in turn, rests against an angle plate which is fastened to the planer platen. One edge of the piece is then planed. This finished edge is then placed next to the platen and the opposite edge finished. If one side of the parallel strip is at an angle of 10 degrees with the other, it is evident that the beveled edges of the die blank will have a taper of exactly 10 degrees. Care should be taken to see that the finished side of the blank bears on the platen at both ends, after it is clamped in place, in order that the beveled edges be made parallel. There should be no trouble in this connection if all chips have been carefully removed, as the blank, when pressed against the taper parallel will tend to move downward. A piece of thin paper, placed beneath each end of the work, will, however, enable one to determine whether or not the work is bearing properly on the platen.

After the steel strip is planed to fit the bolster, a piece of sufficient length for the die is cut off, and the die is ready to be laid out. Before this is done, however, a templet or master blank should first be made. Sheet steel is used for this purpose, the thickness of which will depend somewhat upon the size of the templet; for comparatively small work, steel about 3/32 inch thick will suffice. The outline of the templet should be laid out very carefully, and finished, by filing, to conform exactly to the required shape and size of the hole to be cut in the die blank. As the die we are considering is a plain blanking die, it will only be necessary to make a templet having the required outline of the blank. If, however, the die were to be of the blanking and piercing type, the location of the holes to be pierced in the blank would be laid out on the templet to facilitate locating them in their proper place in the die.

After the templet is accurately finished, the top surface of the die blank should be brightened with a piece of coarse emery cloth, and the surface prepared for laying out by either applying a solution composed of one part bluestone, and ten parts water (sulphate of copper), or by heating the die blank as described in Operation Sheet No. 74. The surface will then be either coppered or blued, depending upon the method employed, and on such surfaces all lines made by a sharp scriber will be bright, and made plainly visible by the contrast with the darker background.

The templet, or master blank, can now be used for laying out the die. It is first clamped centrally on the face of the die blank by the diemakers' clamp shown; then by following the outline of the templet with a sharp scriber, its shape is transferred to the face of the blank. Before locating the templet, however, the most economical way of cutting the blanks from the stock must be determined, that is, the way to obtain the greatest number of blanks from a given weight of stock. It will be seen then that the way in which the die is laid out will depend, to a great extent, on the shape of the blank. The die shown in Operation Sheet No. 75 is laid out in the way best adapted to most blanking operations, that is, so that the blank is cut at an angle of 90 degrees with the edge of the stock, but while this layout might be considered typical, it is not the most economical one for the particular shape of the blank shown. In this case, it is more economical to cut the blanks diagonally, with reference to the edge of the stock, as shown in Fig. 2. By comparing this illustration with Fig. 1, which shows the scrap from a section of stock which has been blanked in the usual manner, the saving in metal by diagonal blanking is apparent, as a much narrower strip of stock can be used. More blanks can also be obtained from a given length, as will be understood by noting the difference between the dimensions *a* and *b* in Figs. 1 and 2. When thousands of blanks are to be produced, the saving in metal that is effected is considerable.

When the shape of the blanks is such that there would, unavoidably, be a considerable amount of metal between the punched holes, the stock can, at times, be cut to a better advantage by so locating the stop, or gage pin (which regulates, by its position, the amount of metal left between the punched holes) that sufficient metal is left between the holes to permit the strip being turned around and again passed through the press. If a large number of blanks are to be made, however, a double blanking die would be preferable. The most economical layout can often be determined easily and quickly by cutting out a few paper templets, using the steel master blank as a gage, and arranging these in various ways until the best method of blanking is ascertained.

After the outline of the templet has been transferred to the die blank, the centers of the holes to be drilled for the purpose of removing the core, should be located. In the October issue, the way in which this core is removed, and the hole finished to conform to the master templet, will be explained.

* With Shop Operation Sheet Supplement.

LETTERS UPON PRACTICAL SUBJECTS.

PUNCH AND DIE FOR UNIFORM IRON BLANKS.

The accompanying engravings show a punch and die for the production of two 0.014 inch thick iron blanks, having almost identical outlines and proportions, and required to be produced in equal numbers. The blanks to be cut are shown in Fig. 2, together with a central piece of scrap resulting from the blanking operation. In addition to the blanking out of the pieces, two small holes, not shown in Fig. 2, are pierced at one end. By examining the design of the punch and die in Fig. 1, it will be seen that the tool is essentially made on the compound principle, the blanks being pierced and cut out complete in both the upper and the lower die at the same time, and simultaneously ejected from each, together with the central portion *A*, Fig. 2, or, in other words, one of the parts required, *C*, is cut out by the upper half of the die, or what is commonly called the punch, and the other blank, *B*, is cut out by the lower half of the tool, or what would be called the die. In Fig. 2, the pieces cut out have been shown with differently inclined cross-section lines, in order to more plainly indicate the work done by, and the action of, the tool illustrated. The three laminations—the two pieces to be cut, and the central piece of scrap—slide by gravity from the face of the die into a box at the rear of the press, the press being tilted for this purpose. The die, as will be seen, is made on the sub-press principle, four pins being used in each of the corners to properly align the upper and lower dies, thereby lessening the liability of accidentally shearing the edges, and at the same time insuring quick and accurate setting, which cannot be obtained conveniently by any other method. The tool is placed in an inclinable, overhanging, open-backed power press, running at 80 strokes per minute.

The general principles on which this die works are so simple that by comparing the shape of the pieces to be cut, as shown in Fig. 2, with the layout of the die in Fig. 1, no explanation can make the general working of the die any plainer than the engravings themselves. The construction of the die, however, may be of some interest. The holders consist of flat castings, machined where necessary, having four bosses, one at each corner, for the sub-press pins, and having projections or ribs cast where there are no outside cutting edges, for the purpose of strengthening the holder, and providing a backing for the sections. The tool steel pieces which form the cutting edges of the dies, are planed, drilled and tapped, and the piercing holes reamed slightly tapered, after which these sections are hardened and finished all over by surface grinding. Prior to the hardening of the cutting sections, however, grooves are planed transversely in them as shown in the small section between the plan of the upper and lower die in Fig. 1. These grooves are ½ inch wide and ⅜ inch deep; they are planed on the under sides and serve to decrease the tendency of the ends of the long steel pieces pulling away from the holder and rising up, thereby destroying the assembled condition of the punch and die, and making refitting of some parts necessary.

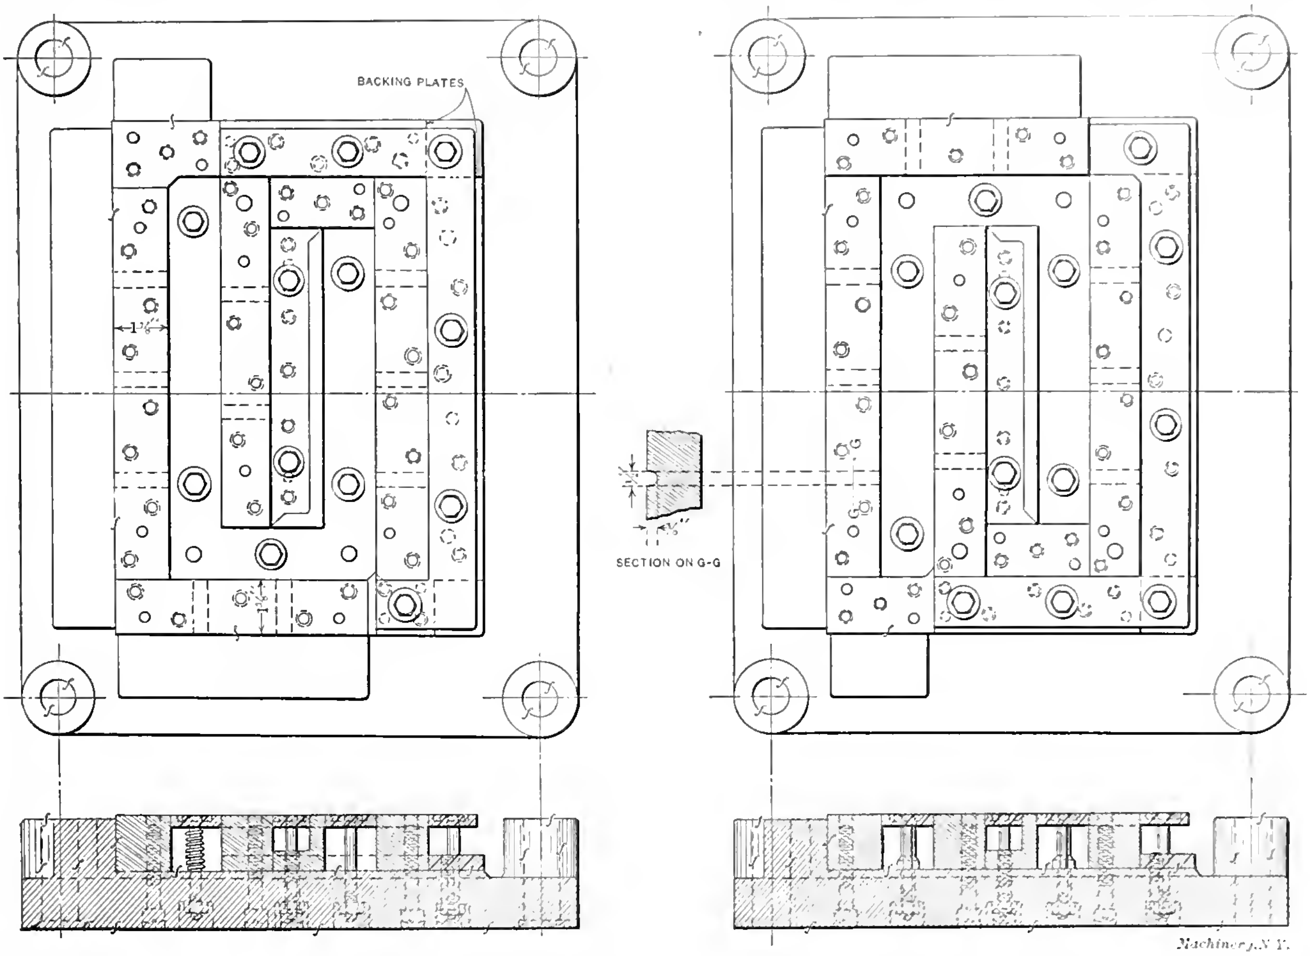

Fig. 1. Plan and Section of Upper and Lower Portions of Die for Cutting Pieces B and C in Fig. 2.

The constant impact common to blanking operations affects the long hardened steel members in these dies to a marked degree. After about ½ inch has been ground away on the top by repeated sharpenings, the long pieces will strain the threads on the screws which secure them to the face of the body of the die, and due to this strain, the long pieces will warp, the ends usually rising up. The grooves on the side next to the holder may not be an absolute cure for such undesirable conditions, but they tend to eliminate these troubles to a considerable extent. If the sections should warp in hardening, they may be straightened and replaced in their respective locations on the holders by peening on the top, care being taken not to strike near to the cutting edge. The steel parts of the upper and lower die having outside cutting edges are held in position not only by the screws coming through from the back, but also by ½ inch thick backing plates, doweled and screwed firmly to the holder.

The strippers are made of ½-inch boiler plate, and are planed on the outer face. They are forced to the top of the dies by coil springs made from ⅛-inch wire, and their movement is limited by the heads of ⅜-inch hexagon screws. The nuts on the lower ends of these screws are prevented from turning by a groove filed in the side with a small round file, and pins driven into the counterbored seats, fitting with their ends in the grooves. All adjusting of the strippers is done from the top of the dies. It will be noticed that stripper plates are provided for the sheet outside of the die, as well as for the parts which are cut out by the die. When the die was first designed, no stripper plates were provided for the outside, as the sheet iron from which the blanks were cut did not seem to require any stripping on the outside edges; but it was noticed that when the die was in operation, the outer edges of the stock sometimes bent down at quite an angle when the tool was cutting, resulting in unsatisfactory work when cutting blanks from the stock at places where the fit was slightly imperfect. The outer edges of the die also dulled more quickly than the inner edges, where strippers were used from necessity. By adding outer strippers to the die to clamp the stock, the troubles mentioned were overcome, and better work was turned out at the same time as the intervals between grindings became longer. Several years of experience have proved that when cutting sheet metal in large dies, it is by far the best practice to clamp the stock when cutting. When the stock is not so clamped, it is very liable to have a tendency to spread the die by straining the outer sections, or to cause other troubles.

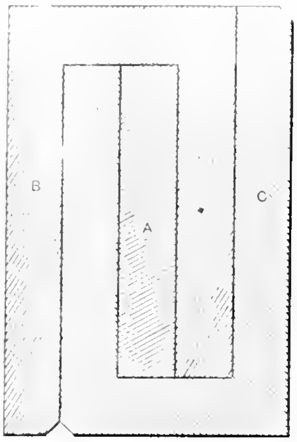

Fig. 2. Pieces B and C, cut by Die in Fig. 1, and the Scrap Piece A resulting from the Operation.

The piercing punches are driven into the holders, which is sufficient to hold them securely in place. Openings in the press ram flange are provided to allow the piercings to escape. In connection with this die, especial attention should be called to the small amount of scrap resulting from cutting out both of the odd-shaped blanks at once, the scrap for each two blanks being only the piece *A* in Fig. 2 and, of course, a narrow strip on each side of the stock used.

ENGINEER.

FORGING AN EYE-BOLT.

Some time ago the writer had occasion to make some 1¾-inch eye-bolts, that is, eye-bolts having 1¾-inch shank, for generators, and with the tools at hand he found it a rather difficult job. In the first place a 2 by 4 inch machine steel bar was hammered down enough for a shank about 2 inches in diameter. The piece was then cut off about 4 inches from the shoulder, and a 2-inch hole punched in the center, which hole was thereafter increased to 3 inches. The corners were then cut off, as shown at *B* in Fig. 2, and the inside and outside corners around the hole were removed in order to procure a circular section at this place. The result was a fairly good-looking job, but the time it required to make the forging was too great, it having required about three hours to make the first eye-bolt, and when the time was cut to 2½ hours, it was considered as doing well.

The writer, however, was not satisfied, and asked the superintendent for permission to make a forming tool, but, for some reason, this was refused. But later, receiving an order for as many as 12 eye-bolts, he undertook to make the tool "on his own hook," the superintendent having gone away for several days. The tool was made, and the time was cut to three quarters of an hour on each eye-bolt, and by using the furnace, they could be made in one-half hour each. It took the writer and a helper about five hours to make the forming tool, and there was four hours machine work on it, making a total of nine hours or a total cost, including shop cost, of about $11.00. Considering the cost of the first eye-bolt to be in the neighborhood of $4.00, including the shop cost, the writer thought that the saving in time more than paid for the tool. In the following is described how the tool was made.

One of the best of the eye-bolts previously made was filed up smooth and well rounded for the purpose of forming the tool. A ring was also made of 1¼-inch round machine steel, 3¼ inches inside diameter, as shown at *A*, Fig. 2, intended for making the first indention in the tool. After this, two pieces of locomotive driving axles were obtained, and two pieces or plates made, 7 inches square by 2½ inches thick. The corners of these were hammered, as shown in Fig. 1. The two pieces were heated, and the ring placed between them, and then hammered together. After this, a piece of 1½-inch round steel was used for forming the groove for the shank as shown at *A*, in Fig. 1. The plates were then again heated, and after having removed the scale, the eye-bolt was put in place between them, and once again the plates were hammered together, after which the edges were worked up with a bob-punch to get them sharp. Then the eye-bolt was put between the plates again for the final blow.

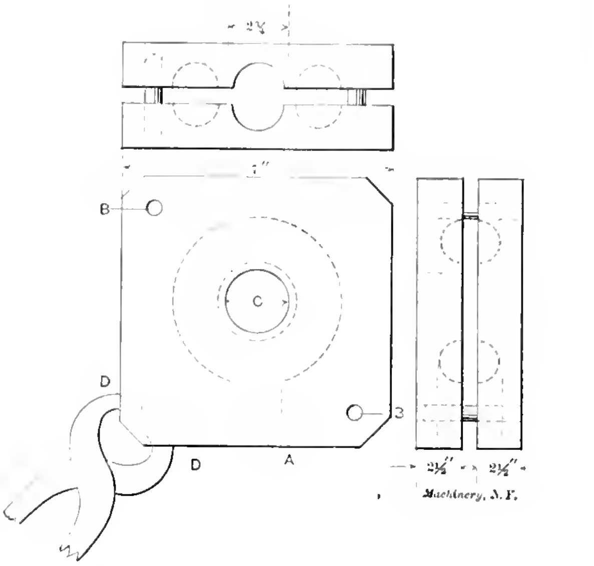

Fig. 1. Former or Die for Eye-bolt Forging.

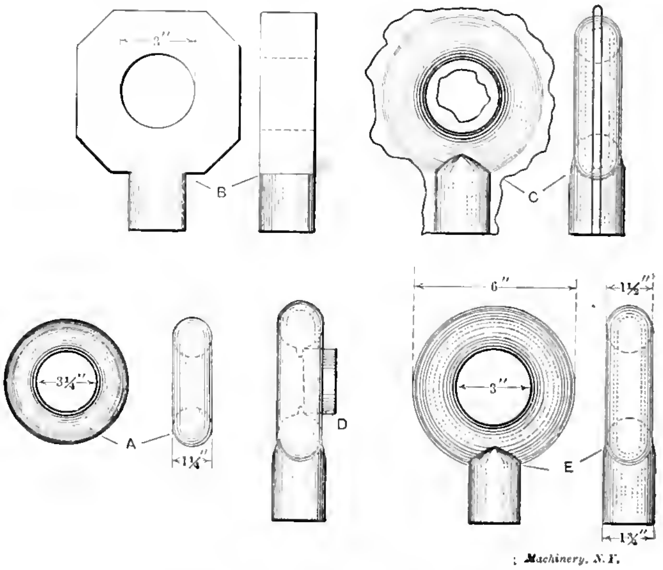

Fig. 2. Successive Steps in Forging an Eye-bolt.

When the steel plates had cooled off, two holes were drilled at opposite corners, as shown at *B* in Fig. 1, while the eye-bolt still remained in place. The plates were then bolted together, and a hole drilled through the center, as shown at *C* in Fig. 1. This hole was bored out to 2¾ inches diameter. The bolts were then taken out, and the holes at the corners drilled for ⅞-inch pins, which were then driven into the bottom part, with the ends tapered slightly on the outer end, so as to enter the holes in the upper part of the tool. The pins were of such length that when the dies were placed together, the pins

were below the surface of the dies. Finally holes were drilled in one corner of the upper die at *D*, Fig. 1, to fit the jaws of the tongs for handling it.

The blank forgings are now made in the same way as before, and as shown at *B* in Fig. 2. The blanks are placed between the forming dies, and these are hammered together, and when the eye-bolt is taken out, the surplus metal will be found around the outside of the eye-bolt and in the hole, as shown at *C*, in Fig. 2. This fin is cut off from the outside, and the eye-bolt is then again heated and placed in the die for a final blow. Then a short piece of steel, 3 inches in diameter and about 1½ inch long, as shown at *D*, Fig. 2, is placed on the die of the steam hammer, and a light blow will clean out the inside edge of the eye-bolt, leaving it finished as shown at *E*, in Fig. 2, excepting for cutting the shank to the proper length.

Decatur, Ill. GEORGE T. COLES.

A ROLLING OPERATION ON TYPEWRITER PARTS.

There are a great many interesting operations, common enough in some shops, which the workmen in other shops seldom or never hear about. A shop which has many things of interest and value to the wide-awake machinist is the Remington-Sholes typewriter factory. One of the many interesting operations carried out in this shop is a process for rolling a head on a stamped punching. The process may not be new, but it is certain to be of interest to many of the readers of MACHINERY. In Fig. 1 is illustrated a small detail for a typewriter in full size; at *A* is the piece as cut in a die from stock about 3/32 inch thick. This part is cut in the sub-press die *B*, in Fig. 2. The piece shown at *C*, Fig. 1, is the same part with a head rolled on it. It will be noticed that there are some fins around the edge of the rolled or formed portions. At *D*, in Fig. 1, the piece is shown trimmed off, the trimming being done in a sub-press die, as shown at *E*, in Fig. 2. The stem of the piece is inserted in the slot in the lower die shown at the top. It is clamped by means of the eccentric lever shown at one side, the trimming being done by the upper half of the die.

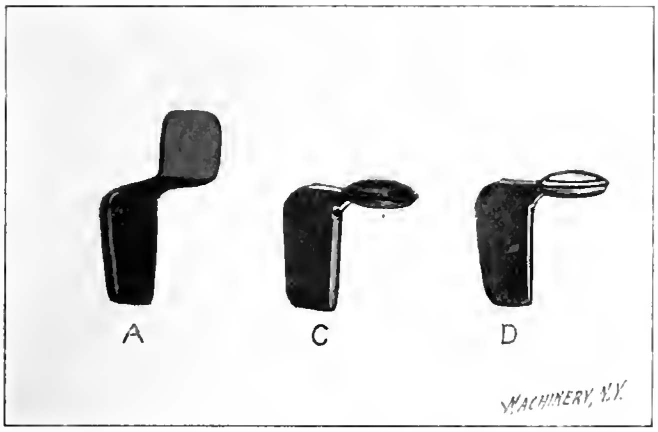

Fig. 1. Part Stamped and Rolled to Shape, at Various Stages of Completion.

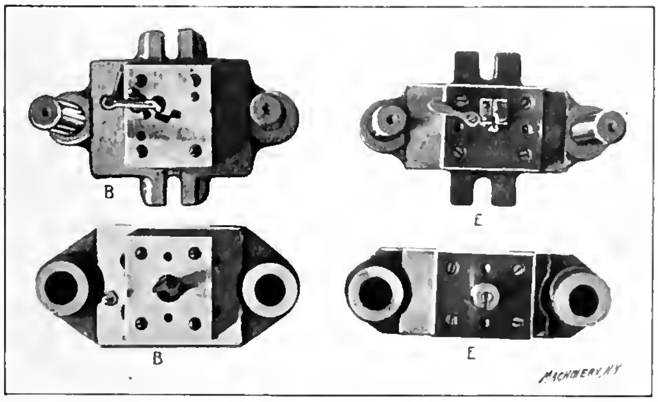

Fig. 2. Sub-press Dies used for Stamping and Trimming Part in Fig 1.

It would be very difficult, if not entirely impossible, to do a satisfactory forming job of this type in a punch press. The work is done in a special rolling device, the elementary principle of which is shown in Fig. 3. The heads *F* and *G* of the device rock up and down about pivots, as shown, between the positions indicated in the full lines and the positions shown in the dotted lines. The piece to be formed is held in a die between *F* and *G*, and the heads, as they rapidly move up and down, gradually are fed toward each other, thereby rolling the metal into the shape indicated. The appearance of one of these heads, *G*, is shown in Fig. 4. ETHAN VIALL.

Decatur, Ill.

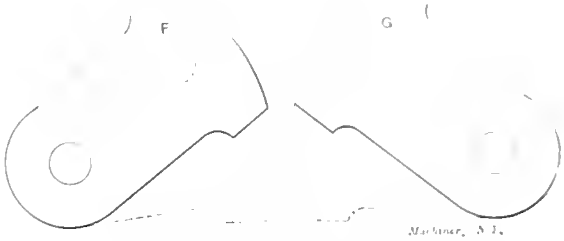

Fig 3 Principle of Rolling Device.

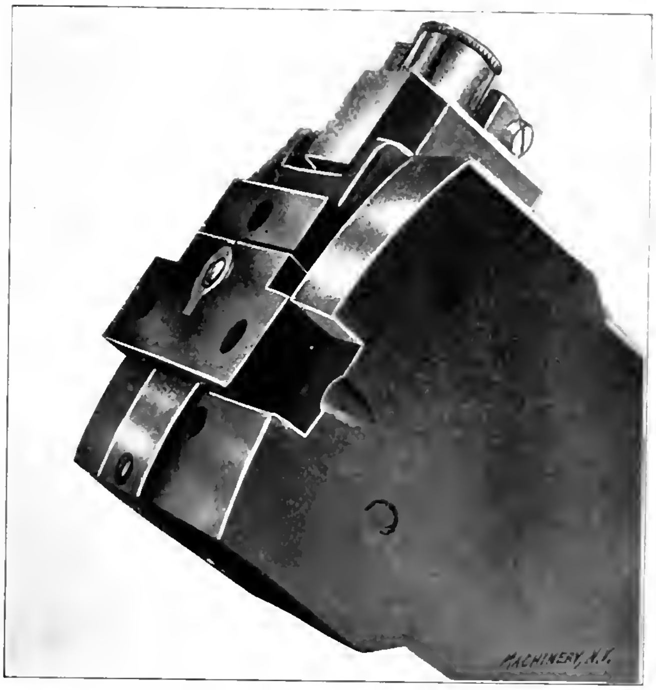

Fig. 4. One Head of Rolling Device, showing Construction of Work Holder.

MAKING BLUE-PRINTS WITHOUT A FRAME.

It may not have occurred to many of the readers of MACHINERY that blue-prints of small size can be made without a blue-printing frame. An ordinary window can be used if the sun shines through it, and a blue-print can be made in any window. An ordinary thick bath towel is placed behind the print, the tracing being placed against the glass. The towel should be folded into two or three thicknesses and arranged so that no wrinkle or uneven part lies against the print. A small drawing board may then be placed against the towel, but it is better to tack the towel at its corners to the board. It is also advisable to attach the tracing to the printing paper by small gummed stickers, to keep them in the proper position and to prevent sliding. Ordinary stickers cut into narrow strips will be sufficient, and need engage only a narrow surface on both the paper and the tracing, to serve the purpose. The print can then be frequently looked at without disturbing the relation, and can be easily torn off without injuring it or the tracing. Fragments of the stickers are easily scraped off. The printing paper and tracing can be held by a blank projecting edge against the window while the towel and board are being pressed against them. Any suitable means for holding the board in place may be used.

Another improvised printing outfit used by the writer consists simply in spreading the towel evenly upon the floor where the sun can strike it, placing the printing paper and tracing upon it, and then merely covering these with a thick

plate of glass. When first laid down, the glass may be pressed downward with considerable pressure, after which its weight alone will be sufficient to keep the paper smooth. This will be the case if two or three thicknesses of bath towel are used. This plan works perfectly for sheets 10 × 15 inches and below, this being the size used by the writer. Larger prints could doubtless be made in this way if weights were put upon the corners of the glass.

Another very practical way of making small prints is to use a smooth board with a slightly curved face. A tack placed in each corner of the tracing and print will cause them to snugly lie against the curved surface of the board, making a sharp and clear print. No glass is needed. C. E. BURNAP.

Battle Creek, Mich.

TO SET OVER TAIL-STOCK TO TURN A TAPER.

In these days of taper turning attachments, it is not often that one has to set over a tailstock to turn a taper. Sometimes, however, this has to be done, and the methods usually given are not only clumsy and troublesome, but almost invariably end up with the statement that no account has been taken of the effect produced by the uncertain depth to which the center holes have been drilled. It is not conducive to one's respect for the author of a rule, after figuring out by proportion how much to set over a tailstock to turn a taper of 0.650 inch on a piece 3 21/32 inches long, to be told that this is only approximate and the exact setting must be determined by trial. As a better method, and one which not only eliminates all figuring, but also gets rid entirely of the uncertainty of the center holes, I venture to offer to the readers of MACHINERY a method which I have used for some time in the instrument shop of the Emerson McMillin Observatory.

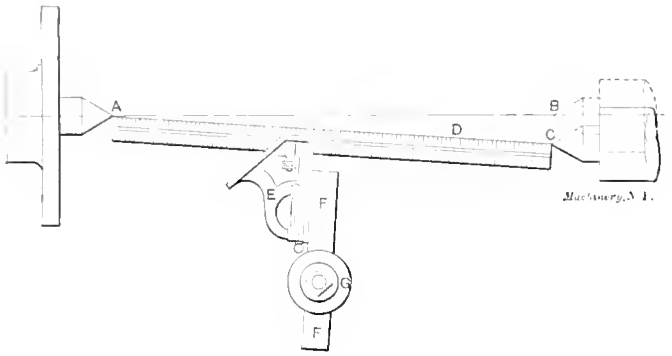

Fig. 1. Method of obtaining Setting for Taper Turning; First Step.

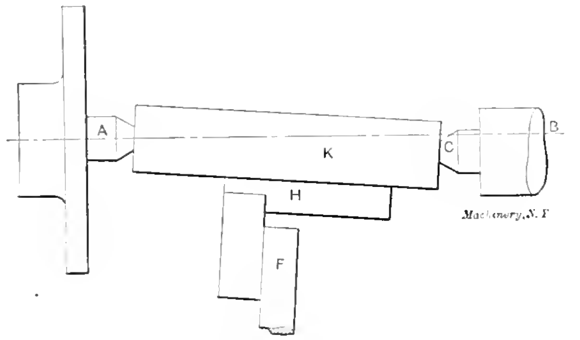

Fig 2 Setting the Tail-stock for Taper Turning Second Step

The piece to be turned should first have its ends faced off [illegible] smooth cut taken over about two or three inches [illegible] the centers being accurately in line. Then take [illegible] of the lathe and move the tail-stock until the [illegible] the centers are exactly one foot apart, as shown [illegible] tail-center *B* being dotted. Then, in any conve[illegible] over the tail-center exactly one-half the required [illegible] that is, the distance *B C* should be [illegible] per foot. A piece *F*, which has [illegible] on at least three sides, should [illegible] tool-post *G*. This piece should be about the [illegible] used in the lathe. A machinist's [illegible] one foot long, and preferably with a sliding head, should be held against the side of *F* and this latter turned in the tool-post until the edge of the blade *D* "cuts" the points of the centers *A* and *C*. The piece *F* should then be clamped, care being used to prevent changing this adjustment in clamping. It is evident that the side of *F* will now make an angle with a perpendicular to the axis *A B* of the lathe, which is equal to half the angle of the required taper. Now move up the tail-stock, and place the piece to be turned (*K*, Fig. 2) between the centers. Then hold a small square *H* against the piece *F* and set back the tail-stock until the blade of the square shuts out the light when held against *F* and brought up to the piece *K*. Should *K* be longer than one foot, obviously the tail-stock should be set over more instead of being set back. If care be used in each step of this process, a taper three or four inches long, when tried with a chalk line along its side, just as it comes from the lathe, will show a bearing for its entire length. While it has taken some time to describe this process, I do not think it takes over three minutes in actual practice to set over a tail-stock to turn a given taper after the work is ready. H. C. LORD.

Columbus, Ohio.

HOME-MADE TOOLS FOR DIE-MAKERS.

A few home-made tools are shown in the accompanying engravings. The construction of these tools is very simple, and they will make a desirable addition to a die-maker's collection. During several years experience as die-maker, the writer has noted with considerable interest many different methods of locating round piercing punches in a punch holder, the means employed differing as widely as the men who used them, ranging all the way from the crude method of transferring through the die by means of a twist drill, to the accurate master plate which is in almost universal use in the watch-making factories.

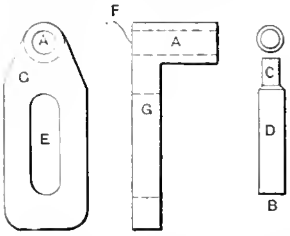

Fig. 1. Device for Locating Holes for Punches in Punch Holders.

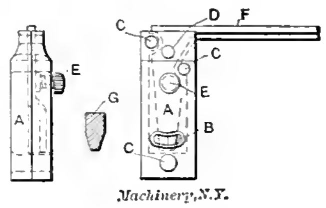

Fig. 2. Die-makers' Square or Protractor.

In Fig. 1 is shown a device which the writer has used considerably for locating the punches for small open dies, with the best results. The bracket *G* is made from tool steel, and the hole *A* is ground so that it is accurately at right angles with the face *F*. This can best be done on the face-plate of the bench lathe, using a revolving steel lap charged with diamond dust or carborundum. When using the tool for locating small round punches in the punch holder from the die, a piece of drill rod is first turned up, as shown at *B*, so that the diameter of the portion *C* equals the size of the hole in the die, and the part *D* is a close sliding fit in hole *A*. The piece *B* is then pressed into hole *A*, and the end *C* of the pin is placed in the hole in the die. One of the punches, that has previously been put into the punch-holder, is now permitted to enter its corresponding hole in the die, and when this is done, scribe lightly through the elongated hole *E* with a bent scriber on the punch-holder. After this, the die and bracket *G* are removed and a hole drilled and tapped in the punch-holder for a clamping screw in the center of the scribed outline. No great accuracy is needed, as the slot *E* should be enough larger than the screw to admit of considerable side-play, and the screw can be placed anywhere within the length of the slot. After having drilled and tapped this hole, the die and punch are again assembled, and carefully levelled up with parallels. The bracket *G* is placed on the punch-holder, and the screw in slot *E* is put in position and tightened, thereby binding the bracket to the punch holder, a bent screw-driver being used for tightening up the screw, if it has a slotted head. It is evident that the end of pin *B* which locates hole *A* of the bracket *G* now being clamped to the punch holder, is exactly in the position which the punch should

occupy in the finished tool, because end C of pin B enters the corresponding hole in the die. All that therefore remains now is to place the punch-holder on the face-plate of a lathe, indicate the pin, in the usual way, so as to insure the hole being bored central, remove the locating bracket, and bore the hole for the punch. This method, of course, leaves a small threaded hole in the punch-holder, but this can easily be plugged up. Should it, however, be objectionable to have a tapped hole in the punch-holder, the bracket may be held to the punch-holder with a little solder on each side, care being taken that the bracket is held down firmly to the holder when the solder is applied.

In Fig. 2 is shown a die square, which, when carefully made, is a very handy little tool. As will be seen, the blade can be adjusted from a 90-degree angle, or a perfect square, to an angle slightly larger or slightly smaller than 90 degrees. This tool is used for measuring the clearance of dies. By this means the die maker can measure the angle of clearance without the use of a regular protractor, and he can set this tool to the angle required for different jobs. The body part A is made of tool steel in two pieces, each side being recessed to accommodate the blade F. One side has a slot cut through it at B, which is bevelled and graduated. The rivets C shown serve to hold the two parts of the body together. The blade F is made of tool steel and is pivoted on the pin D, and locked by means of a knurled screw E, the point of which rests on a hardened disk, to prevent marring the blade. The projecting part of the blade is bevelled, as shown in the enlarged section at G, to allow the light to be more readily seen under it when in use.

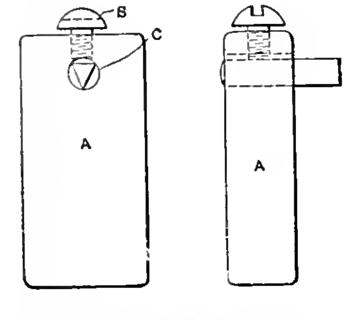

Fig. 3. Tool for Cutting or Scraping the Edges of Thin Templets.

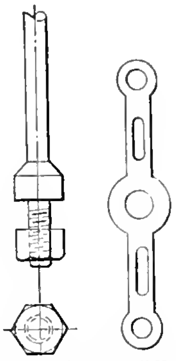

Fig. 4. Handy Holder for Thin Templets.

The tool, Fig. 3, is used in squaring up the edges of thin templets. The body part A is of tool steel having the corners nicely rounded, so as to be convenient for handling. A hole is drilled and tapped in the end for the screw B, which holds the pin or cutter C in position. This cutter is milled off on three sides, and is then hardened, and afterwards ground in the bench lathe, using a tool-post grinder with a cup wheel. When the cutting edge gets dull, the screw B is loosened, and the cutter C is turned around one-third of a revolution, so that the next cutting edge can be presented to the work. When all the edges are dull, the tool can again be ground on all the three sides.

The tool shown in Fig. 4 is a simple templet holder for small templets, which does away with the soldering on of a piece of wire, in which operation one usually manages to get part of the solder over the edge of the templet, which, whether left on or filed off, does not add to its accuracy. Another advantage of this holder is that when using a templet which is thin, and therefore has a tendency to spring, washers can be roughed out approximately the shape of the templet, only a little smaller, and the templet can be placed between them and the nut screwed up to hold the templet between the washers. It can then be held firmly in a flat position. As an example may be shown the templet at the right side in Fig. 4, which is very thin, and would be difficult to work through a die in the ordinary way, but by making two washers or guides, not illustrated, of approximately the same shape as this templet, it may be held straight and flat. When the washers holding the templet are long and narrow, as in the present case, it is well to bend them a little before binding with the nut, so as to prevent the ends from lifting up when the nuts are tightened.

SPECIAL SHOP CAR FOR CURVES OF SHORT RADII.

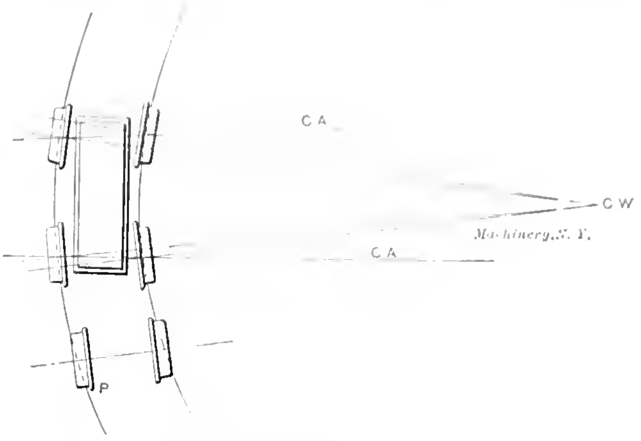

Fig. 1. Action of Car-wheels shown in Fig. 2 when on a Curve of Short Radius.

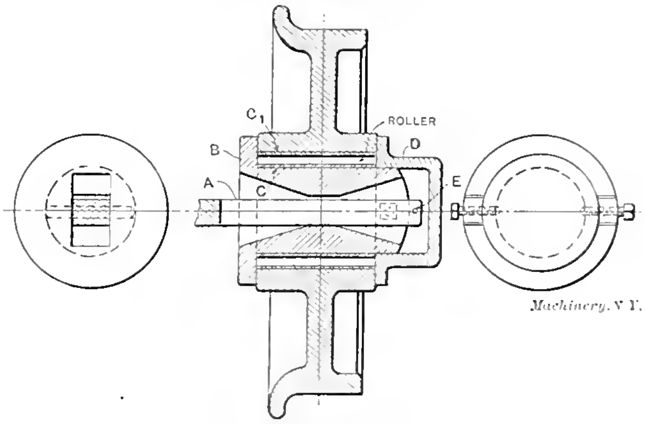

Fig. 2. Construction of Car-wheels for Curves of Short Radii.

In manufacturing establishments, where small cars are used for transferring material and other supplies from one point to another, it is common to have turn-tables for changing the direction of the cars. Under these conditions, the car must be run onto the turn-table with some care, especially when the wheel base of the car is as long as the turn-table will admit, and much time is often lost in placing the car and swinging the turn-table to bring the car into position to take the new direction. For this and other reasons, curves instead of turn-tables are preferable, but in a manufacturing plant it is obvious that the curves must needs be of such short radius that cars of special construction are necessary. The object of this article is to describe a car that was especially designed to meet these requirements, *viz.*, a car that will automatically adjust itself from running on a straight track to running on a curved track of short radius, say twelve feet, and which on passing the curve readjust itself again to straight running. The accompanying illustration, Fig. 1, shows a car of this type with wheel flanges on the inside of the rails. The dotted lines marked *CA* show the direction of the center lines of the wheel axles which are rectangular in section, and rigidly fixed to the frame of the car with their depths perpendicular. The dotted lines *CW* show the direction of the center lines of the wheel-bearing sleeves. These sleeves are malleable castings cored parallel and an easy working fit (all the way through) in the up-and-down direction, but in the forward and rear direction the cored axle-seat is only parallel for about one-sixth of the length of the sleeve. This short parallel part of the axle-seat in the sleeve is directly above the center of the rail, and from each end of this short parallel part to each end of the sleeve, the cored axle seat flares, in both forward and rear directions, an amount depending on the radius of the curve the car is intended to traverse. This short parallel part must be loose

enough on the axle to let the sleeve swivel the full amount which the flared parts permit.

Now, if the car is pushed or pulled forward or backward, the axle is forced against the short parallel part of the axle-seat, and if the car is on a straight track, the wheel bearings will stand parallel with the axles. When a curve in the track is reached, and the flange of the wheel comes in contact with the rail, as shown at *P* in the engraving, Fig. 1, the wheel will force the sleeve to swivel, and the short parallel part of the axle-seat in the sleeve will be thrown out of line with the axle, but will always have a tendency to come back into line, and will do so as soon as the car reaches a straight piece of track.

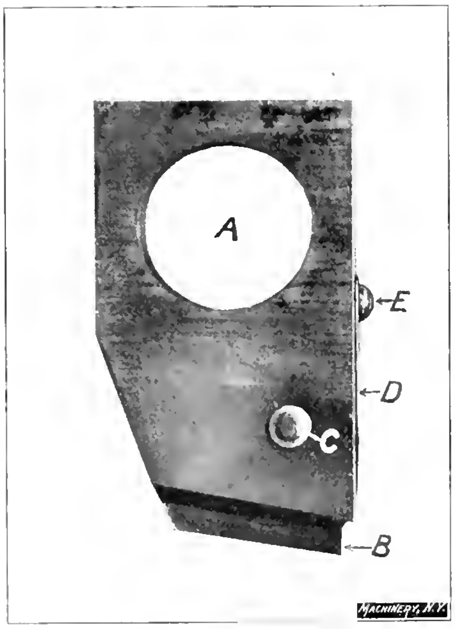
In the detail construction in the engraving, Fig. 2, *A* is the axle, *B* is the wheel-bearing sleeve, *C* is a thin steel casing split lengthwise and pressed on the sleeve with the split at the top, and C_1 is a thin steel bushing in the wheel-hub. (If C_1 is split, it must be done spirally.) The part *D* is a cap with two set-screws in it to keep the wheel in place on the sleeve; *E* is a pin driven through the end of the axle between the end of the sleeve *B* and the inside of the cap *D*. The end of the sleeve *B*, where the pin goes through the axle, is convex in the forward and rear directions, the radius of the convexity being the distance from that end of the sleeve to the center of the short parallel part of the axle-seat. When the pin in the axle is against the highest part of the convex end of the sleeve, the end of the axle should clear the inside of the cap *D* by about one-eighth inch. JAMES T. GRIMSHAW.

Detroit, Mich.

TOOL FOR GRADUATING.

A very good tool for graduating work in the milling machine, when the index head is used for spacing, is shown in the engraving below. The tool is held stationary on the arbor in the same manner as a regular milling cutter, and the work is moved back and forth under it, the table stops being used to get the correct length of stroke. The body of the tool is made of machine steel, ½ inch thick, 1½ inch wide, and 2¾ inches from the top to the cutting point. The hole *A* is bored for a 1-inch arbor.

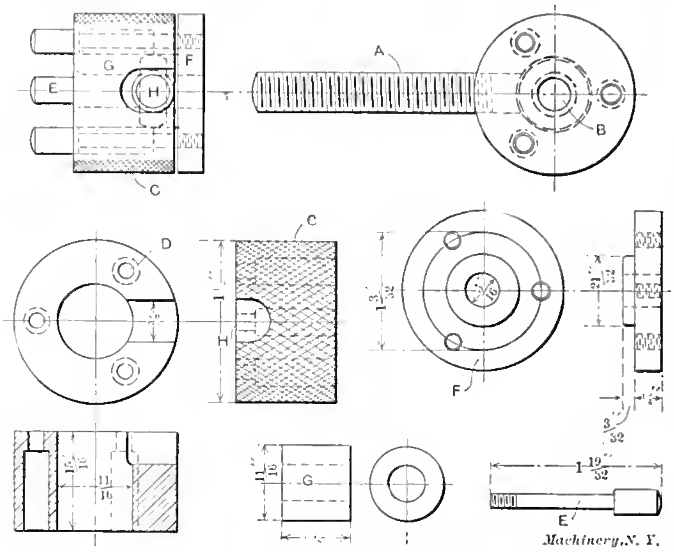
The cutter blade *B* fits freely into a slot milled in the machine steel body. It is made of ¼ x 1-inch tool steel, hardened and tempered, and the cutting edge is ground to a 60-degree angle. The cutter is also ground at an angle of 80 degrees to the front edge of the body for clearance. The pin *C* which holds the cutter in the slot is of ¼-inch drill rod. The spring *D* at the front of the tool, which keeps the cutter in proper position when cutting and allows it to ease-up when backing out, is ¼ inch wide and 1¼ inch long, and is held by a small screw *E*. Rapid, clean work can be done with this tool without danger of breaking the point. ETHAN VIALL.



Tool for Graduating.

INTERESTING DRILL JIG.

The drill jig described in the following is so simple in its construction, and so easily manipulated, that I think it will be suggestive for improvement in drill jig design to some of the readers of MACHINERY. In the upper part of the line engraving the jig is shown assembled, with the piece *A* to be drilled in place in the jig. In the lower part are shown the details of the device. The piece to be drilled is turned and threaded in the screw machine, from bar stock, and the spherical head slab-milled in the milling machine. The hole to be drilled is the hole *B* in the head. The main body *C* of the jig is knurled to permit a good grip in handling, and is bored to 11/16 inch diameter, which corresponds with the diameter of the spherical head of the piece to be drilled. The three small counterbored holes *D* permit of the introduction of the feet or plungers *E*, around which are placed small helical springs. The stems of these feet *E* pass beyond the body *C*, and are threaded on the upper ends, the threaded portions entering into the cover *F*. The jig is now complete except for the bushing *G*, which, of course, is hardened, and made of tool steel. This bushing is pressed into the body *C*, and is just long enough to leave, when it is pressed down flush, sufficient room for the flattened head of eye-bolt *A*. The slot at *H* allows clearance for the stem of *A*, which latter provides a very convenient handle when drilling. In the event of a piece with a shorter stem being used, a small handle can be driven or threaded into the side of the body *C* to hold it while drilling.



Drill Jig of Simple but Interesting Design.

With the feet *E* resting upon the drill press table, and the thumb and fore-finger on either side of the body *C*, press downward in order to remove the piece; then, after inserting a new blank, the pressure on the body *C* is released, and the small helical springs bring the body *C* up against the cover *F*, thereby holding the work securely. The jig is now turned over, and, using *F* as a base, the hole is drilled through the work from the bushing *G*. C. H. RAMSEY.

Paterson, N. J.

AUTOMATIC LATHE STOP AND TELL-TALE.

I have seen one or two devices around the shop for automatically stopping the lathe, or warning the operator when the tool had reached the end of its cut, which were very primitive in design, but served the purpose well.

One way of stopping the lathe is to hang a weight on a cord which is attached to the shipper and which passes over a rod on a level with the bottom of the shipper. The weight is set on the back V of the lathe in such a position that when the carriage has reached the end of the cut, it will push off the weight, which will cause the shipper to be pulled over, thus stopping the machine. This device is used mostly on lathes with jobs running half an hour or so, and where the operator is running some other machine.

Another arrangement used by the piece workers on roll turning, where they do not stop the lathe at all, is a telltale. It is a strip of sheet steel fastened by one end to the carriage and set in such a position that when the tool has reached the end of the cut, it will rub against the faceplate, making a noise like an old style watchman's rattle, thus notifying the operator. PAUL W. ABBOTT.

Lowell, Mass.

PUNCHES AND DIES FOR CAN ENDS.

I was much interested in Mr. Washburn's description of his toggle drawing punch for can ends (see February, 1908, issue of MACHINERY), as I have been closely connected with the can business for a few years. I like the toggle punch for shallow, unembossed, push-through work, but for the general line of can tops and bottoms I prefer a single action combination die, as there is usually some embossing to be done in addition to the cutting and drawing of the bottom; a top with an opening is also usually required on fruit and vegetable or "packers'" cans. This opening is used for filling, and is later closed with a cap. It has been found that a lip on the mouth of a can end is essential to rapid and economical production, as it makes the entrance of the body into the ends more easy, and also maintains a good tight fit so as to make a good joint with the least amount of solder.

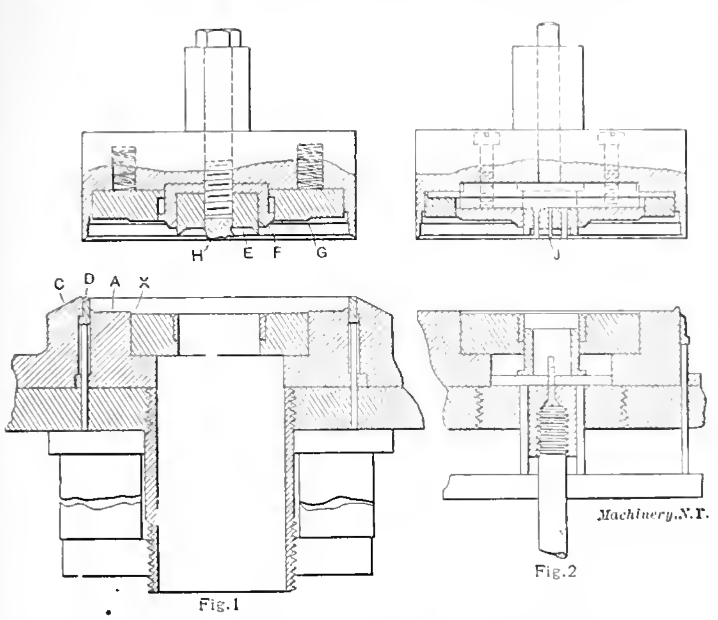


Fig. 1 Fig. 2

Figs. 1 and 2. Punches and Dies for Can Covers and Bottoms.

The style of punch and die that produces a large portion of the can ends used by packers and supplied by the so-called can trust, is shown in Fig. 1, and might be termed a single action, cutting, drawing, and embossing combination. In addition to the operations mentioned, the "single" dies, and especially those of odd sizes, are further combined so as to make bottoms and tops with various size openings ranging from 1⅜ inch to 3¾ inches in diameter; and even after this was accomplished the blank from the 1⅜-inch opening was bumped up into a roofing tag.

The gang dies are of identical construction, and are part of a line of machines that make a can and make three tops and three bottoms at each stroke; the sheet of tin is turned over to cut three more of each at the next stroke; then the stock goes to another gang press that makes six can caps and ten smaller caps for bottles. By this time the sheet is so well decorated with holes that it can be handled only with a pitchfork. This scrap is shipped to a detinning plant. The blanks from the can top openings are worked up under other presses, usually automatic. Some sheets make as high as twenty-four tops and bottoms and a relative number of smaller pieces.

The engraving above of the die will probably need some slight explanation. Center block *A* is made the same diameter as the outside of the can body, as this part determines the smallest possible diameter of the inside of the can end. The center block is bored out to receive die centers made for different size openings, and as these all come within the diameter of the panel *X*, the height of all must be alike at this point, though the contour may vary inside the diameter of the panel. It is my practice to make the contour of the die centers lower than the rest of the bottoms, which makes it possible to run out tops as required, and by removing the punch only and changing to punch centers adapted to bottoms, as shown, bottoms can be made without changing the die or setting the die or press, which results in a considerable saving of the die setter's time when only one or two dies are available.

It will be readily seen that it is not necessary to have solid die centers or center blocks for bottoms, as the punch center determines the convexity and the size and shape of the panel, provided the die center does not interfere. Sometimes tops are required without the panel; then the die center is raised an amount equal to the height of the panel, and the punch center shortened an equal amount, and a separate knockout used. The part *C* is the cutting edge, and *D* the pressure ring which can have a bevel of from 20 to 25 degrees, as a shallow draw has so little tendency to wrinkle, and because such wrinkles can be ironed out with a high pressure from the rubber barrel, there being little danger of bursting the end.

The cutting edge of the punch is bevelled to fit the ring, which permits considerable upsetting before it is necessary to refit. This cutting edge of the punch is 5/16 to 3/8 inch ahead of the embossing or bottoming point; this feature permits the die maker to upset and fit the punch to the cutting edge and ring without sinking back the entire interior of the punch, which means a great saving of time, when one considers that the punch can be fitted eight or ten times before sinking back. The diameter of this portion is made 0.010 inch to 0.012 inch larger than the proper size up to within 3/32 inch of the knockout, then bored the proper diameter to draw the metal to the size of the center block; this double diameter draws, makes the end too large, and then redraws most of it to the proper size, leaving the lip flared out slightly, as shown exaggerated in the views of the tops and bottoms—a small detail that saves thousands of cans and many pounds of solder, and results in a higher speed of production. The forming punch *F* forms the metal around the hole blanked by punch *E*, while *G* forms the bead and panel and acts as a knockout through the springs as shown. The punch parts are held by a cap-screw, and a bit of soft rubber *H* insures the shedding of the blank.

In the roofing tag combination, the blanking punch is fitted with a pick-up piercing pin *J* (Fig. 2) pointed to burst a hole instead of piercing it, and slightly reduced in diameter so as to pick up the work. Knock-off pins are provided, and they and the knockout ring are operated by a ⅜- by ½-inch bar actuated by the pin shown in the shank of the punch. The punch center and ring are slotted to make room and give action to the stripping bar. The die space is filled up with a forming post, forming and stripping ring and stripping pins supported by the threaded plug screwed into the die plate. The ring is intended mainly to hold the blank control on the down stroke, so the center pins are some little shorter than the others. A stud instead of a pipe now supports the rubber barrel, as there are now no blanks to go through. This seems like a lot of work to save a small piece of tin, but I know of one factory that makes 25,000,000 of these blanks yearly. I want to call attention to the difference between these two punches: The knockout in Fig. 1 begins to strip the work an instant after it is formed, and the work lies on the die but falls with the movement of the stock, the press being inclined as usual. With the style shown in Fig. 2 the work is picked up almost to the top of the stroke before falling, hence it is out of the way and permits easier movement of the stock. The roofing tag must be picked up high enough to drop clear of the die; if it drops in the die the next piece will be spoiled.

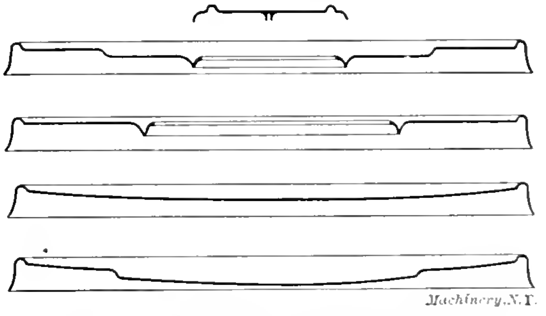

Fig. 3. Plain and Paneled Can Tops and Bottoms

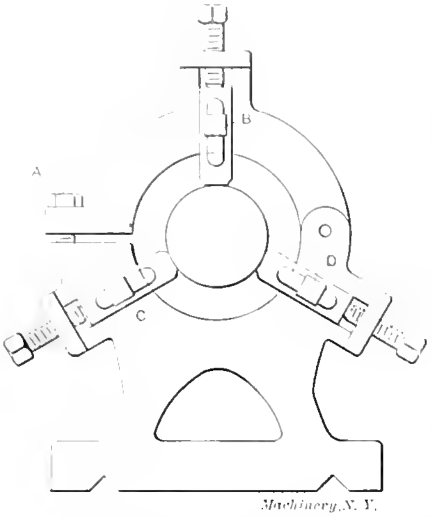
SIRIUS.

SETTING THE STEADY-REST.

After reading Mr. J. J. Voelcker's remarks in the May issue of MACHINERY, relating to the use of the steady-rest, I would say that his remarks are very good as far as they go, but one of the most important suggestions has been left out, which is necessary to make the subject more complete. This important point is that of setting the steady-rest. It seems to be quite common among machinists simply to set the steady-rest by screwing down the jaws upon the work until they have what they think is a running fit between the work and the jaws. This, of course, is a very poor way, especially for finished work, and would, as Mr. Voelcker says, need emery cloth, with the cloth side next to the work, in order to prevent marring the finished surface. Even then, however, there is a liability of scratching the work if it has to be run for any length of time, because the steady-rest is set too positive to allow for expansion of the metal by the heat due to friction. The writer has always found that the best way to set the steady-rest is that indicated in the accompanying illustration. Referring to the engraving, the binding screw *A* should be screwed down with the fingers. This gives the workman a chance to adjust the tension of the jaws on the work every few minutes, and especially when filing the work, this gives very good results, as the nut can be adjusted according to the expansion of the work. It is admitted that emery cloth is a good thing to use in most cases, but there is no need of it if the precaution mentioned above is taken, providing the jaws have ordinarily smooth faces. The nuts on the bolts *B*, *C*, and *D*, for adjusting the jaws themselves, should be tightened positively with a wrench as soon as the work has been set central.



Setting the Steady-rest.

New Britain, Conn. J. W. DICKINSON.

DIE-HOLDERS FOR MARKING MACHINE.

In the manufacture of tools requiring a great many different marks to designate the different parts, the cost and up-keep of the dies is no small item. Having this in view, the idea of dies or type to lock in a form was submitted [illegible] marking machine, and the holder, Fig. 1, [illegible] s and an alphabet, were made, in which [illegible] in detail), were held in place by a [illegible] fastened by screws *C*. This holder [illegible] *B* would break at *D*, and, there [illegible] from side play, the type would [illegible] this, the holder shown in Fig. 2 [illegible] and insert *E* are held from side [illegible] milling away the tongue of the center piece, as shown by dotted lines, while screw *H* takes up end play. To change the type in the holder, Fig. 1, it was necessary to remove screws *C* and take off *B*. To change in the other holder, screws *G* are removed, when the side can be taken off leaving the type and insert free. With this holder an average of 750 impressions, of from 2 to 25 letters and figures each, are made daily on annealed tool steel. With three sets of figures and an alphabet, the range is very large, and can be increased at a fraction of the cost of separate dies for each mark. Our range, at present, embraces over 200 different marks.

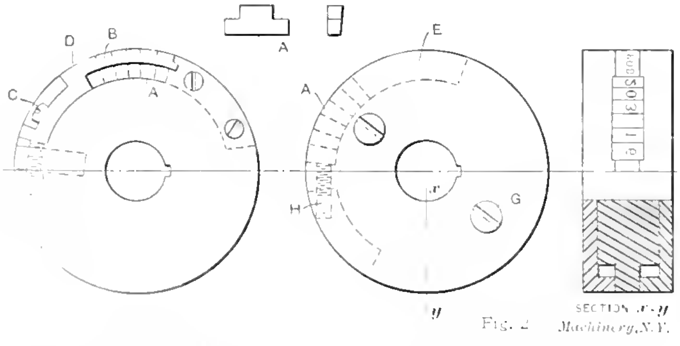


Fig. 2

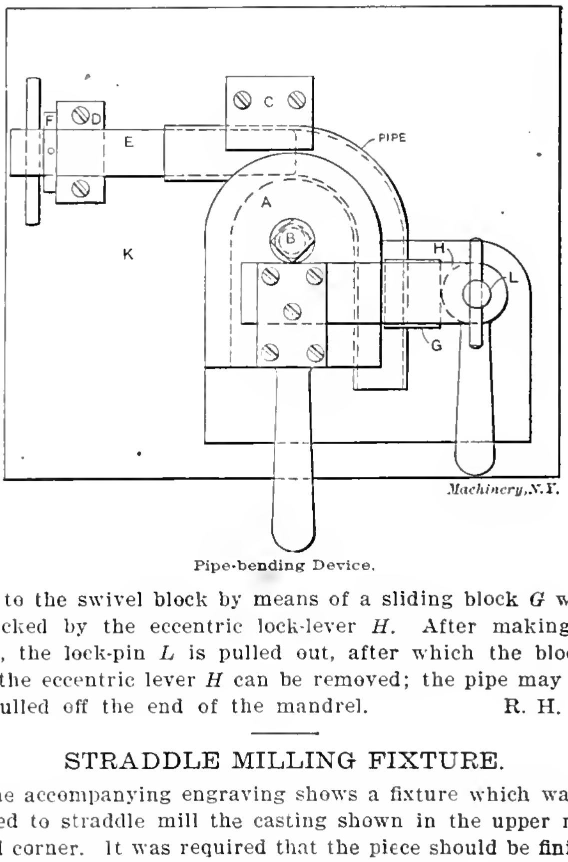
Two Types of Die-holders for Marking Machine.

Muscatine, Iowa. F. P. HEBARD.

PIPE-BENDING DEVICE.

The illustration shows a pipe-bending device which will be of value to anyone wishing to bend pipe without the trouble of filling it with sand or other materials. The mandrel *E* is held on base *K* by the steel block *D*. Stop collar *F* is set and pinned on the mandrel in such a position as to allow the end of the mandrel to project slightly past the center line of swivel block *A*, which is pivoted at *B*, and rounded out for the pipe. The backing block *C*, which also fits the pipe, is set so as to allow the pipe to slide over the mandrel *E*, and keeps it from buckling while it is being drawn off the mandrel.

The pipe is shown in the illustration after having been bent at right angles. Before making the bend, the swivel block *A* is set in a position parallel with the mandrel *E*, and the end of the pipe is then placed on the mandrel. It is held to the swivel block by means of a sliding block *G* which is locked by the eccentric lock-lever *H*. After making the bend, the lock-pin *L* is pulled out, after which the block *G* and the eccentric lever *H* can be removed; the pipe may then be pulled off the end of the mandrel. R. H. M



Pipe-bending Device.

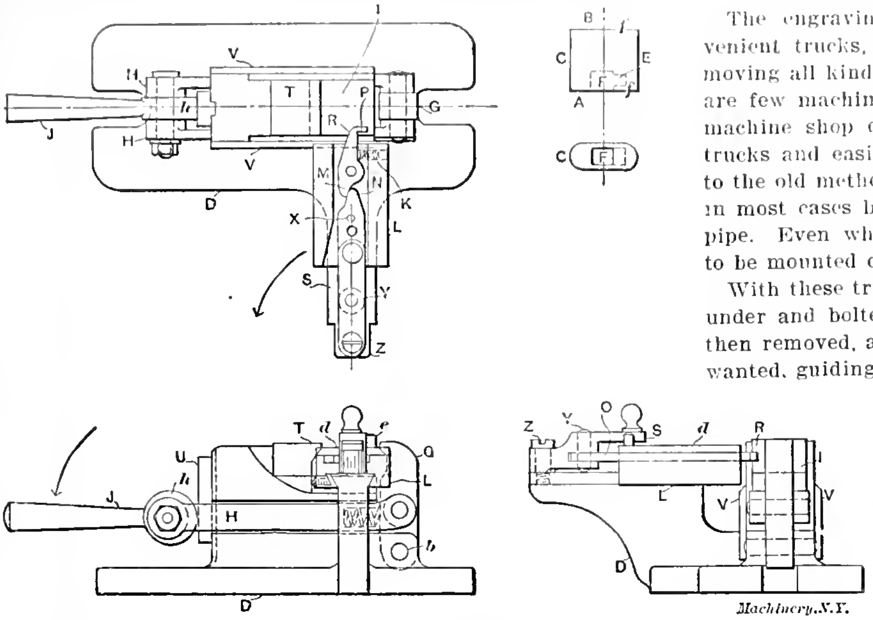
STRADDLE MILLING FIXTURE.

The accompanying engraving shows a fixture which was designed to straddle mill the casting shown in the upper right-hand corner. It was required that the piece should be finished on the two ends *A* and *B*, and that these ends should be approximately square with the side *C*, which is rough. It was important that the top surface *A* should be a certain distance from the side *E* of the cored hole *F*, and that the length from *A* to *B* should be kept constant. It was decided to use a hand miller for the operation, finishing one piece at a time.

The fixture consists of a base *D* of cast-iron, planed off on the bottom, and having a key to fit the slot in the milling machine table and holes in the ends for the usual holding down bolts. The flat side of the work rests on the hardened tool steel plate *I*, and the side *C* is pressed against the jaw *T* by the clamp *G*, thus locating the work square with the cutter spindle. The work is held down by the action of the beveled surfaces of the jaw *T* and the clamp *G*, acting on the upper round corner of the work. The clamp is pivoted at *b* to the

base of the fixture, and is operated by the eccentric *h* through the two connecting rods *H* which are attached one on each side of the clamp. The base is cut away to allow clearance for these connecting rods, and the hardened tool steel plate *U* is let into the back of the base for the eccentric to work against. The side plates *V* are fastened to the sides of the base to keep out the dirt. A coil spring forces the clamp *G* away from the work when the eccentric is released.

To keep the distance between *E* and *A* of the work constant, it is necessary to gage from the surface *E*, and the locating piece must enter the hole *F*, which is less than 7-16 inch square. The locating piece must also be withdrawn a sufficient amount after the work is properly located and clamped, in order to clear the cutter. The edge *P* of the locating piece *R*, which is pivoted to the slide *L*, rests against the surface *E* of the work. The slide *L* is dove-tailed on the bottom to fit the base of the fixture. One end of the lever *O* is pivoted to the slide at *X*, and the other end to the center *Y* of the arm *S*. This arm *S* is pivoted at one end *Z* to the base of the fixture, and has a small knob in the other end to serve as a handle.



Milling Fixture of Ingenious Design.

The plate *d* is placed over the slide to keep out the dirt and also carries the stud *e* to limit the movement of the arm *S*. A small coil spring *K* keeps the end *M* of the locating piece *R* in contact with the lever *O*.

To operate the locating mechanism which is illustrated in the position in which it is just at the time the work is clamped, the arm *S* is turned 90 degrees to the left in the direction of the arrow. This moves the end of the lever *O*, pivoted at *Y*, to the left, and the opposite end *N* of this lever to the right. By the action of the coil spring *K* on the locating piece *R*, the end *M* follows *N* to the right, and the opposite end *P* moves to the left away from surface *E* into the square opening of hole *F* of the work. The action of the arm in moving through an arc of 90 degrees also pulls back the slide, since the lever *O* is pivoted to it. When the arm *S* moves through the first few degrees, the slide has no appreciable backward movement, while the lever *O* has a comparatively large movement at the end *N* to the right. This difference, caused by the location of the pivot points of the moving parts, is such that the end *P* of the locating piece is first moved to the left, away from the surface *E*, into the square opening of hole *F* of the work, before the slide starts back. The latter part of the movement of arm *S* pulls back the slide enough so that part *R* will clear the cutters.

In locating the piece, the opposite action, of course, takes place; the first part of the movement of the arm causes the slide to advance, and the last few degrees movement causes it to remain practically stationary, while the end *P* of the locating piece *R* is moved to the right. With the locating mechanism withdrawn and the clamp *G* loosened, the operation is as follows: The work is laid on the plate *I* and up against the jaw *T* and held there with the left hand, while with the right, the arm *S* is swung through an arc of 90 degrees to the position in the engraving. The work is then moved until the surface *E* comes in contact with the locating piece, and the operator, with his right hand, throws the eccentric lever *J* downward in the direction of the arrow, which causes the clamp *G* to grip the work tightly, thus holding it down, and holding side *C* square with the cutter. The arm *S* is swung in the direction of the arrow, pulling the locating mechanism out and away from the work. The table is fed towards the cutters in the usual manner.

In operation, this jig proved to permit very rapid manipulation, and the quality of the work was all that could be desired

Orono.

TRUCKS FOR MOVING MACHINERY.

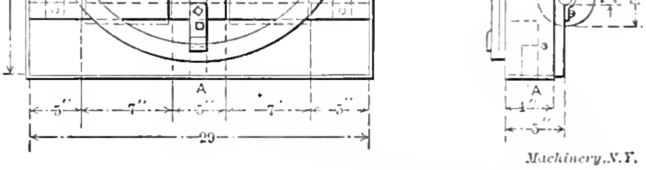
The engraving, Fig. 1, illustrates one of the most convenient trucks, or "dollys," as the shop men call them, for moving all kinds of shop machinery, that I have seen. There are few machines, such as are usually found in the average machine shop or factory, that cannot be mounted on these trucks and easily moved wherever desired, without resorting to the old method of rollers and a crowbar or two—the rollers in most cases being short lengths of shafting, or even steam pipe. Even when rollers are used, the machine usually has to be mounted on skids.

With these trucks, the machine is jacked up, the trucks run under and bolted fast to the legs. The jacks or blocking is then removed, and two or three men push the outfit wherever wanted, guiding the trucks by means of short iron bars placed in the holes shown at *A* in the line engraving Fig. 2. The body of the truck is made of five pieces of oak, 29 inches long and 5 inches square, securely mortised and bolted together, and bound on the outside by a band of iron 3/16 inch thick and 4 inches wide.

The four rollers, placed as shown, are made of cast iron, and are 6¾ inches long, 5 inches in diameter, and revolve on a piece of 1¼-inch shafting firmly strapped to the frame. This arrangement of four rollers makes turning the trucks much easier than would be the case with two long rollers. It also admits of a much more rigid frame.

On top of the framework is mounted an arrangement similar to the "fifth wheel" of a wagon. Firmly fastened to the upper half of the wheel is a piece of heavy channel iron about 4 inches wide, with a channel 2 inches deep. On top of this, two pieces of iron, ½ inch thick, 5 inches wide, and 10 inches long, with slots in them 6 inches long, are riveted. Blocks of hardwood, with slots to correspond to those in the plates, are fitted into the channel. The rivets, running through these blocks, prevent the bending of the plates where the slots weaken them, and also make a much more solid job with little additional weight. The slots in the plates allow the bolts, which are inserted from below, to be adjusted to accommodate different widths of legs. The wood blocks are slotted all the way out on the inner ends so that the bolts may be taken entirely out, if necessary.

Ethan Viall.



Figs. 1 and 2 Truck for Moving Machinery.

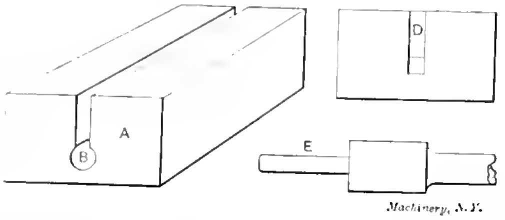
SHOP KINKS.

A DEPARTMENT OF PRACTICAL IDEAS FOR THE SHOP.

Contributions of kinks, devices and methods of doing work are solicited for this column. Write on one side of the paper only and send sketches when necessary.

A DRILLING KINK.

We had a number of pieces similar to *A* in the engraving below to machine with a slot having a round bottom or hole *B* through the entire length. No milling machine was available for the job at the time. The slot had to be somewhere near central with the hole, and this is the way we did the job. The block was first planed square all over, then a slot was planed out to the proper depth. Piece *D* was set in the slot as shown to form a square hole and act as a guide for the long pilot *E* of the counter-bore. The four sides of the square hole, one of which was formed by the inserted piece *D*, guided the counter-bore central with the slot and at the right distance from the bottom of block. In this way we did a very satisfactory job.

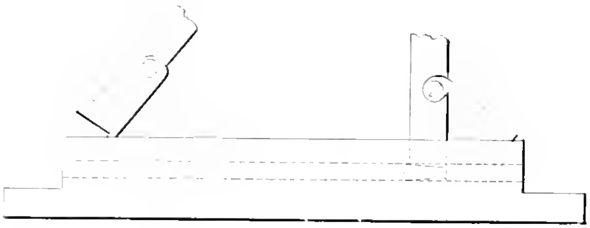


Machinery, N.Y.

E. S. WHEELER.

LATCH FOR LIFTING PLANER TOOLS.

Every machinist knows that when planing T-slots the tool has to be blocked or else lifted on the return stroke. The former process is hard on the cutting edge, and if the clapper be a heavy one, the latter is tedious for the planer hand, with the ever-present risk of a momentary lack of vigilance on his part and the resultant ruined tool or work. To obviate both blocking and lifting the tool, I made some latches, as shown in the engraving, and applied them to the slotting tools. They need no explanation, and can be used wherever the work permits the tool to swing clear at each end. For a case where the slight rubbing of the latch on the return stroke is undesirable, a pad of fiber is put on with two number 0 screws.



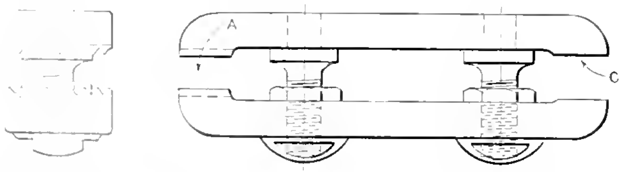
Machinery, N.Y.

DONALD A. HAMPSON.

Middletown, N. Y.

A HANDY SCREW THREAD GAGE.

When cutting threads on screws and bolts, whether by threading dies or in a lathe, much time is wasted by gaging the threads with either a nut or a ring thread gage of the ordinary type. In the case of a piece held between lathe centers, in order to gage the thread with the ring gage, it is necessary to remove the piece from between the centers. The Dresdner Bohrmaschinenfabrik A.-G., Dresden, Germany, is making a gage for measuring the threads of screws, which serves the same purpose as a ring gage, but saves the user considerable time. This gage is shown above. The end marked *A* fits over the threads, and the end marked *C* is supposed not to pass over the threaded screw, when threaded to the right size. Thus, not only can the size of the threads be tried, but at the same time the gage acts as a limit gage.

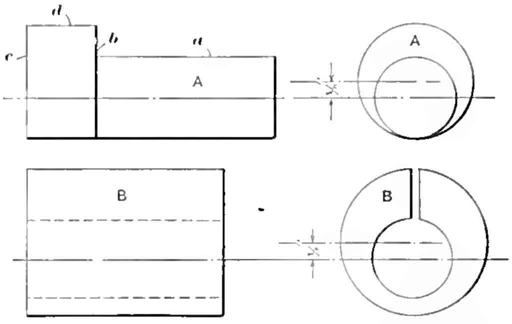


Machinery, N.Y.

OSKAR KYLIN.

TURNING AN ECCENTRIC.

The job shown at *A* below, is one which I have to do quite often, and the following is the best way I have found of doing it. First I made a split collar *B*, the outside diameter of which was turned to fit a collet chuck. In making the eccentric, a piece of steel ⅛ inch larger than the finished size is used. This is chucked in a three-jawed chuck with about ⅛ inch throw, and the end *a* turned to finished size. The side *b* is then faced, and the piece is cut off, allowing enough to finish the face *c*. The piece *A* is then inserted into the hole in the collar *B*, which is held in the collet chuck, and the surfaces *d* and *c* finished.



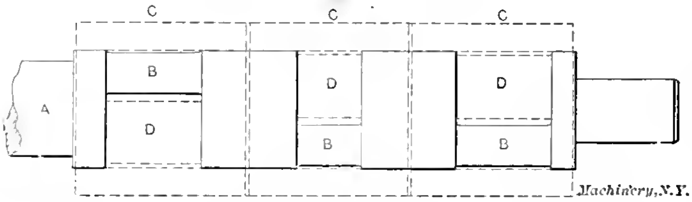
Machinery, N.Y.

ORIGINAL.

ONE WAY OF DOING A DIFFICULT JOB.

A rush order came to our department for a dozen shafts such as shown in the illustration. The immediate hurry, combined with the doubt that the order would ever be duplicated, made it imperative that some method should be devised to make them right away, regardless of whether or not a little more time and thought would enable us to do the work in a way more satisfactory in the long run. The additional tools we had to make cost so little and worked so well, that I think a description of how we finished the shafts will prove of interest to the readers of MACHINERY.

The shafts *A*, which were 8¼ inches over all, were first laid out with care, with two of the crank-pins *B* directly opposite the third one. The larger part of the shaft was finished to 15/16-inch diameter, and the crank-pins *B* turned to 5/16-inch diameter. The latter were first roughed out as much as they would stand without supports, and then the shafts were all finished to size. Here is where our special tools came in. These consisted of four tool-steel bushings nicely reamed to fit the shafts, and, in addition, three plugs of ½-inch round stock, two of which were ¾ inch, and one, ½ inch long. The three smaller bushings *C* were heated to a dull red and dipped in oil to prevent them from stretching when in use. The crank-pin on the left was first turned to size, then a plug *D* was squeezed in, and a collar, which was a nice snug fit, forced on. The relation the collar and plug have as a support for the shaft while the next crank-pin is being turned can now be readily seen. In this manner the three pins were finished, each time a collar and stud being added. When they were all turned, one large collar took the place of the three smaller ones, the plugs *D* still remaining. Then the part *A*, and the two ends, were turned. The shafts, when examined, were found to be true, besides being finished in good time considering the nature of the turning.



Machinery, N.Y.

PEDRO.

SHOP RECEIPTS AND FORMULAS.

A DEPARTMENT FOR USEFUL MIXTURES.

This page is intended to be used only for the publication of such shop receipts as the contributors know from experience to be practicable. Receipts are solicited on the condition that the contributors personally know that they are reliable. The fact that a receipt is old and supposedly well-known does not bar it, provided it has not already appeared here.

411. SOLDERING KINK.

When soldering, and no acid is handy, a common tallow candle will answer the purpose. JOHN B. SPERRY.

Aurora, Ill.

412. CHALK PREPARATION FOR TRACINGS.

Mix thoroughly one pound of pulverized chalk with one-quarter pound of borax. Rub some of this mixture into a chamois skin, and rub the tracing carefully with this. This preparation is superior to pure chalk. REX MCKEE.

Joliet, Ill.

413. MARKING FLUID FOR BLUE-PRINTS.

The following receipt for marking fluid for blue-prints has given me satisfaction. The fluid is composed of potassium oxalate, 1 ounce; gum arabic, 1 dram (60 grains); water, 6 ounces; cobalt-blue to color.

Staten Island, N. Y. WILLIAM H. DAVID.

414. CEMENT FOR ARC LAMP CARBONS.

The short ends of old arc lamp carbons may be cemented together to form rods which burn quite well, and are no more brittle than ordinary carbons. The cement required is made by mixing potassium silicate and carbon dust to a consistency of a thick paste. The ends of the short carbon pieces are faced off square, and, after application of the paste, are pressed together by hand. O. G.

415. USEFUL SALVE.

While a great many shops now have facilities for attending to shop accidents, the necessity is often felt by the mechanic working in a small shop, or outside, for a useful salve to be applied to wounds in case of accident. The writer has made the following salve himself, has used it, and knows that it is far in advance of most articles for sale in drug stores at ten times the price. The ingredients are as follows: Two parts of swallow oil, five parts of petrol wax, two parts eucalyptus, and two parts of beeswax. ARDEN.

416. TO REMOVE RUST FROM SMALL STEEL PARTS.

Rust may be removed from small steel parts such as screws, nuts, pins, etc., when they are not badly pitted, by dipping them into a dilute solution of sulphuric acid. To prepare the acid bath, pour the acid little by little into a bowl partly filled with water. After each addition of acid, try one of the rusted parts, and continue trying until the proper strength is obtained to eat the rust off clean. Better results will be obtained in this manner than by working to a set formula. Let the parts remain in the acid bath until cleaned of rust, then remove and wash in soda water, and then in benzine. Finally dry the parts and brighten in sawdust.

S. W. GREEN.

417. PREVENTING SERIOUS RESULTS FROM INJURIES FROM RUSTED OBJECTS.

Everyone knows how a small wound caused by rusty pieces of metal oftentimes develops blood poison, or lockjaw. The following old-fashioned but infallible "first aid to the injured" may therefore be of value to remember. Ordinary brown sugar is heated on the surface sufficiently hot to produce a smoke, and the wound is held in this smoke for several minutes. No serious results will follow after this treatment, and all soreness will be taken out of the wound even though the application takes place some time after the accident. The smoke given off by burning woolen rags is equally effective, and, as they are more often available, particularly to a man "off on a job," to keep this simple remedy in mind may be well worth while. DONALD A. HAMPSON.

Middletown, N. Y.

418. WHITE LEAD AND TALLOW OF EVEN CONSISTENCY AT ALL TEMPERATURES.

In order to keep white lead and tallow soft in winter and summer alike, so that it can be applied with a brush to finished parts of machinery before shipping them, and for use in fitting keys, etc., prepare a mixture composed of five pounds of white lead and fifteen pounds of tallow. Heat this in a suitable receptacle, and stir until the ingredients are thoroughly mixed. Then remove the mixture to a cool place, and add two quarts of linseed oil, continuing to stir the composition until it becomes cold, as otherwise the white lead will settle to the bottom. This mixture will always remain of the same consistency at all temperatures. R. S. F.

419. ZINC PAINT FOR OIL WELLS.

Persons having occasion to paint oil wells of bearings, or any surface coming in contact with either hot or cold oil, will find a zinc paint consisting of 25 pounds oxide of zinc, 3 gallons gloss oil, and 1 quart linseed oil, cut with turpentine, and bleached with ultramarine blue, to be one of the best coverings ever made. The surface to be covered should be absolutely free of all greasy or oily substances; if proper care is taken, the paint will not crack and will retain its pure white appearance indefinitely. The paint can be blown into water jackets of bearings, filling the sand holes, and as it dries rapidly, will be found excellent for the purpose.

ELECTRO.

420. BROWN-PRINTS.

The following solution will change the color of blue-print paper to a dark brown: Borax, 2½ ounces; hot water, 38 ounces. When cool, add sulphuric acid in small quantities until blue litmus paper turns slightly red, then add a few drops of ammonia until the alkaline reaction appears, and red litmus paper turns blue. Then add to the solution 154 grains of red crude gum catechu. Allow this to dissolve, with occasional stirring. The solution will keep indefinitely. After the print has been washed in the usual way, immerse it in the above bath for a period of a minute or so longer than necessary to obtain the desired tone. An olive brown or a dark brown is the result. JOHN B. SPERRY.

Aurora, Ill.

421. BLACK FINISH FOR STEEL.

The pieces to be blackened should first be polished with No. 120 emery cloth. After polishing, the surfaces should be cleaned carefully, and then the work placed over the fire and drawn evenly to a second blue. Then, the work is dipped in lard or sperm oil, from which it is immediately removed, and all loose oil shaken off. This prevents the forming of blisters. An old piece of rubber, for instance a piece of old garden hose, is then placed on the fire, and as it burns, the work is held over the flame and smoke that comes from the rubber, until it is covered with a thick coat of black soot. The work is then removed from the fire, and permitted to cool off slowly. When cool, it is rubbed with an oiled cloth. All this must be done in one heat. E. W. NORTON.

Tarrytown, N. Y.

422. TO SAVE BURNED OR OVER-EXPOSED BLUE-PRINTS.

Blue-prints that have become burned or over-exposed, may be saved by the use of the following formula: Make a saturated solution of bichromate of potash, and keep a supply on hand in the blue-print room. If a print becomes over-exposed, wash it in the usual manner in a tank or tray of water, after which place it in another tray which should contain a mixture of two parts water to one part of the saturated solution of bichromate of potash. Allow the print to remain in the tray containing the solution until it shows a deep blue color and the white lines are clearly defined (which requires but a few seconds), after which the print should be thoroughly washed and rinsed in clear water. The proportion of the bichromate of potash may be increased or diminished as the occasion requires. This solution also acts equally as well when applied to white-prints made from vandyke negatives. Prints, as well as expense, and time, may be saved by the use of the above solution. J. C. HASSETT

Meadville, Pa.

HOW AND WHY.

A DEPARTMENT INTENDED TO CONTAIN CORRECT ANSWERS TO PRACTICAL QUESTIONS OF GENERAL INTEREST.

Give all details and name and address The latter are for our own convenience and will not be published

TESTS ON CAST IRON CYLINDERS.

J. A. J.—In testing cast iron cylinders used for dryer rolls on paper machines 18 inches diameter, 120 inches long with the heads secured by cap-screws, which is the most severe test, 100 pounds per square inch steam pressure or 100 pounds cold water pressure? 2. Is there any difference in the sizes of the molecules of steam and water?

A.—1. Theoretically the stresses imposed by 100 pounds steam pressure and 100 pounds water pressure are the same, but for the purpose of a test to determine the tightness of the joints, water pressure is to be preferred. Small leaks are easily discernible with water that would escape detection with steam. Moreover, small steam leaks soon "take up," in the parlance of steam fitters, whereas small water leaks close very slowly, the sealing depending on the rusting of the metal. Compressed air is more searching than either water or steam; it will escape through a very minute aperture, and the leaks have no tendency to seal themselves. Water pressure obtained with a pump is more severe on the structure of cast iron than steam pressure because of the water hammer due to the pump action. 2. The chemical combination H_2O exists in three forms, *i. e.*, ice, water, and steam, and it is supposed that the size of the molecule is unchanged in all three states.

MILLING SPIRALS—INVOLUTE SYSTEM OF GEARING.

J. G. I.—1. What is the method of figuring the angle to which to set a universal milling machine table for cutting a given spiral? 2. Is not the involute system for standard cut gears exclusively used?

A.—1. To calculate the angle of the spiral to be milled on a cylinder, the lead of the spiral and diameter must be known. Then the formula is:

$$\text{Tangent } a = \frac{D \times \pi}{\text{lead}}$$

in which a = angle of the tooth with the axis of the gear,

$\pi = 3.1416$,

D = diameter of piece.

For example: What is the angle of a spiral with its axis that makes one turn in 27.22 inches, the diameter being 3½ inches?

$$\text{Tangent } a = \frac{3\frac{1}{2} \times 3.1416}{27.22} = 0.40403,$$

the tangent of 22 degrees.

2. The involute tooth is the form most used in the United States for cut gearing, but it is by no means exclusive. Cast gearing is generally made with cycloidal teeth, and some users of cut bevel gears prefer the cycloidal to the involute system.

TO DRILL SMALL DEEP HOLES—SAND-BLAST FINISH ON TOOLS.

V. A. W.—1. How are oil holes drilled in the so-called oil twist drills used for deep hole drilling? The holes in the samples before me are only about 5/32 inch in diameter and about 8 inches deep. They follow the twist of the flute. 2. How is the beautiful gray color produced on drills and milling cutters that is characteristic of the product of some small tool manufacturers?

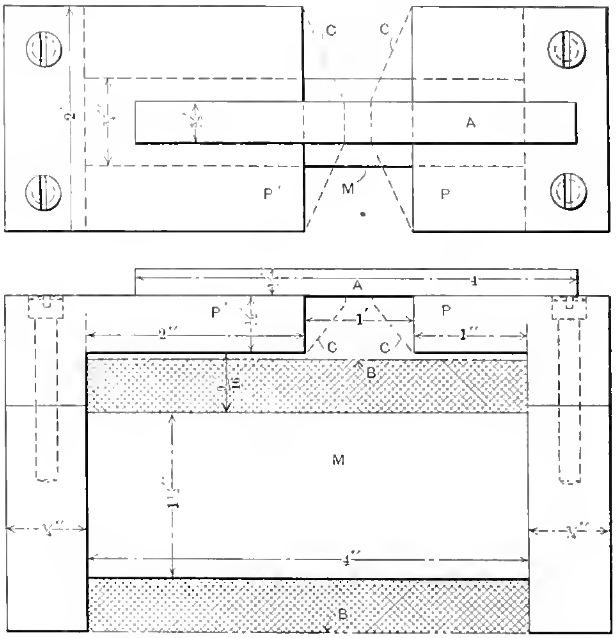
A.—1. The holes are drilled before the drill is twisted, the blanks being rough-fluted, the drill twisted, and then finished in the usual manner. The drilling of the oil holes is done progressively by small twist drills, arranged in order of length, each drill deepening the hole made by its predecessor only ½ or ¾ inch. The hole is begun with a short, stiff drill which starts the hole perfectly straight and true, and the following drills are guided by the section of the hole first drilled. This practice avoids the use of a long slender drill to drill the first part of the hole, and enables the drilling to be done much faster than would be possible otherwise. For a description of this practice in drilling small deep holes in pneumatic hammer handles, see MACHINERY, December, 1902, page 231, engineering edition. 2. The beautiful gray color noted on twist drills, milling cutters, etc., is doubtless produced by the sand-blast process used by some makers to remove the burned oil and oxide resulting from the hardening process. It is merely incidental to this method of cleaning, but because of the beautiful, frosted surface it has a merit of its own. We believe that the same result is also obtained by electrolysis, the tools being suspended in an electric bath. The passage of the electric current removes the oxide and leaves the surface in much the same condition as that produced by the sand-blast process.

CONSTRUCTION OF A MAGNETIC CHUCK.

C. M. W.—Please give me instructions for making a magnetic chuck to hold pieces of ⅜ × ¼ × 4-inch hardened steel for grinding, etc. I wish to use the chuck on an incandescent lighting circuit, and desire to know the size of wire and the quantity required for winding the magnet.

Answered by William Baxter, Jr., Jersey City, N. J

It would not be possible to give all the information you desire without writing an answer that would fill a book. We can say, however, that if the magnet *M* is made of cast-iron or wrought-iron and wound with wire up to the lines *B*, it will hold the steel piece *A* if a direct current is passed through the wire. The force with which *A* would be held against the poles *PP'* would depend upon the kind of metal, the number of ampere turns of magnetizing current flowing around *M*, the distance between the ends of *P* and *P'*, their shape, and the general conformation of the whole structure. The ampere turns are obtained by multiplying the number of turns of wire in the magnetizing coil, by the current strength in amperes. The force with which the poles *P P'* will hold the bar *A* is determined by the aid of the simple formula:



Machinery,N. Y.

$$F = \frac{AB^2}{72{,}000{,}000},$$

in which *F* is the tractive force in pounds, *A* is the area of contact between bar *A* and the poles *PP'* in square inches, and *B* is the magnetic density in lines of force per square inch passing through the surface of contact. To find the force with which *A* is held, all that is necessary is to know the magnetic density *B*. The way in which this is found we cannot give briefly, but you can find it in any good book on electrical engineering. If *M* is made of wrought iron, the pull will be about three times as great as with cast iron, other things remaining equal. If the ends of *PP'* are shaped as indicated by the dotted lines *C*, the pull will be further increased. You could wind the coil with No. 20 B. & S. gage magnet wire, and connect it in series with four or five 16-candle lamps; that is, connect so that the current passes through the lamps and then through the coil. If the wire does not get dangerously hot, and the magnet is not strong enough, connect more lamps in the group, putting the second lot of lamps in parallel with the others.

NEW MACHINERY AND TOOLS.

A MONTHLY RECORD OF APPLIANCES FOR THE MACHINE SHOP.

A LINE OF ATTACHMENTS FOR THE LEBLOND MILLING MACHINES.

The R. K. LeBlond Machine Tool Co., 4609 Eastern Avenue, Cincinnati, Ohio, builds a line of milling machines which is well known to the readers of MACHINERY. To extend the usefulness of these milling machines over as wide a range of work as possible, the builders have designed a very complete and ingenious line of attachments. We show herewith half-tones and line drawings of these various attachments, together with numerous illustrations showing their application to general shop work.

Worm and Spur Gear Hobbing Attachment.

The device shown in Figs. 1, 2 and 3 is designed particularly for the hobbing of worm-gears, but, as will be explained later, can be used for spur gears as well.

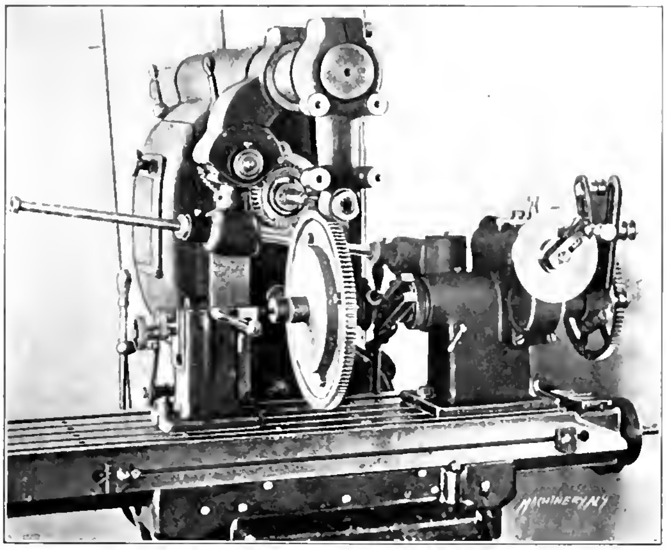


Fig. 1. Hobbing Attachment for the LeBlond Milling Machine Cutting a Larga Worm-wheel.

The head- and foot-stocks of this arrangement are those of the builder's standard plain dividing head, the attachment itself consisting of means for connecting (through the index worm or directly as required) the spindle of this dividing head by change gears with the spindle of the machine, in such a way as to give the required ratio of rotation between the hob and the wheel. This connection is made through a flexible transmission system consisting of bevel gear joints and a splined shaft, which permits absolute freedom of adjustment between the index head and the spindle. On the threaded nose of the latter is screwed a spur gear, meshing with a corresponding gear on a short spindle, supported by a bracket clamped to the over-hanging arm of the machine. This short spindle carries a bevel gear meshing with a mate keyed to a short vertical shaft from which the splined shaft is driven, through another pair of bevels. The connections from these through to the back side of the head can be readily followed by comparing Figs 1 and 2, where the machine is shown in two different adjustments, to each of which, as will be seen, the arrangement readily adapts itself.

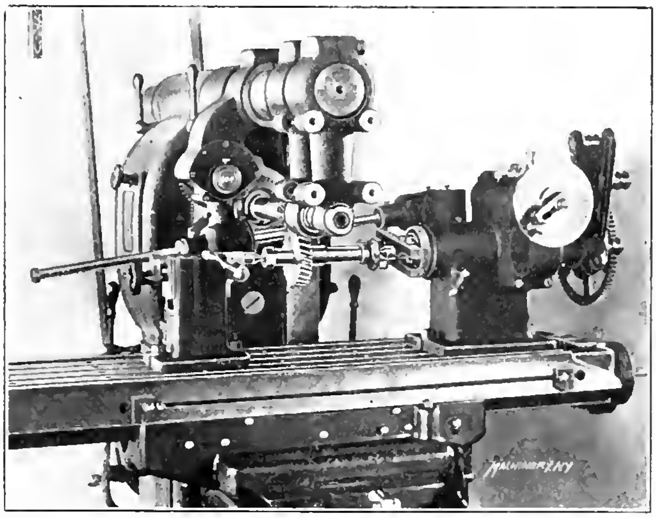

Fig. 2. Cutting a Small Worm-wheel with the Change Gearing Directly Connected to the Work Spindle.

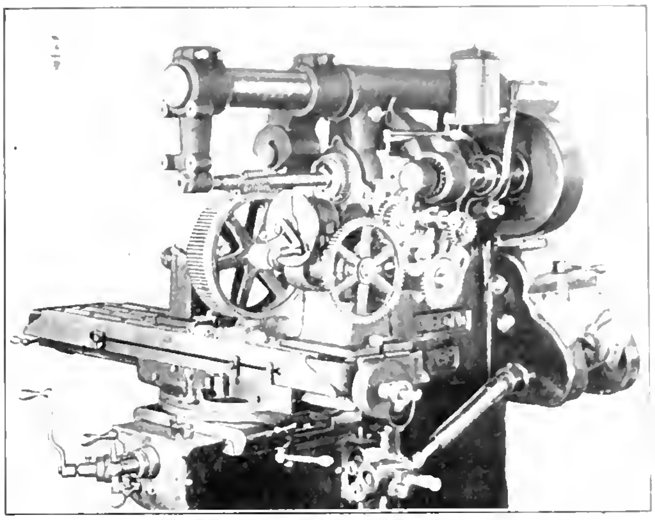

Fig. 3. Hobbing a Spur Gear with the Hobbing Attachment on a Universal Milling Machine.

The quadrant carrying the change gears for obtaining the desired ratio between the cutter and work spindles is best seen in Fig 3. The driving connections are so arranged that the driving shaft from the change gears can be connected either directly to the spindle for cutting wheels of few teeth, or through the indexing worm and worm-wheel for large numbers of teeth. In Fig. 1 the attachment is set up for hobbing a worm-wheel having many teeth, so the connection is made through the index worm of the dividing head. In Fig. 2, on the contrary, a worm-wheel of few teeth and for a multiple threaded worm is being hobbed, so the ratio of rotation is too high to be conveniently transmitted to the worm gearing. Under ,these conditions the change gearing is attached directly to the work spindle.

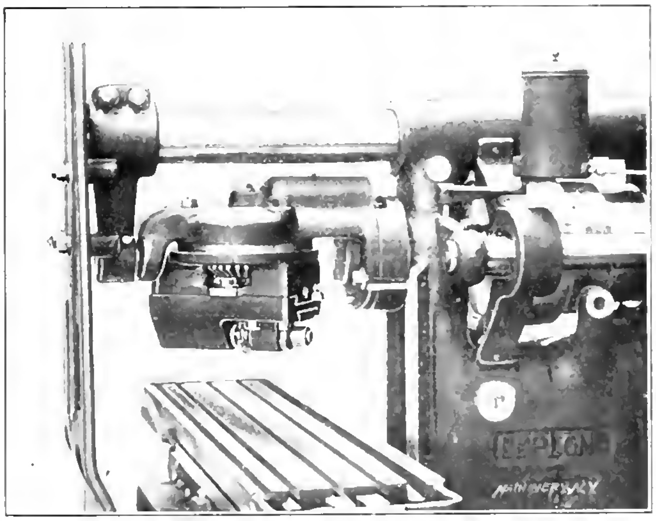

Fig. 4. Universal Spiral Gear Cutting Attachment.

The advantages of the positive method of hobbing worm-wheels are well known. The positive connection between the wheel and the hob makes unnecessary the preliminary gashing of the former, and so materially reduces the time and cost of doing the work. In some cases it may be done in from one-fourth to one-fifth of the time required for the method which combines gashing and hobbing on a freely running work spindle. A very fine feed is provided, and the work can

be fed into the hob automatically and tripped when the teeth have been cut to the proper depth.

The worm-wheel shown in Fig. 1 has 120 teeth, 0.390 inch circular pitch, and is a trifle over 15 inches in diameter. The coarse pitch worm-wheel in Fig. 2 has 26 teeth, 6 pitch, quadruple thread, and is 2 5/8 inches diameter. This gives a ratio of 6½ to 1, requiring the change gearing to be connected direct to the spindle, as explained. The gears are hobbed complete in 12 minutes apiece, with power feed.

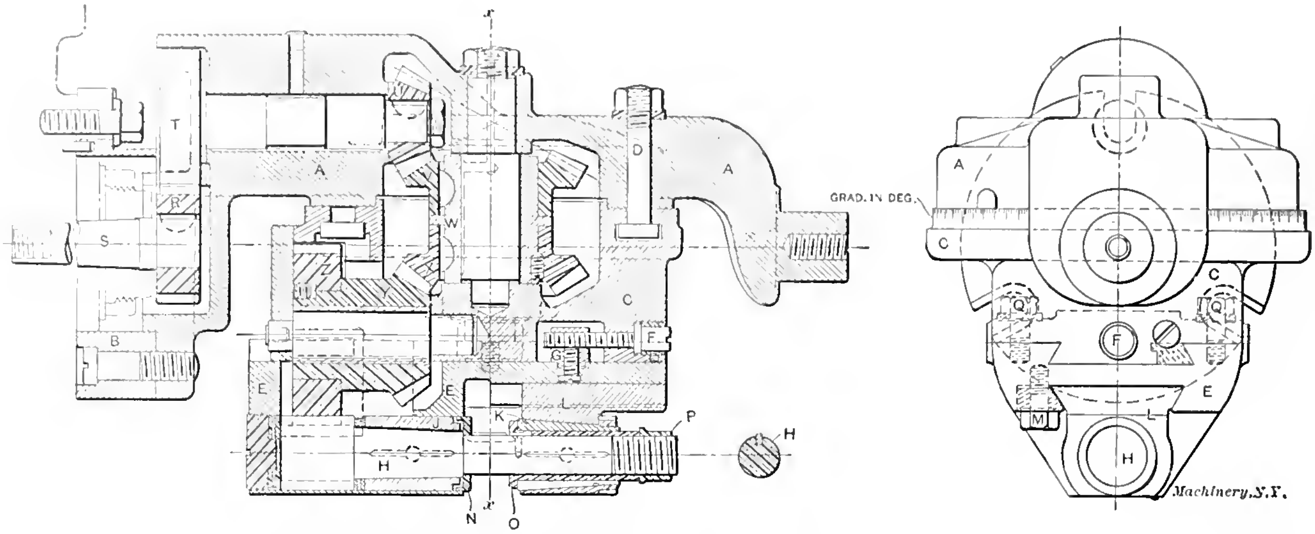

Fig 5. Details of Construction of the Spiral Gear Cutting Attachment.

Perhaps the most interesting use of this attachment is for the cutting of spur gears by the hobbing process. This process has been previously described in MACHINERY,* and the principle of its operation fully explained. It requires simply that a suitably shaped hob be rotated in the proper ratio with a spur gear blank, and fed through it at a suitable speed, the hob being set to cut teeth to the correct depth. The hob must also be set at the helix angle of its thread, as measured on the pitch line, if it is to give the proper shape to the teeth of the gear. It will be seen that this attachment, as described and shown in Figs. 1 and 2, furnishes the required movements and adjustments, except for the setting of the hob at the helix angle. To accomplish this, it is only necessary to use the device on a universal machine, as shown in Fig. 3, bringing the table around so that the work and the hob are in the proper angular relation to each other. Under these circumstances, with the hob set at the proper depth and the proper change gears mounted in place, the hob may be started at one edge and fed through, finishing the work complete at one passage. This method of cutting spur gears has the well-known advantages of cutting all numbers of teeth for a given pitch with a single hob, and of giving a large output, owing to the fact that the cutting action is continuous, and does not require the return of the cutter and the indexing of the blank, as is required by the usual method of performing this work on the milling machine or automatic gear-cutter.

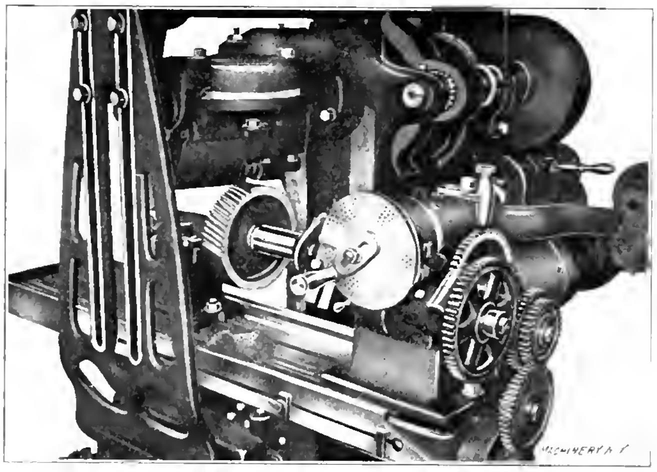

Fig 6. Cutting a Spiral Gear of Large Diameter and Large Lead.

A set of compound gears is furnished for reducing the feed in the ratio of about 20 to 1. The reason for requiring this very fine feed is that the advance of the cutter per revolution should be in proportion to the number of teeth of the gear. For instance, in cutting a spur gear with 60 teeth, if we wish to feed the work past the cutter at 0.060 inch per revolution of the work, it will be necessary to set the feed to equal 1/60 of this amount or 0.001 inch, per revolution of the cutter.

The spur gear being hobbed in Fig. 3 is 8 pitch 102 teeth. The capacity of the device is for work up to 16 inches in diameter, the spur gears and worm-gears alike.

Universal Spiral Gear Cutting Attachment.

There are two noticeable points of difference between the universal spiral gear cutting attachment shown in Fig. 4, and most other attachments which have been built for the same purpose. One of these differences is the fact that in this case the cutter is mounted so that it can be centered on the vertical axis about which the angular adjustment is effected. This being the case, the work may be centered with the cutter, which is then swiveled to any angle desired throughout the whole 360 degrees, without requiring recentering. The other feature of the construction, plainly evident in Fig. 4, is the manner in which the supporting head of the device has been off-set vertically, so as to raise the cutter nearer the center line of the spindle, and thus increase the maximum vertical distance obtainable between the top of the table and the bottom of the cutter. If it were not for this offset and for the change in the method of driving required by it, the capacity of the machine under the cutter for work mounted on the table or on centers, would be materially reduced.

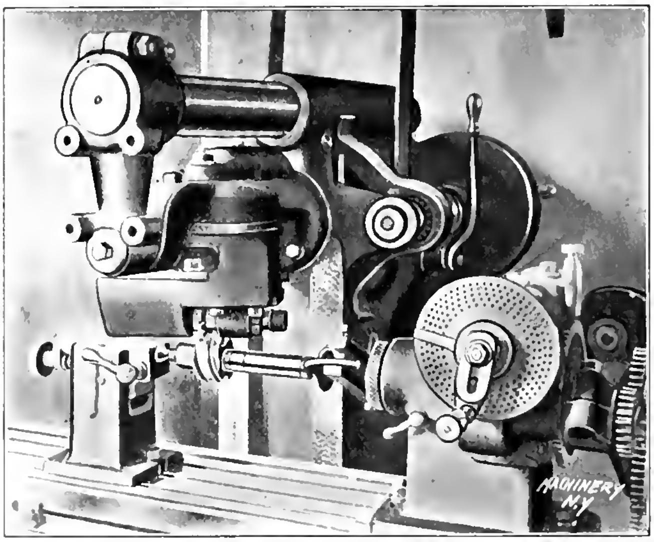

Fig. 7. Cutting a Spiral of Short Lead on the Plain Milling Machine, an Operation Impossible on the Universal Machine without Special Attachments.

---

* See [illegible] Cutting Machinery, March, 1908, issue of MACHINERY.

The mechanism of this device is best understood by reference to Fig. 5. The body *A* of the device is clamped, through collar *B*, to the front of the column at the end, and is provided at the other, or outer end, with a bearing entering the hole in the outer support for the arbor (see Fig. 4). The attachment thus does not have to depend entirely on its own rigidity in supporting the cutter, but has the additional stiffness of the over-hanging arm to depend on. To *A* is clamped the swivel base *C*, by means of bolts *D* entering a circular T-slot in its outer face. This arrangement provides for the adjustment of *C* to any angle throughout a full circle about the vertical axis *xx*. It is centered on its seat in *A* by means of the internal shoulder shown. The exterior surface, as seen at the right, is graduated in degrees to indicate the setting obtained. Dovetailed to *C* on horizontal guides is the spindle head *E*. The adjustment along the slide is effected by shoulder screw *F*, seated in *C*, and nut *G*, clamped to *E*. This adjustment provides for the centering of the cutter on *xx*, the axis of angular adjustment.

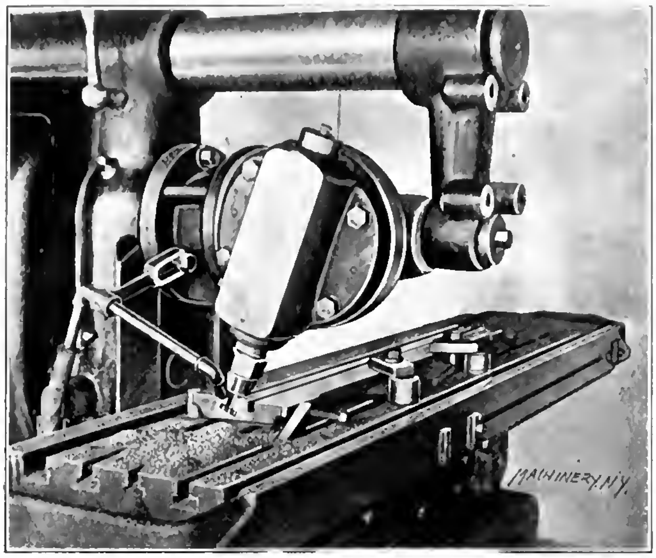

Fig. 8. The Universal Milling Attachment cutting an Inclined Slot.

The main bearing of the spindle *H* is tapered ⅝ inch to the foot, and runs in a bronze bearing *J*, fast in head *E*. An outboard bearing *K* is also provided. This is tapered and is drawn by the nut shown into a taper seat in the removable bearing support *L*. This bearing, which is thus adjustable for wear, is removed bodily with *L* when changing cutters. For this purpose *L* is mounted in a dove-tail slide on the under side of spindle head *E*, being clamped there by bolt *M*. The cutter is clamped between collar *N* and the flange on sleeve *O*, which latter is pressed against the cutter by nut *P* at the outer end of the spindle. For locking the horizontal adjustment of *E*, used for centering the cutter, bolts *Q* and *Q* are provided.

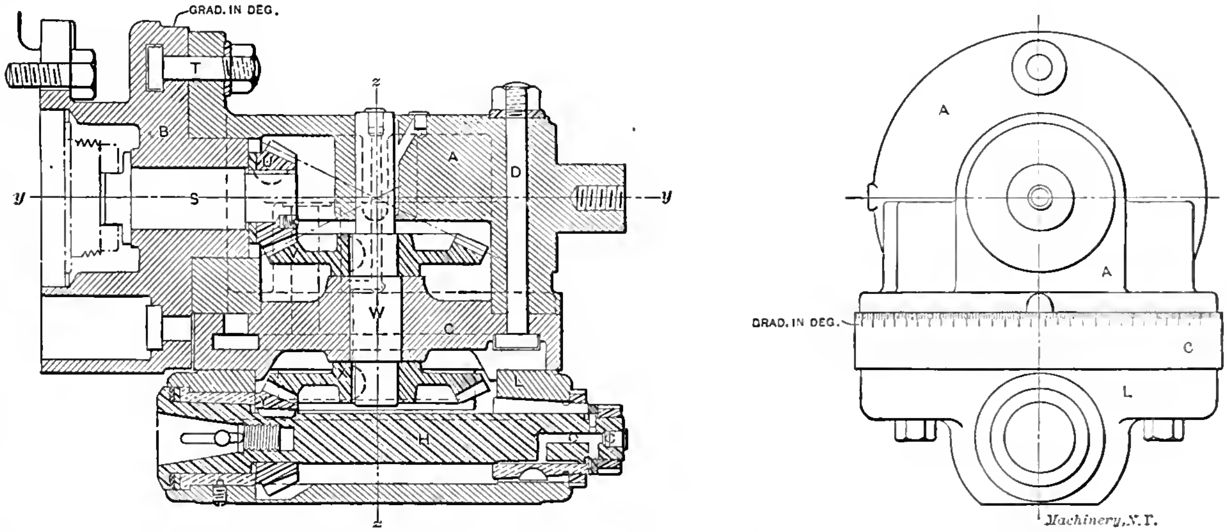

Fig. 9. Details of Construction of the Universal Milling Attachment.

The drive is taken from the main spindle of the machine through a pinion *R*, keyed to a taper shank *S*, driven into the spindle hole. This meshes with a gear *T*, which has a shaft integral with it journaled in casting *A*, and carrying keyed to it at its outer extremity bevel pinion *U*. This pinion meshes with bevel gear *V*, keyed to bronze sleeve *W*, to which is also keyed another bevel gear *X*. This sleeve revolves on the stud about whose axis the angular adjustment of *C* on *A* takes place. Bevel gear *X* mates with bevel gear *Y*, which is bronze bushed and revolves on a stationary stud. On the shank of *Y* is doweled gear *Z*, which engages pinion teeth cut at the left-hand end of spindle *H*. The teeth of *H* are made of sufficient length to provide for the longitudinal adjustment of the head *E* when centering the cutter. It will be seen from the end view that the bottom of the spindle head is flattened off as close as possible to the outside diameter of the driving pinion, so that the cutter may project beyond all parts of the attachment far enough to do such work as rack cutting, if required.

Two examples of the use of this attachment are shown in Figs. 6 and 7; in both of these cases a plain milling machine is used in combination with the same plain indexing head to which the hobbing device is shown attached in Figs. 1, 2 and 3. This combination of plain index head and spiral gear cutting attachment converts the plain milling machine into one of the universal type. In Fig. 6 a spiral gear of large diameter and small helix angle is being cut, so the head is set at but a slight angle from a position parallel with the spindle of the machine. As may be seen, the head is connected by change gears with the table feed screw, the same as for the universal arrangement. In Fig. 7 the attachment is shown performing work which the universal milling machine is incapable of doing except with special appliances. This work is the cutting of spiral gears of such large helix angle (or, in other words, of such short lead) that it would be impossible to swing the table through the required angle, thus necessitating the use of a right angle drive for the spindle, or the doing of the work with the vertical milling attachment. The possessor of the plain indexing device and this spiral gear attachment, therefore, is in some respects better equipped for

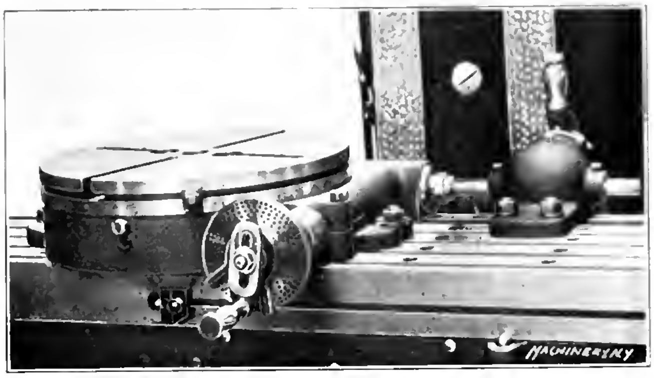

Fig. 10. Circular Milling Attachment with Automatic Feed and Throw-out.

spiral work than if he had a milling machine of the universal type. He is not, of course, able to do either indexing or spiral cutting on taper work, but otherwise he is provided for. This attachment may also be conveniently used for thread milling.

Universal Milling Attachment.

The universal milling attachment shown in operation in Fig. 8 and in detail in Fig. 9 is of something the same construction as the spiral gear cutting attachment, though it is built for a wider range of work, and so differs in the details of its construction. As may be seen in Fig. 8, the cutter is mounted in a taper hole at the end of the spindle, instead of centrally between two bearings, as in the previous attachment. No end movement is provided for the spindle, and there is no necessity for keeping the distance from the center line of the spindle to the face of the spindle bearings down to a minimum, as the work required of the device is mostly in the nature of end milling, or other operations in which this clearance is not vital. These considerations simplify the design of the device. An additional movement is provided, however: an adjustment at any angle throughout the whole circle, about the axis of the main spindle of the machine.

In Fig. 9, *A*, the main body of the device, is supported at the outer end by the over-hanging arm as in the previous case, while at the other end it is fastened to a flange *B*, which is in turn made fast to the face of the column. Bolts *T*, entering the circular T-slot in *B*, provide for clamping body *A* in any angular position about axis *yy* of the machine. Swivel plate *C* is clamped to *A* by bolts *D* entering the T-slot in the former, so that the spindle head L, which is fastened to *C*, may be adjusted at any desired angle about axis *zz*. Graduations in degrees are provided for both of the swivel movements with which the spindle is thus provided.

The device is driven by a short shaft *S*, having a tongue on its inner end entering the slot cut in the nose of the spindle. Bevel gear *U*, keyed to the outer end of *S*, engages bevel gear *V* keyed to shaft *W*, which latter is journaled in body *A* and swivel base *C* of the machine. The lower end of *W* has keyed to it bevel gear *X*, meshing with bevel gear *Y* on the spindle, which is thus revolved at the same rate of speed as the main spindle of the machine. It will be seen that the drive is simpler than in the case of Fig. 5, partly because the offset to give increased working range in the device is not required, and partly because the drive of the spindle is less restricted, so that a direct bevel gear drive may be used in place of the spur gearing of the previous attachment. The spindle *H*, shown in Fig. 9, is provided with a special taper for a collet with a threaded shank. It will also be furnished with a regular No. 7 Brown & Sharpe taper having a hole for a through bolt, to be used in drawing the taper shanks to their seats or ejecting them for removal.

In Fig. 8 the attachment is shown engaged in milling an angular T-slot, the work shown being the table of the cutter and reamer grinder built by the same firm. Other operations for which it is adapted are for such a variety of work as drilling, key-seating, and milling of spirals of too great an angle to be done with a cutter driven directly by the main spindle of the universal milling machine. Special conditions are readily met, the device often obviating the necessity for angular mills, since the spindle can be swiveled to any angle of the horizontal or vertical plane. It will be noted that the

front bearing is tapered 3/8 inch per foot, with a hardened and ground journal. The rear bearing is straight, and is adjusted by drawing in the split taper bushing.

Circular Milling Attachment.

Fig. 10 shows a circular milling attachment with automatic feed and throw-out, which is adapted to be used especially with a vertical attachment such as shown in Fig. 12, for the finishing of all kinds of cylindrical surfaces, on work which can be conveniently held on a circular table.

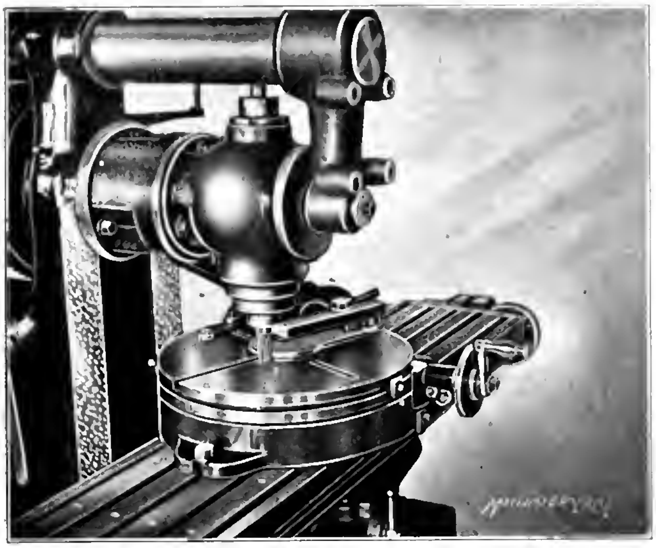

Fig. 12. Use of the Circular Milling Attachment in Finishing Straight and Circular Surfaces.

The details of this device are shown in Fig. 11. The circular base of the device, A, is clamped to the milling machine table. Table B rests on base A and is centered with it by a circular rib which closely fits a machined circular opening in the top of A. To a seat in this circular rib is clamped worm-wheel C, which, in combination with worm D, forms the means for revolving the table, and at the same time serves as a gib for drawing B down to its bearing on A. The center of B is provided with a tapered socket for convenience in holding arbors or studs for centering work, and other special uses. The extended hub provided for this taper hole is connected by ribs with the body of the table, so as to make the whole very rigid, and able to resist distortion due to the clamping of the work on its upper surface, without cramping the table on its guiding surface.

Worm D may be operated by a crank and index plate at the outer end, of the same kind as used on the builder's standard dividing head, thus permitting the dividing of work clamped to the table with the same facility. Graduations in degrees are also provided on the outside diameter of the table, so that angles may be conveniently laid out without the use of the index plate. For a quick movement of the table, the worm may be thrown out by an eccentric device, not shown in Fig. 10, but incorporated in the later design shown in the line engraving, Fig. 11. This consists of an eccentric sleeve E in which the worm and worm shaft are mounted. By rocking this by means of knob I, the worm may be thrown into or out of engagement at will. A stop screw G on the sector flange of the eccentric limits the inward movement to give the proper amount of play to the worm, and a clamp nut at the same point furnishes means for retaining it in either the in or out position. A set-screw H, at the front of the base, bears against a thin strip of the bearing of the table, which has been separated from the remainder of the base by the saw cut shown. This provides means for clamping the table in position while the cut is being taken, either for the rapid indexing with the worm thrown out, or for hand indexing through the worm and dividing plates.

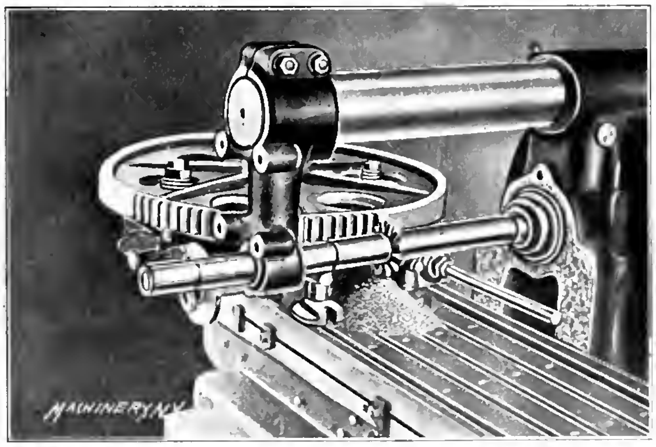

Fig. 13. Using the Circular Milling Attachment as an Indexing Device for Cutting a Large Gear.

The power feed for the device is obtained from the gear box without interfering with the regular transverse, cross, and vertical feeds, so that either of these may be used on the pieces without having to be disconnected for the circular feed. This makes it possible to finish very conveniently parts that have both plain and cylindrical surfaces to be milled. A telescopic feed rod is provided, leading from a shaft held in a bracket on the side of the column of the machine, and connected by chain and sprocket wheels with the shaft on the feed box. This telescopic shaft is connected with reversing gear box J, clamped on the milling machine table. The bevel gear and its shank K to which the telescopic shaft is pinned are seated in an eccentric bushing L, which may be rocked by means of lever N. Feed shaft O leading from the circular attachment, passes through reversing box J and is keyed to sleeve M, on which are formed a pair of bevel gears. The drawing shows lever N in its central or vertical position, in which bevel gear K is out of mesh with the gears on sleeve M. By throwing lever N to one side or the other, eccentric sleeve L is rocked and bevel gear K is thrown into engagement with one or the other of the two bevel gears M, thus giving motion in either direction to feed shaft O, as required.

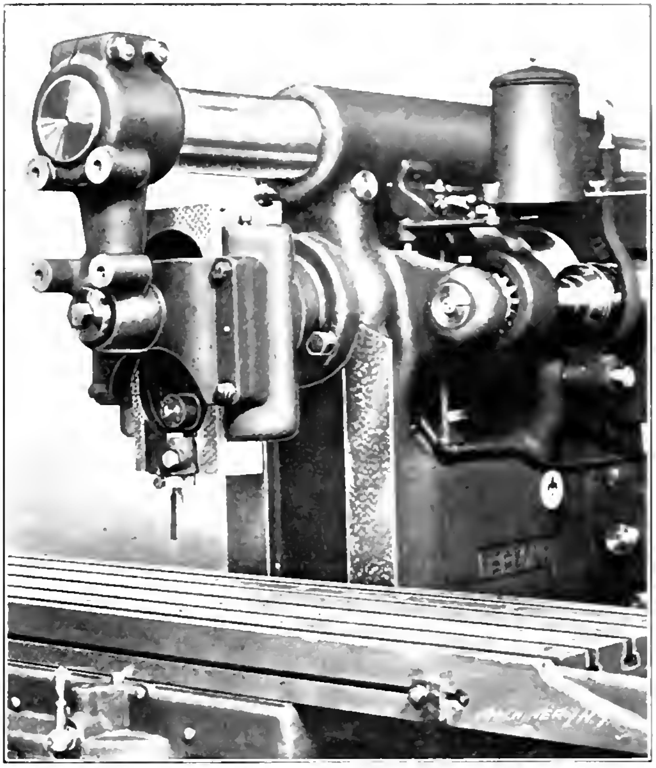

Fig. 14. Attachment for Slotting in the Milling Machine

Shaft O is connected with bevel gear P by means of clutch Q, which is operated by a long rock shaft V, connected with a handle at the front of the base. By means of this handle, the automatic feed is stopped and started. Bevel gear P meshes with a mating gear R on worm-shaft D, thus completing the connection required for the automatic feed. S and S are ball bearings to take the thrust of the worm, thus making the operation of the feed easy even under the heaviest cuts. For cases in which the indexing is not required, a hand-wheel is used on the upper end of shaft D in place of the index crank, thus making either the power or hand operation of the device equally easy. The periphery of the circular table

is provided with a T-slot in which is clamped adjustable tripping dog *T*, which may be set to depress plunger *U* at any desired point, thus rocking rod *V* and automatically throwing out the feed.

The design of the device is very compact so that the vertical capacity of the machine is not unduly reduced by its use. Figs 12 and 13 show two examples of its use. In the first case a piece of work which requires both straight and circular milling is clamped to the table, giving a good opportunity for the use of longitudinal and circular feeds in succession, as provided for by the independent connections previously mentioned. The vertical milling attachment, built by the same makers, is employed in this case. Most of the work for which the circular attachment is adapted is best done with the vertical attachment. In Fig. 13, however, is shown a case in which the cutter is driven directly by the main spindle, and the attachment is used primarily for indexing. This case is the cutting of a large gear—too large to be swung in any index centers, and so large that even if it could be swung, the cutting point would be so far above the bearing surface of the table that heavy cuts could not be taken. Arranged as shown, the pressure of the cut is vertically downward, and it may be supported, if required, by a rim rest clamped to the platen. The large diameter of worm-wheel provided is especially suited for indexing work of this character. The wheel is centered by a plug or arbor driven in the taper hole bored in the center of the table.

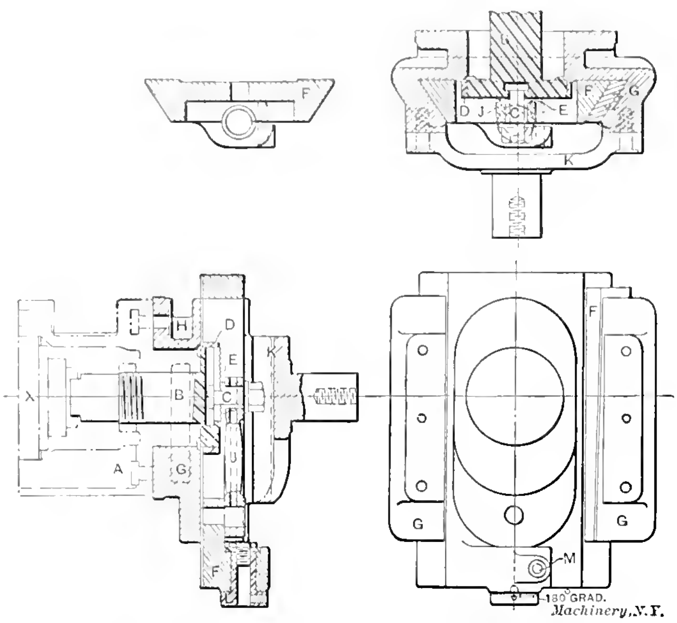

Fig. 15. Details of Construction of the Slotting Attachment.

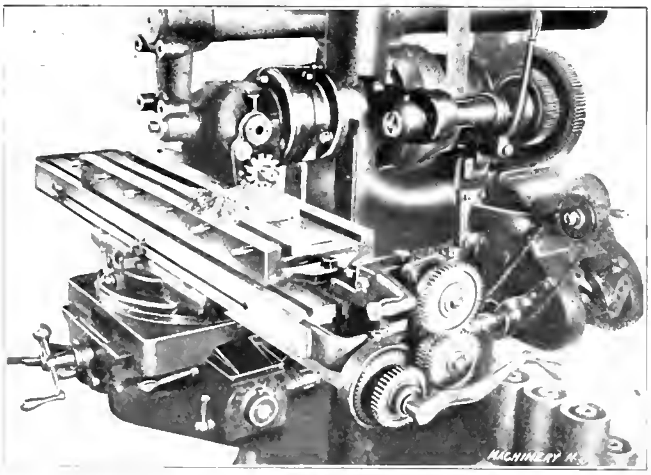

Fig 16 Change Gear Attachment for Spacing in Rack Cutting and Similar Operations.

Slotting Attachment.

The exterior of a slotting attachment for the milling machine is shown in Fig. 14, and its details are indicated in the line drawing Fig. 15. The special features of this attachment are that it can be swiveled through an angle of 360 degrees, that it is supported by the outboard bearing, and that the stroke is adjustable. It thus has a stiffness and a range of action which should make it a very useful device for such work as die making, light manufacturing, etc.

A flanged cap *A* is bolted to the face of the column. This cap has a bearing for crank-shaft *B*, whose inner end is provided with a tongue fitting the groove in the face of the nose of the spindle. The face of the crank disk is slotted for the head of bolt *C*, and has a ring *D* shrunk on it to prevent the bolt from escaping. Fitted over *C* is the bushing *E*, which serves as a crank-pin. The flange of this bushing where it rests on the face of the crank disk is serrated, to match corresponding serrations on the disk. By this means the crank may be adjusted for different lengths of stroke, with the assurance that the adjustment will not slip under any conditions of service. The tool slide *F* is gibbed in a swivel guide *G*, which may be adjusted to any angle about axis *x-x*, and clamped in the required position by bolts *H* entering the T-slot in base *A*. The tool slide is operated from the crank by connecting-rod *J*. The construction of the tool slide and the way in which it is gibbed to *G* will be best understood from the upper sectional view of the figure. A saddle *K* is bolted to the face of *G*, and is provided with a pivot which enters the hole of the overhanging arm, thus supporting the whole arrangement very firmly. The tool itself is held in bushing *L*, whose flange is graduated in degrees, so that the cutting edge may be revolved and presented to the work at any angle required. The bushing is clamped by bolt *M*, which locks it on the split hub principle. The gib between *G* and *F*, it will be noticed, is provided with a tongue fitting a groove in *G* to keep it in position. It is tapered and so is adjustable for wear.

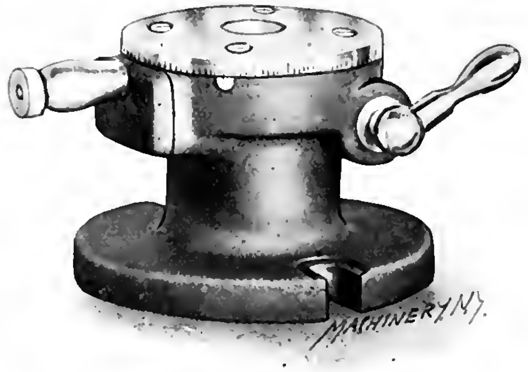

Fig. 17. Vertical Index Head for Slotting Screws, Finishing the Heads of Bolts, and for Similar Work.

Rack Spacing Attachment.

For rack cutting either the universal milling attachment or the spiral gear cutting attachment (both previously described), or the regular rack cutting attachment built by this firm, shown in Fig. 16, may be used. The work, if short, may be held in a regular milling machine vise, or if longer, in a special rack cutting vise such as shown. For indexing the table longitudinally, a new attachment is provided. This attachment, which involves the use of change gears, obviates the necessity for reading graduations on the collar for spacing the teeth. The device consists of a bracket bolted to the table and carrying a quadrant, on which the necessary change gears may be mounted to connect the feed screw and the locking disk. This locking disk is made in two sections and is reversible, one side containing two notches and the other one, for spacing whole or half revolutions. Fifteen change gears are furnished for spacing, giving all diametral pitches from 3 to 6 by half pitches, from 6 to 16 by whole pitches, and from 16 to 32 by even pitches. Circular pitches from 1/16 inch to 1/2 inch by 1/32 inch, and from 1/2 inch to 1 inch by 1/16 inch, are available.

In Fig. 16 will be seen the supplementary connection mentioned as being used for driving a telescopic shaft for the circular attachment, independent of the regular table, saddle and knee feeds. As stated, it consists of a pair of sprocket wheels and a chain, of which the driven member is supported by a special bracket, and drives the outer end of the telescopic shaft.

Vertical Index Head.

The half-tone, Fig. 17, and the line engraving, Fig. 18, illustrate a vertical index head which will be found convenient for such work as cutting clutches, milling the heads of screws, and taking other cuts of a similar nature. The spindle *A* is of steel, and has a tapered bearing in the base *B*, in which it is held by the nut *C*. The latter is split and provided with a lock screw to maintain the adjustment. The upper end of the spindle is provided with a large flange which covers the end bearing at the top of the base, and protects the index ring *D* from chips, oil, etc. This index ring is fastened to the flange of the spindle by screws and dowels, and is locked by bolt *E*. Handle *F* operates a clamp bushing, made on the plan commonly used for holding tools in place in the screw machine turret. In indexing the work, handle *F* is unlocked to release the spindle, lock bolt *E* is pulled out, and the spindle, by grasping the flange or the work, is revolved to the next indexing point, where the lock bolt is allowed to drop in place again. The spindle is again clamped by handle *F* and a new cut is taken. Twenty-four notches are provided in the index ring, so that 2, 3, 4, 6, 8, 12, and 24 divisions may be obtained. The spindle has a No. 11 Brown & Sharpe taper hole, in which may be driven the shanks of chucks, threaded arbors, studs, etc., for holding the work. The whole attachment is very rigid and capable of performing severe service.

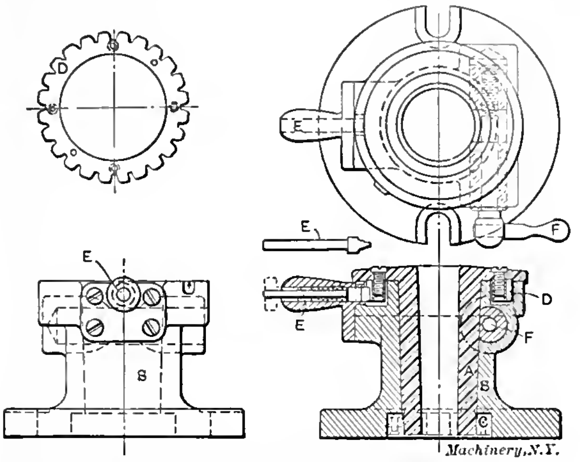

Fig. 18. Elevation, Section and Plan, showing Construction of the Vertical Indexing Head.

KEY-SEATING ATTACHMENT FOR SHAPERS AND PLANERS.

In Fig. 1 is shown a key-seating attachment built by the Cincinnati Shaper Co., Cincinnati, Ohio, attached to a shaper of the same make. The attachment consists of a knee with floating jaws for holding the work, and a cutter bar provided with means for feeding and relieving the cutting blade, and for attachment to the tool-post of the shaper. Special attention has been given to the matter of quick acting and secure means for holding the work, and convenient and strong mechanism for controlling the adjustment and relief of the blade. Owing to the rapidity of manipulation possible and to the fact that the cut is taken on the drawing stroke, the output of the device is very high.

Description of the Attachment.

The holding arrangement for the work, as is best seen in the line drawings, Figs. 2 and 3, consists of a knee *A*, provided with ways, in which jaws *B* and *B* are drawn together by the right- and left-hand screw *C*. A bushing, *D*, is provided, having a flange seated in a counterbored recess in the knee *A*, and having an outside diameter closely fitting the bore of the work in which it is desired to cut the keyway. In clamping the work in place, it is simply slipped onto *D* and screw *C* is tightened to bring the jaws *B* up against the work, which may be either rough or finished, without altering the conditions under which the work is held, since it will be seen that the gripping points are of the "floating" variety, adapting themselves to any surface or dimension presented. When so held, the work is located on the bushing *D*, by the bore, so that the key-seating is assuredly true with the hole.

The cutter bar *E* passes through an eccentric hole cut in bushing *D*. It is clamped to the head of the ram through a universal joint at *F*, the connection being made by a screw *G*.

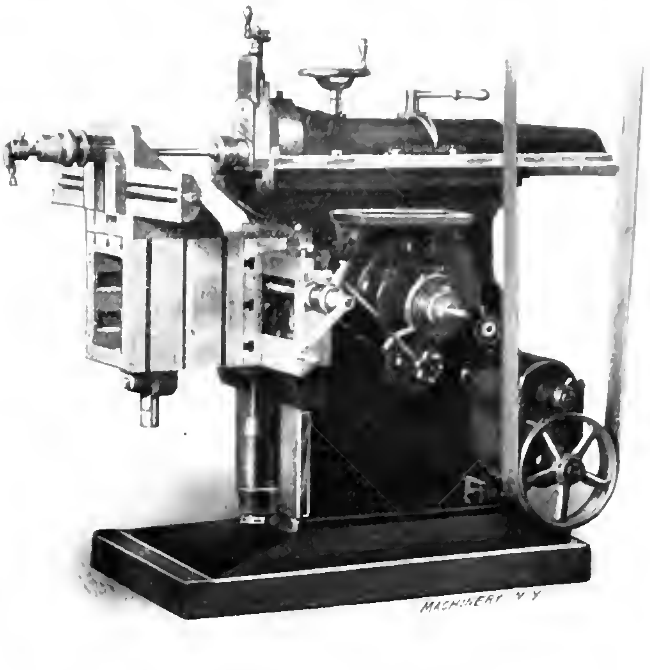

Fig. 1. Key-seating Attachment applied to Cincinnati Shaper

Provision is made in this universal joint to prevent the cutter bar from rotating. The cutter *H* is made from a simple block of tool steel, with a cutting edge formed to give clearance and top rake. It fits loosely in a slot cut through the bar as shown. A groove is cut across the rear edge, engaging the eccentric pin formed on the end of feed rod *J*. (The small details shown will assist in getting an understanding of these various parts.) By means of feed rod *J* the cutter is fed downward and relieved on the back stroke, since any rocking movement imparted to it effects a vertical movement of *H*. A slot, of course, is cut in the bottom of bushing *D*, as shown in the detailed section, to permit the cutter to project through into the work. A corresponding slot is formed in the cutter bar itself to give clearance room for chips.

Feed rod *J* extends to the front end of the cutter bar, where it is keyed to lever *K*, by means of which the operator controls the cross movement of the cutter. A screw *L*, entering a recess in *J*, prevents it from being shifted longitudinally. An eccentric *M* is keyed to an extended hub on bar *E*, and projects over a hub of corresponding diameter on lever *K*. Screw *N* has a projecting pin which enters a groove cut in the periphery of the hub *K*, thus tying it to eccentric *M*, while still permitting it to revolve. *M* and *K* may thus be pulled off of *E* and *J* respectively, to which they are keyed, and

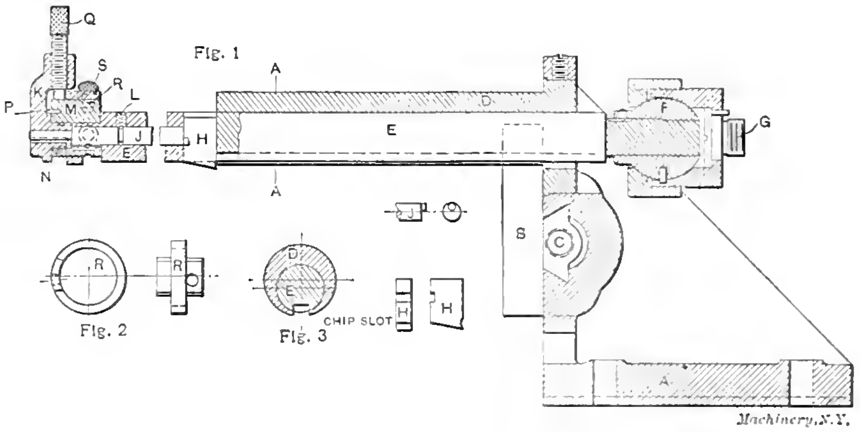

Fig. 2. Section through Cutter-bar of Key-seating Attachment.

replaced if desired, being handled as a single unit. *M* is fastened to *E* by a set screw *O*, when the device is in operation.

The movement of *K* may extend through an arc of 180 degrees. In the upright vertical position shown, cutter *H* is extruded to the limit of its movement. If *K*, in Fig. 3, were swung vertically downward toward the right, *H* would be withdrawn to the limit of its upper movement. The swinging of *K* in a downward direction is limited by the striking of a projection on its hub against stop pin *P*, driven in eccentric *M*. The upward movement is limited either by the striking of the point of adjusting screw *Q* against the periphery of eccentric *M*, or against the projection on adjustable stop collar *R*, which may be clamped in any desired position on *M* by thumb-screw *S*.

Method of Operating.

Having thus described the mechanism, we are able to follow the method of operating the device. First, lever *K* is turned around 180 degrees from the position shown, to its lower vertical position, thus entirely withdrawing cutter *H* within the bar. Thumb-screw *O* is then loosened, and eccentric *M* is withdrawn, taking arm *K* and the attached parts with it. The work is then slipped over bar *E* and onto bushing *D*, which fits its bore. Floating jaws *B* are then clamped on the work, holding it securely. Eccentric *M* and lever *K* are next replaced in position and clamped there by screw *O*, lever *K* remaining in its downward position. Adjusting screw *Q* is now set so that it nearly touches the eccentric in this position, and the shaper is started up, it being understood that the stroke is set properly for the work in hand.

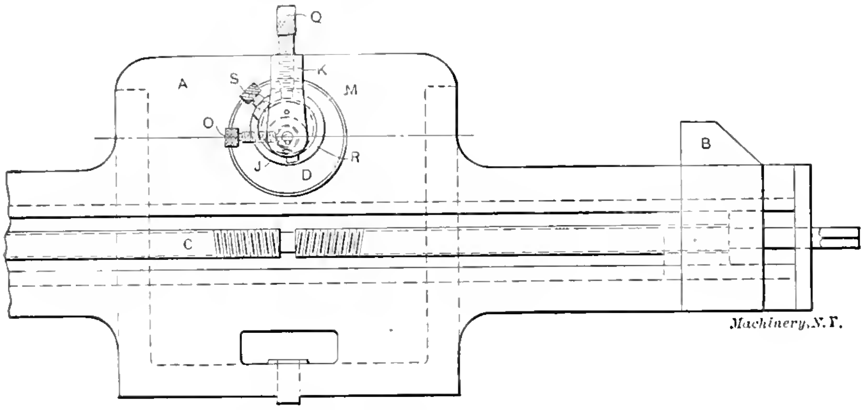

Fig. 3. Face View of Attachment showing Vise Jaws for Holding Work.

As the ram commences its cutting stroke, which is the inward stroke in this case, the operator throws the lever *K* around in the direction opposite to the hands of a watch, until the point of screw *Q* stops against the eccentric surface of *M*. This, as explained, throws blade *H* downward, probably far enough to take its first chip. When the blade has passed through the work, the operator, with his hand constantly on *K*, again swings it back against stop pin *P*, meanwhile unscrewing *Q* a trifle more. At the beginning of the next cutting stroke he again swings it around in a counter-clockwise direction until the point of *Q* again stops against the eccentric surface of *M*, this time further around, causing *H* to project out a little further and take a second chip. This operation of feeding in deeper on the cutting stroke and relieving on the return stroke, is continued until the key-way has been cut in the work to the proper depth. This depth is located by stop collar *R*, which is adjusted on *M* to limit the movement of *K* to the position that gives the proper depth of key-way. *R* is clamped in its position by thumb-screw *S*. The key-seating being then completed, arm *K* is returned to its lower position so that the cutter blade is withdrawn; then *K* and *M* are removed (thumb-screw *O* is loosened) and the finished work is slipped off of bushing *D* and a new piece placed in position, after which *K* and *M* are again replaced and the operation proceeds as before.

As evidence of the capacity of the device to handle repetition work in large quantities, it may be mentioned that 400 pieces [illegible] in the machine in Fig. 1, were key-seated [illegible] minutes apiece. The key-way was ¼ inch wide, ⅛ inch deep and 7 inches long. The material was high grade steel casting.

Practice in Finishing Gear Blanks in the Shops of the Builders.

One feature of the shop practice of the Cincinnati Shaper Co., is dependent on the use of this attachment. Owing to the fact that the key-way is cut true with the bore, no matter what the condition of the outside surface by which it is gripped, this operation may be performed immediately after the chucking. As is common practice in making gears of the first quality, gear blanks in this shop are finished on a true lathe arbor. The key-way being cut before turning, an opportunity is afforded for putting a key in the arbor for driving the gears. A gear thus mounted on the arbor is shown in Fig. 4, together with the arrangement of the tools in the special slide rest which is used for facing the blanks. Since it is not necessary to depend on the forced pressing of the arbor into the work for driving the latter, it is possible to press a snugly fitting arbor of the kind shown, into the key-seated bore of the blank to the same point every time in such position that the edges of the finished faces will overhang slight clearance spaces on the arbor. When so arranged, the double roughing tool may be fed down until it rough faces the two sides of the gear down almost to the arbor. Returning the cross-slide, the two facing tools at the rear may be brought up, finishing the sides completely, clear down to the bore, and running out into the slight clearance spaces mentioned.

The fact of the blank being keyed prevents the longitudinal shifting of it on the arbor which might take place if the latter were pressed into the work no more firmly than would be the case here, with holes varying slightly in diameter. In order to slip easily on an arbor lengthwise, the work must rotate on it as well, and this rotation is prevented by the key. The finish turning of the blanks is done on true gang arbors, on which the work is stacked to the full capacity of the arbor. Owing to the fact that two sides of the gears are faced in the same operation, they are true with each other and with the bore, so the gang arbor is in no danger of being sprung when the work is tightened up on it. This makes a very rapid and very accurate method of finishing small gear blanks that are made in large quantities.

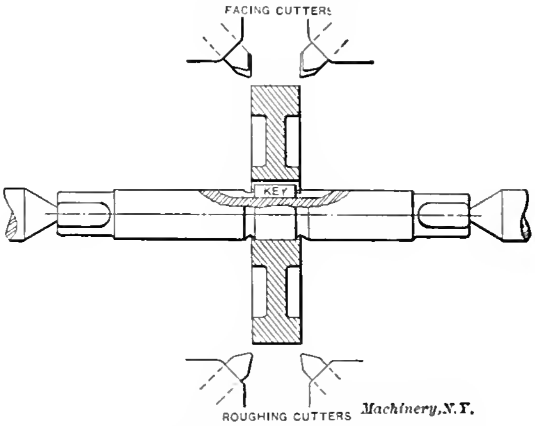

Fig. 4. Facing Gear Blanks, mounted in the Lathe on a Keyed Arbor.

Range of Sizes.

The bars *E* are made in seven sizes, to cut all key-seats up to 1-inch in width, in holes from 9/16 inch upwards, in diameter. Bushings *D* are furnished in any desired size to fit the bore of the work to be key-seated. Bushings for cutting tapered key-ways will be furnished if desired. The device is evidently applicable to the planer, as well as to the shaper.

GEARED FEED DEVICE FOR THE CINCINNATI LATHE.

A positive-geared feed device, giving six changes, has recently been applied to the Cincinnati 16-inch engine lathe, by its builders, The Cincinnati Lathe & Tool Co., Cincinnati, Ohio. This feed box, as may be seen from an inspection of the half-tone engraving in Fig. 1 (where it is shown attached to the lathe) and of the line engraving, Fig. 2, is of original

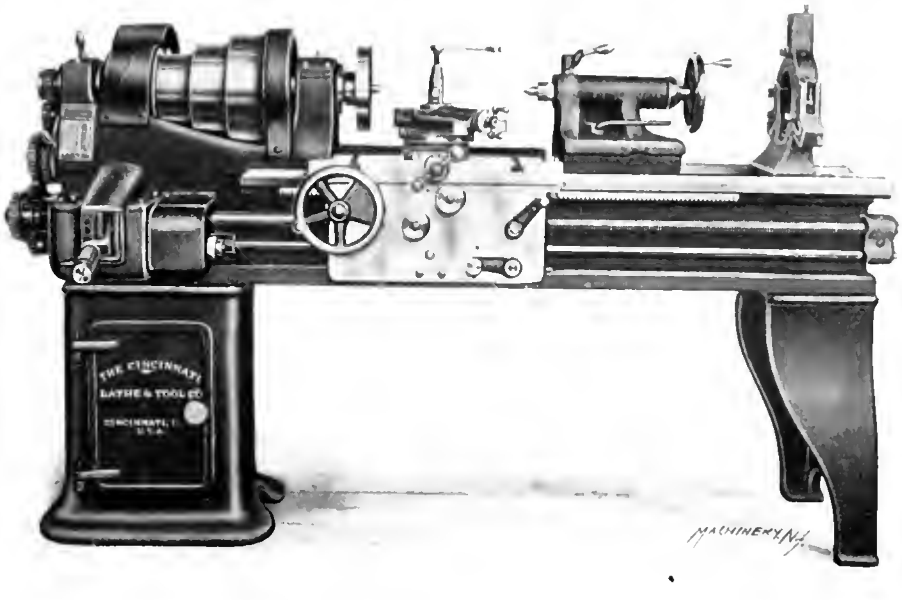

Fig. 1. Cincinnati Lathe provided with Improved Quick Feed Change Device.

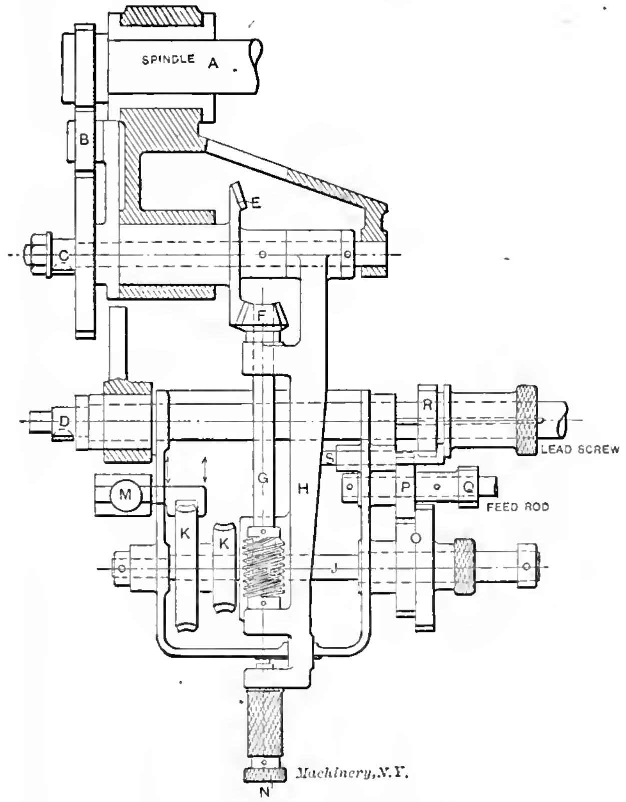

Fig. 2. Arrangement of Feed and Screw Cutting Connections for the Cincinnati Lathe.

and interesting construction, and seems to have been so designed as to accomplish its work with very few parts and simple mechanism.

Referring to the line engraving for the details, *A* is the lathe spindle which, through the usual reversing tumblers *B*, drives the stud gear shaft *C*. From this, connection for threading may be made with the lead-screw *D* by the usual change gears. Mounted on the change gear stud on the inside of the head-stock, is bevel gear *E*, meshing with a pinion *F* driving a worm-shaft *G* which is supported by bearings in swinging arm *H* pivoted about shaft *C*. To shaft *J* in the feed box is splined a triple worm-wheel *K*. Any one of the three wheels composing this may be shifted into position under worm *L* by means of a slide *M* on the outside of the box. The inner extension of this slide embraces the largest of the wheels and so controls the axial position of all three. Arm *H* extends out through the feed box at the front of the lathe, where it is provided with a lock bolt *N*, by means of which it may be fixed at any one of four different vertical positions. To change the rate of feed, *N* is pulled out and arm *H* raised until the worm *L* is out of reach of the worm-wheels *K*. Then fork *M* is shifted to bring that one of the three worm-wheels corresponding with the desired feed into position beneath the worm. Arm *H* is then dropped to the corresponding vertical location for that wheel and locked in place by bolt *N*. The three changes thus obtained are doubled by means of the double sliding gears *O* which may be shifted to engage with either *P* or *Q* on the feed rod, thus giving six changes in all, varying from 16 to 100 turns per inch. This is sufficient for general manufacturing work.

In addition to these speeds which are instantly obtainable, 22 additional changes ranging from 5 to 64 per inch, may be obtained, to suit special cases, by using the regular change gearing between *C* and *D*, and shifting sliding gear *R* on the lead-screw into engagement with gear *P* on the feed rod, which is thus driven from the spindle. To make it possible to drive the feed rod in this way, without interfering with the regular drive through the worm gearing, a lock bolt *S* is provided, having a finger engaging a groove in slip gear *R* and projecting into the feed box in the path of the swinging movement of arm *H*. Bolt *S* and arm *H* are so placed that the former prevents gear *R* from being thrown into mesh with *P* until *H* is raised to its extreme upper position, where engagement with even the largest of the worm-wheels *K* is impossible.

This lathe has been previously built in two forms, either with the Emmes patent quick change gear device, or with plain belt feed. The lathe with the feeding device we have just illustrated is intended to take the place of the belt feed machine, and will be furnished at the same price. The range of feeds provided appears to be suitable for ordinary work without requiring the use of the change gears at all for feeding. It will be noted that the feed is independent of the screw-cutting motion, so that the lead-screw is not operated except when required for actual threading. The machine shown in the illustration has a 3-step cone and double back gears. If required by the purchaser, a 5-step cone and single back gears will be furnished instead.

EBERHARDT BROS. UNIVERSAL AUTOMATIC GEAR-CUTTING MACHINE.

The Eberhardt Bros. Machine Co., 66 Union St., Newark, N. J., has recently built the remarkable gear-cutting machine illustrated herewith. In Fig. 1, a blank is shown, cut with the various styles of teeth which the machine is capable of producing. As may thus be seen, it is practically universal in its adaptability, it being designed for the cutting of spur, bevel, skew, and face gears, besides being useful for gashing worm-wheels. It is intended to fill the requirements of a machine for stocking out bevel gears preparatory to finishing on a planing machine, and, likewise, of jobbing and repair shops for finishing bevel gears by the formed cutter method. This is done without limiting the capacity of the machine for spur gear work, in the way met with in the ordinary automatic spur and bevel gear cutter, provided with a swivel adjustment for the cutter slide. In other words, this machine will finish spur or bevel gears with equal accuracy, and with an equal output.

Structural Features of the Machine.

A heavy base casting is provided, having at one end guides on which the work spindle head is adjustable longitudinally, and on the other, a seat of circular form, on which the cutter head stanchion may be adjusted to the proper angle for any gear from a spur to a face gear. The work head, it will be

seen, is adjustable in two directions. The adjustment of the saddle on the bed is for accommodating different diameters of blanks, and for setting the cutter to the required depth. That of the spindle head on the saddle is at right angles to the first, and is used to accommodate bevel gears and pinions having varying lengths of hub, so as to bring the point of the pitch cone to the proper position. This also is used to set the cutter to depth in cutting face gears. The screws for both of these movements are provided with adjustable dials, graduated to read to thousandths of an inch. The screw which makes the adjustment for the diameter of the blank may be operated from either end, as most convenient.

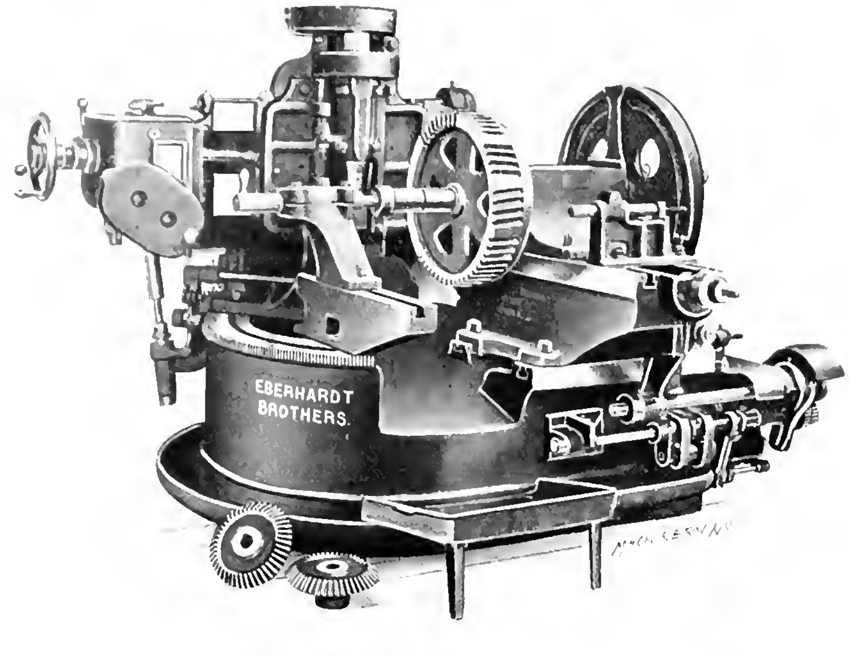

Fig. 1. An Automatic Machine for Cutting Spur and Bevel Gears; also adapted for Worm, Skew, and Face Gears.

The method by which the cutter slide is supported and the cutter driven, may be understood by reference to the line drawing, Fig. 3, in connection with the two half-tones. The cutter stanchion *A*, as has been explained, is adjustable about its circular seat on the top of the base to the required angle. The axis of adjustment is shown at *x-x*. The cutter slide itself, *B*, is mounted on a guide *C*, which swivels through a limited angle on a bearing on the face of stanchion *A*, about axis *y-y*. The slide *C* is set by this adjustment to the required angle for making the approximation necessary when cutting bevel gears by the formed cutter process, and is clamped by bolts *D*. For spur gears, of course, the slide is set in a horizontal position, shown in Fig. 3. For cutting skew gears (much used in steel mill work in place of the more expensive and less easily removed worm-wheel) slide *C* is set to agree with the helix angle of the worm the skew gear is to mesh with. In gashing worm-wheels the same thing is done. For this latter case, of course, the automatic feed is not used, the work slide being fed on the saddle to the proper depth by hand for each cut. It will thus be seen that the cutter slide and work are as strongly supported when the work is set for cutting bevel gears, or even for face gears, as when cutting spur gears.

The Driving Mechanism.

The machine is driven through constant speed pulley *E*, which is connected by bevel gearing with a shaft *F*, whose center line is on axis *x-x*, about which *A* is adjusted. Shaft *F* is connected in turn by bevel gearing with shaft *G*, journaled in cutter head *A*. *G* is connected by spur gearing with shaft *H*, with center line on axis *y-y*, about which *C* is adjusted. This, in turn is connected by spur gearing with shaft *J*, connected at one end with the feed box *K* for the power feed and quick return, and at the other by spur gearing to splined shaft *L*, which drives bevel pinion *M*, supported in a bracket attached to cutter slide *B*. *M* meshes with bevel gear *N*, which is keyed to a vertical shaft which is connected with shaft *O* by change gears as shown, for obtaining the required rate of spindle speed for the case in hand. A pinion on *O* drives the spindle gear *P*. The same provision for adjusting the spindle *Q* lengthwise is made in this machine as with the usual automatic gear-cutting machine. It will be seen from the foregoing that the spindle drive is effected from a pulley of fixed position, without interfering with the two angular adjustments of the cutter slide, or the axial adjustment of the cutter spindle. For making the angular adjustments of the cutter stanchion, a worm is provided, engaging a circular rack secured to the bed. The worm carries a dial graduated to read to minutes of a degree, one degree being a whole turn of the crank.

Feeding and Indexing.

The feed of the cutter carriage is varied by change gears, the quick return remaining constant. The cutter speeds and feeds are entirely independent of each other. The thrust bearings for the feed-screw are placed at each end, so that the screw is not under compression either during the feed or the return of the carriage. This "draw-cut" principle is said to reduce vibration and chattering to a marked degree. The cutter carriage is of exceptional length, and travels on long and narrow guiding surfaces of the same construction as on the spur gear machines built by the same firm. The cutter spindle is in the center of the length of the carriage, thus preventing the possibility of lifting the latter, or "gouging" on the part of the cutter, when beginning the cut.

The indexing mechanism is positive, and is operated by means of a rod from the feed box trip mechanism, as is usual on spur gear cutting machines. As this rod operates through the centers of angular adjustment of the machine, no attention is needed whatever when the stanchion or swivel slides are moved for different angles, or when the head is moved in either direction. The use of chains is eliminated; there are only the two usual dogs to be set to suit the various lengths of face of the gear blanks. The indexing worm runs in a bath of oil and meshes with an index wheel of large diameter, made in halves to insure accuracy.

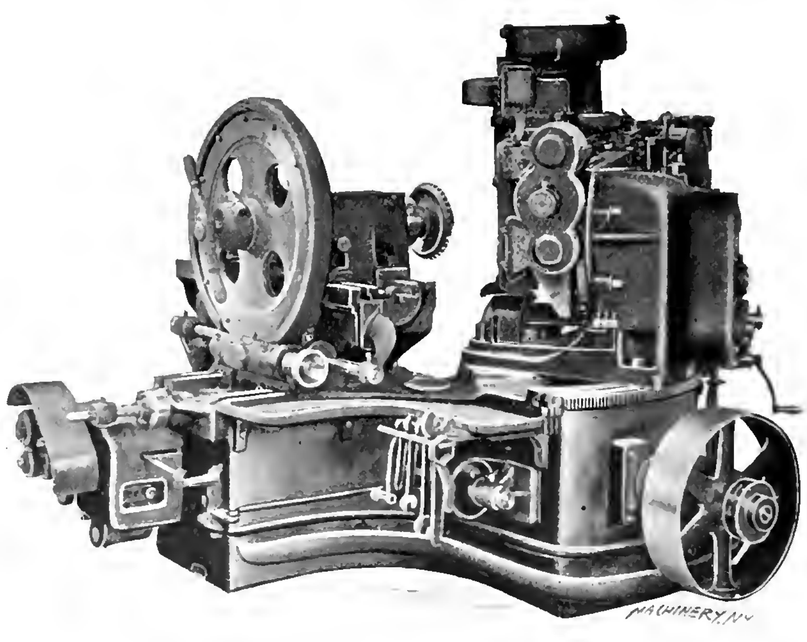

Fig. 2. Rear View of the Universal Automatic Gear-cutting Machine.

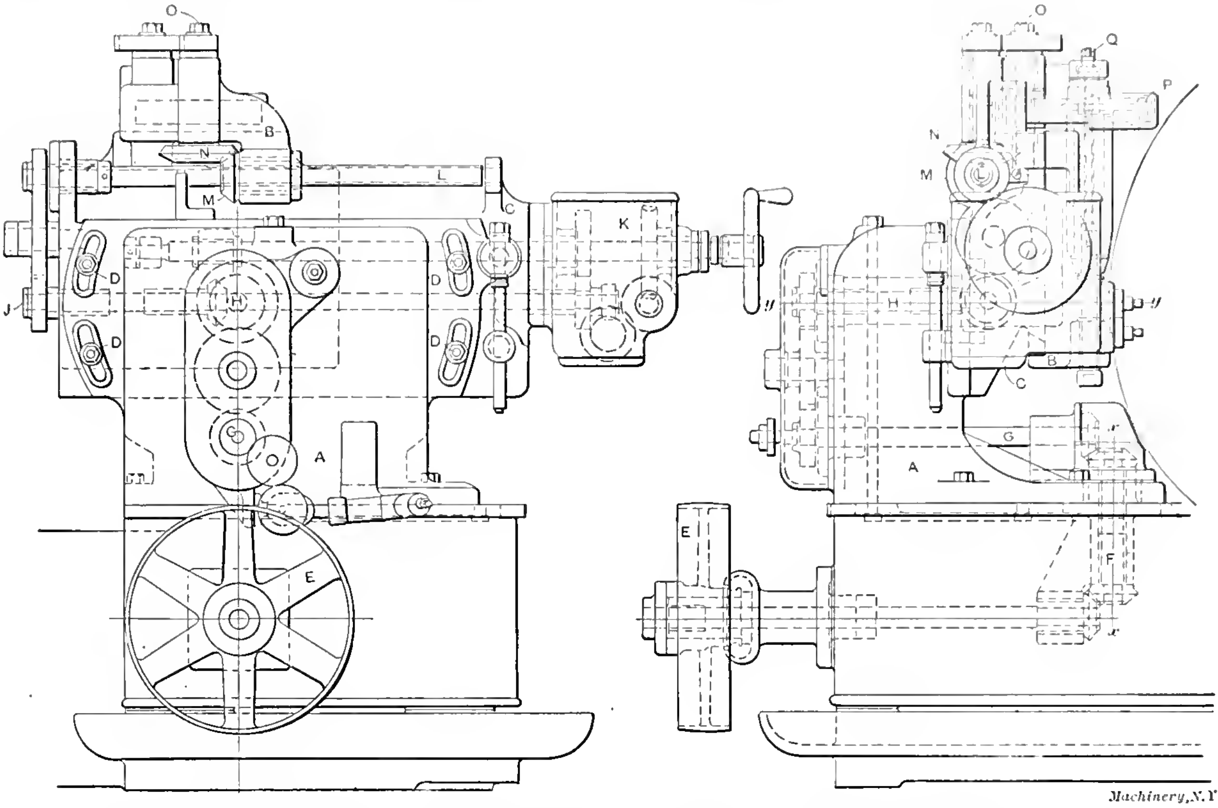
Incidental Features of the Design.

An outside support is furnished for the work arbor, as shown in Fig. 1. This support accommodates wheels up to the full diameter of the machine, and is easily removed. Rim rests are provided to support large gears against the thrust of the cutter. A face-plate is also provided, with chucks and drivers for positively holding and driving wheels of large diameter. The cutter and work spindles have tapered holes, and each is provided with a draw bolt for positively drawing in and forcing out arbors. The work spindle is a machine steel forging, while the cutter spindle and arbor are of tool steel. All driving shafts are of high carbon machinery steel and finished by grinding as, of course, are also the spindles.



Machinery,N.Y.

Fig. 3. Front and Side Elevation of Cutter End of Machine, showing Cutter Slide Adjustments and Method of Driving.

Fig. 1 shows very plainly the convenient height of the machine, and the accessibility of all the parts, such as the hand indexing and feed levers at the left of the machine, near the feed hand-wheel. These are used when setting the machine and are always within easy reach, being about 4 feet from the floor. A number of minor conveniences will be noticed. The change gears are enclosed by hinged covers, and guards are provided for encasing all the gearing. The oiling facilities provided have been carefully studied out. The bearings of all shafts and spindles operating in a vertical position have spiral oil grooves, cut in the opposite direction to the rotation of the shaft, so as to retard the downward flow of the lubricant. Felt wipers are arranged on all the planed bearing surfaces to keep the dirt and chips out, and retain the oil. An oil pump with suitable piping and reservoir is provided for supplying a lubricant, as when cutting steel.

Capacity.

The machine has a capacity up to 48 inches in diameter, and 10 inches face, and will cut 3 diametral pitch in steel and 2½ diametral pitch in cast iron. By taking stocking cuts, heavier pitches can, of course, be cut. One of the first lot of these machines built is cutting 2 diametral pitch in steel as its regular work. It will be noticed that, owing to the construction of this machine, the full capacity, so far as diameter is concerned, is available whatever the angle at which the cutting takes place. This is owing to the fact that the swivel is effected by the cutter slide instead of by the work spindle, so that the latter always bears a definite relation with the clearance cut in the base for swinging work of large diameter.

PRESSED STEEL TROUGHING AND RETURN ROLLS FOR CONVEYOR BELTS.

The question of troughing conveyor belts has always led to controversy, and about the only point that seems to have been definitely settled, is that with deep troughing-rolls the belt must be made so that it will bend to the required shape; and to obtain this shape with the ordinary multiple pulley idler, the belt is sometimes made up with fewer plies of fabric at the flexing part. The rubber protective cover of the belt has little or no tensile strength, and the result of weakening the fabric, especially in cases of the wide belts designed for large carrying capacities, is to bring about a weakening at the very point where the load is heaviest and the bending of the belt most severe.

An improved type, of pressed steel, is shown in the illustration. The carrying-roll, firmly secured to the through shaft which revolves in self-oiling, dust-tight bearings, consists of three parts rigidly fastened together—one straight middle section, and two bell-shaped end-sections, the inner edges of which are flanged so that the center section overlaps each snugly, making a close joint and a well balanced roll. The ends are closed, which prevents entrance of material to interfere with the rotation of the roll or throw it out of balance. A point is also made of the clear height above the supporting

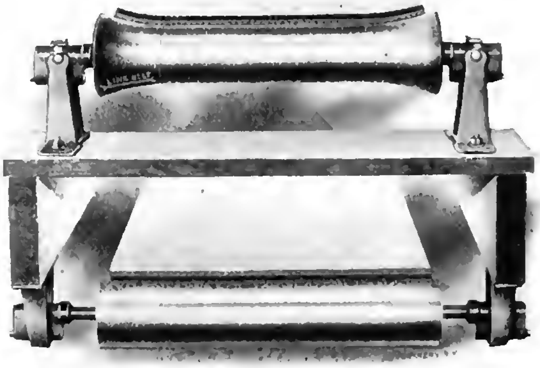


Fig. 1. A Pressed Steel Troughing Roll which gives a Maximum of Life and Carrying Capacity to the Conveyor Belt.

plank, as this effectually removes the roll from possible contact with spilled material. The carrying run is thus over a one-piece roll on which the loaded belt bears evenly for its entire width. The result is that all troughing strain is eliminated and the belt wear is confined to ordinary carrying service; nor does observation show that the difference in diameters of the roll injures the under side of the belt. This is no doubt due to the fact that the roll revolves at the speed of the loaded part of the belt and that rubbing is confined to its edges. The wear here is slight, and it has been found that the life of the belt is determined by the wear on the carrying part rather than on the under side.

The return rolls are of the one-piece, straight-face type, set-screwed to a through shaft which revolves in bearings identical with those on the carrying-run. Both rolls are compact, light and strong, and in service, under severe conditions, show remarkable durability. The lightness and simplicity of construction have so reduced the initial cost that closer spacing is possible, and this, where high speeds and great capacities are desired, prevents sagging of the belt and assures smooth, easy operation, lessened horse-power consumption, and a minimum of belt wear. As the rolls are fixed to the shafts which, as noted, revolve in oil, the lubricating points for each are reduced to two, and these are so accessible that the bearings are always in good condition.

The following considerations should govern the adoption and use of the belt conveyor principle. First, it should be used only for materials to which it is adapted, there being no such thing as a universal conveyor. Second, the more nearly a belt conveyor approaches the flat position, the longer the belt will last, so troughing should be shallow enough to allow the belt to assume its shape naturally and without strain. Third, the belt, however it is made, should be uniformly strong throughout its width, its construction being governed entirely by the material to be handled and the conditions under which the conveyor must be run. The roll just described, when used as it should be, conforms to the above conditions. It is built by the Link-Belt Co., Philadelphia, Pa.

THE DILL DRIVE.

The T. C. Dill Machine Co., Philadelphia, Pa., is building the variable speed drive shown in the accompanying illustrations. As may be seen at the first glance, it embodies an exceedingly ingenious principle of action and is constructed along novel lines, though it somewhat follows the principle of the well-known Sellers drive in the matter of varying the speed by forcing straight disks in between tapered disks, pressed together by springs, the drive being by the frictional contact between the edge of each straight disk and the sides of its mates on the other shaft. By varying the center distances of the two sets of disks, the diameter of the drive on the tapered disks is varied, thus altering the speed. The novelty of the construction consists in multiplying these disks to as great an extent as required to transmit the desired power, and in making them of thin steel stampings, allowing the whole arrangement to be of very compact construction. Refinements have also been introduced in the methods of applying the pressure, and in varying the center distances of the disks.

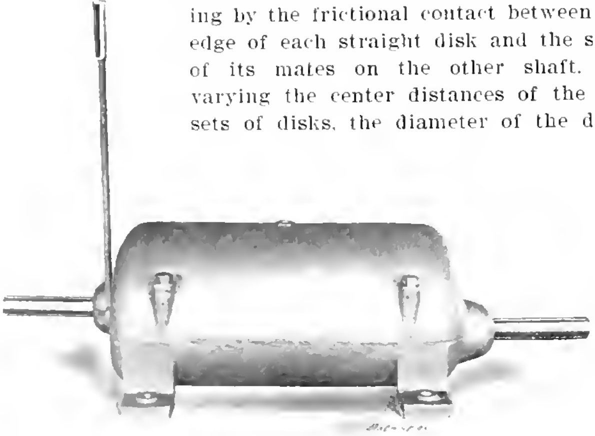

Fig. 1. Dill Variable Speed Drive as supplied for General Use

The Commercial Form of the Device.

A variable speed device of this type is shown in its enclosed form in Fig. 1, and with the cover removed in Figs. 2 and 3. The shaft which extends from the casing at the opposite end from the handle, is the one which receives the power. On a squared portion of this shaft are loosely mounted flat ground disks, punched from steel plate, with the holes to fit the shaft. The driven shaft, which delivers the variable speed from the device, has a similar squared portion on which are loosely mounted similar flat ground disks with squared holes. Between these constant speed and variable speed shafts is mounted a third, whose bearings are supported by arms keyed to a rock shaft, parallel to the other two. On this intermediate shaft are mounted tapered disks which enter the spaces between those on the other two shafts. They are held to this intermediate shaft in the same way as the others, by squared seats. By means of the heavy coiled spring shown, which presses together the flanges which confine them, all the disks in the device are pressed into contact with each other. The rock shaft on which the arms are mounted which support the intermediate shaft, is provided with a handle by means of which the latter may be swung toward either the constant speed or the variable speed shaft. In the first case, the edges of the constant speed disks come in contact with a smaller diameter of the intermediate taper disks, while those of the driven shaft, on the contrary, engage a larger diameter of the disks they engage with. This results in the increase of the speed of the driven shaft. Of course, this shifting of the center distance between the shafts alters the spacing of all the disks, as the straight ones enter or recede from the tapered openings between the tapered disks. Owing to the rapid rate of rotation of the shafts, this side adjustment takes place practically instantaneously, all of the disks being free to move endwise on the squared shafts, as explained, except for the pressure of the coiled spring on the intermediate shaft, which gives the pressure required for the driving.

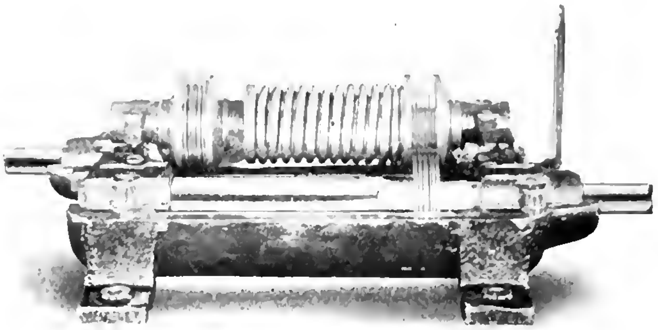

Fig. 2. View of the Dill Drive with Cover removed from Casing, showing the Alternate Sets of Flat and Taper Disks which Transmit the Power.

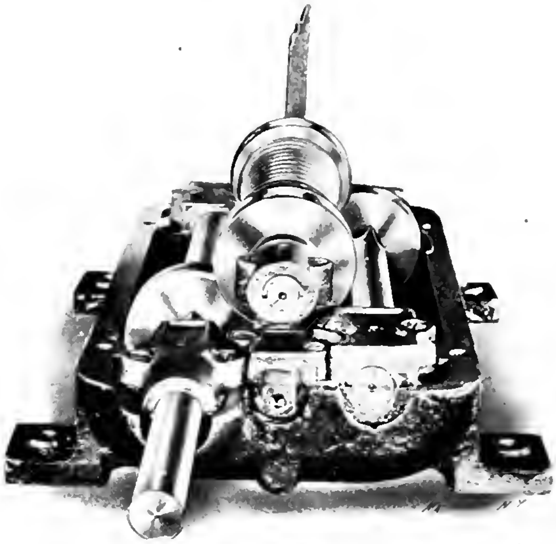

Fig. 3. End View of the Drive, showing the Method of Supporting and Shifting the Intermediate Shaft to change the Speed.

The contact between the flat and tapered disks is but a spot, and as they have a rolling action on each other, the frictional resistance is reduced to a minimum. Great power, while still retaining exceptional endurance, is obtained by first determining the proper pressure from the standpoint of endurance for one disk, and then adding a sufficient number to transmit the power required. The spring is adjusted to suit the load at a given speed, and as the speed is increased the pressure is reduced, and *vice versa*. Owing to the peculiar construction of this spring, constant horse-power output is attained by making the pressure vary with the speed.

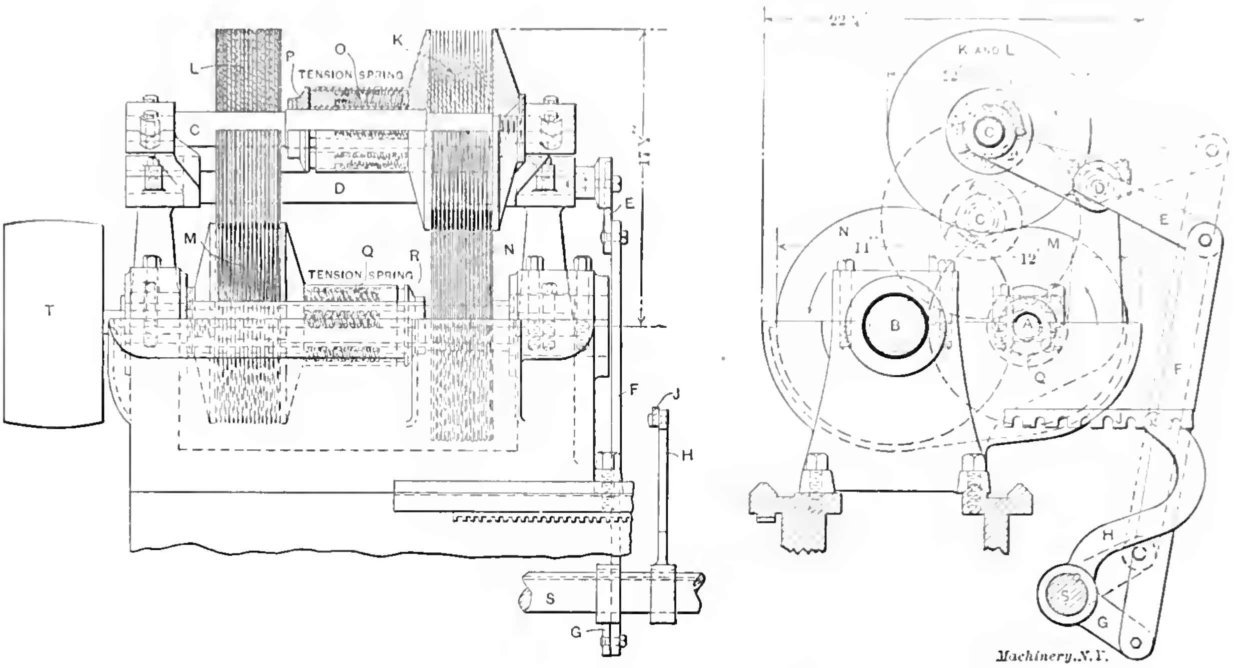

Fig. 4. Suggested Arrangement of Dill Drive as Incorporated in the Head-stock of a 20-inch Lathe.

The apparatus shown in Figs. 1, 2 and 3 shows the drive in the form in which it is being put on the market as a speed box for general use. These speed boxes are made in several sizes, from ½ horse-power up, and with a speed ratio of 5 to 1, though more or less can be had if desired. The drive shown, which is suitable for 5 horse-power, is 23 inches long and 15 inches wide over all, including the extensions for the feet and bearings. The frame proper is only 19 inches long, 11 inches wide, and 9 inches high. The disks are 4 inches in diameter and 3/64 inch thick. The constant speed shaft runs at 400 revolutions per minute. Compactness will thus be seen to be a prime characteristic of this device, as compared with others previously built for the same purpose.

Direct Application to Lathe Head-stock.

Instead of giving the constant-speed shaft a velocity midway between the highest and lowest of the driven shaft, the diameters of the disks may be so arranged that the change of speed is all in the direction of a reduction, so that the highest speed of the driven shaft does not exceed the initial speed. This arrangement is recommended as being a suitable design for incorporating in the head-stock of a lathe or boring mill. Such a modification of the device is shown in the sketch of Fig 4 which suggests a suitable arrangement of the Dill drive as applied to a lathe head-stock.

In this sketch it will be noted that the flat disks *N* (which are fitted directly to a squared seat on the spindle *B*) are 14 inches in diameter, meshing with 12-inch tapered disks *K* on the intermediate shaft *C*. On the other end of the intermediate shaft is another series of flat disks *L* 12 inches in diameter, which intermesh with tapered disks *M* of the same size on the constant-speed shaft *A*. Sufficient power for this application to the lathe may be obtained with a comparatively small number of disks. With the arrangement shown a speed ratio of 30 to 1 is obtainable.

It will be noted that in this case, instead of swinging intermediate shaft *C* from *A* toward *B*, it is mounted on arms *E*, pivoted in such a way that it approaches or recedes from *A* and *B* simultaneously. This construction is still more compact than that shown in the variable speed counter-shafts in Figs. 1 to 3. The change in the movement of the intermediate shaft as compared with the first design, necessitates a rearrangement of the disks. As will be noted, the tapered disks are mounted on the driving shaft and the driving end of the intermediate shaft, while the flat disks are mounted on the driven end of the intermediate shaft and on the spindle. This also necessitates two sets of compression springs, *O* and *Q*, for giving the pressure required for transmitting the power desired. The spreading apart of the disks and the consequent increased pressure of the springs as the speed decreases, gives the increased torque required for transmitting constant power at variable speed—a provision which is necessary in the case of lathes.

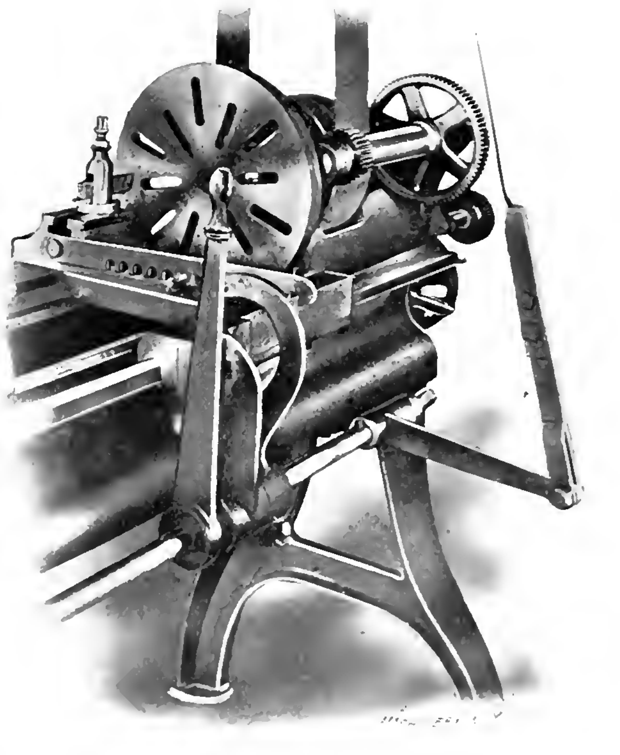

Fig. 5. Arrangement by means of which the Speed of the Drive, mounted on the Counter-shaft, is controlled by the Position of the Tool-post, for Facing, etc.

Automatic Speed Control for Lathes.

The sketch shows an arm *H*, having a pin adapted to engage any one of a number of notches in a link *J* attached to the cross-slide. This arm is connected by link *F* to rock shaft *D*

in such a way as to vary the speed with the position of the cross slide, thus automatically adapting it to the diameter of the cut. This would be very convenient for facing cuts, or for work in which the diameter is constantly varying. The lathe shown in Fig. 5 is provided with a somewhat similar arrangement, intended, however, to be used with a variable speed box such as shown in Fig. 1, bolted to the ceiling. In this case the bell-crank at the rear is connected by a long link with the rock shaft of the speed box on the ceiling. A lever is also provided, as will be shown, by which the speed is changed manually when desired, the lever being so arranged as to slide with the carriage and be always in convenient position for the operator. The lathe in this case is adapted to the variable speed box drive by slipping a special wide-faced pulley over the two largest steps of the cone, thus giving a more powerful drive than the original construction, as well as a more flexible one.

THE NORTON 20 x 192-INCH GRINDING MACHINE.

The machine shown in the two accompanying engravings, is the latest addition to the line of grinding machines built by the Norton Grinding Co. of Worcester, Mass. The machines shown are notable for their great capacity, particularly in regard to length. They are especially intended for grinding long and heavy shafts such as found in stationary engine and marine work, as well as for finishing shorter work, such as spindles, etc. The machine shown is not by any means the longest of this size the builders are prepared to make, though it is the limit practicable with the bed cast in one piece. In the case shown, the base is 30 feet long; for greater lengths it is made in three pieces. That for the largest machine of the series (which is capable of grinding work 22 feet between centers) has a base 42 feet long.

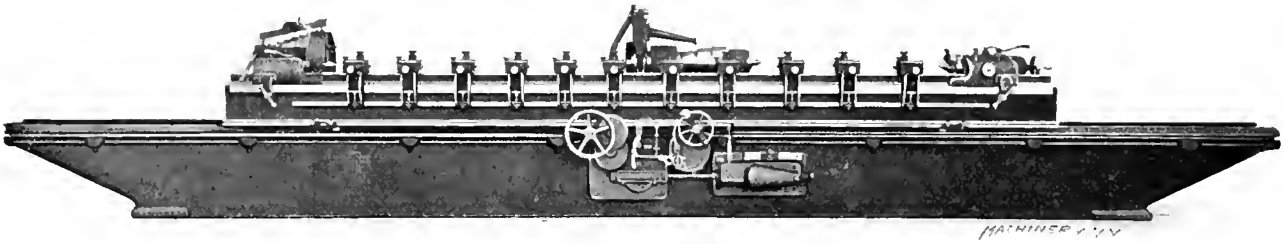

Fig. 1. A Norton Grinder of Unusual Capacity, designed for the Finishing of Heavy Engine and Marine Shafts.

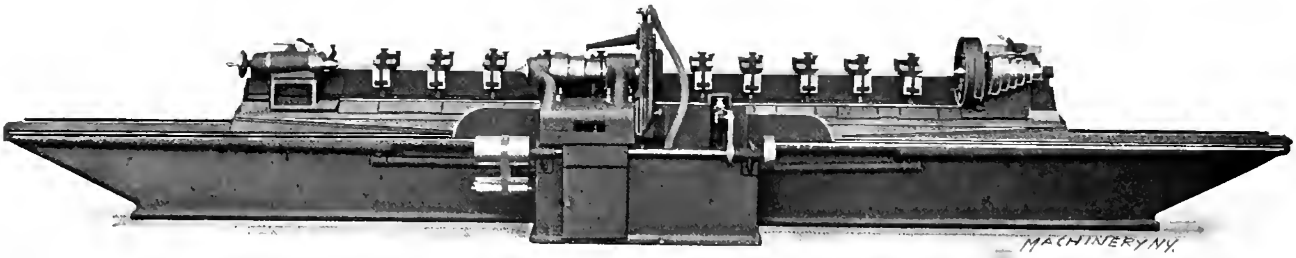

Fig. 2. Rear View of Heavy Norton Grinder. The Bed is made in Lengths of from 8 to 22 feet.

The base casting is unusually heavy, even when its size is considered. The ways are provided with a series of oiling rolls, closely spaced, thus furnishing the lubrication necessary to insure long life and continuous accuracy in guiding ways. An equipment of permanent adjustable wedges is provided for correcting the alignment after the machine has been placed on the foundation. These corrections are made at any time when errors appear, due to the settling of the foundation. The wedges are machined and rest on iron plates, which should be imbedded in the cement foundation and made to line up with a straight-edge and level. This system of adjusting blocks has been previously described in MACHINERY. (See issue of March, 1907.)

This machine has the same general features as the other Norton grinders. In the case shown, it is driven from an over-head counter-shaft, though it can be furnished for self-contained electric drive. It has no provision for grinding tapers, but it made simple and rigid, so that it may do accurate and heavy work, without the complication due to extra adjustments on the table itself. There is, however, an adjustment for the foot-stock to correct the alignment of the centers in case of any wear in the center points. The grinding wheel of this machine is furnished in various widths (from 2 to 4 inches) to suit various kinds of work; it is 24 inches in diameter. The machine will use 20 horse-power to good advantage. From 5 to 20 horse-power should be reckoned on in installing the machine, the amount depending on the character of the work to be produced, and the ambition of the operator.

The smaller sizes, that is, from 96 to 120 inches length between centers, are designed for the grinding of rolls and similar work.

ELECTRICAL FAULT FINDER FOR DETECTING GROUNDS, SHORT CIRCUITS, ETC.

A new and useful instrument has recently been brought out by the Electrical Controller & Mfg. Co., of Cleveland, Ohio. The makers call it a "Fault-Finder." It is intended to be used in detecting and locating grounds, short circuits, open circuits, leaks and other faults in armature and field coils, control circuits, switchboard wiring, or any other electrical connection. It will not only indicate trouble, but will locate it as well. In the case of a motor armature, for instance, a faulty coil can be accurately located and the nature of the trouble defined. If the coil is damaged, the layer in which the fault lies can be determined. In a bunch of control wires in a multiple unit train control or other magnetic switch control, the faulty wire or pair of wires can be promptly located and the nature of the fault quickly found. The instrument consists of a small box, provided with a strap for carrying over the shoulder when testing motors in inaccessible places, such as under cars or on electric over-head traveling cranes. From this small box, leads are connected to telephone receivers (either one or two, depending on the noisi-

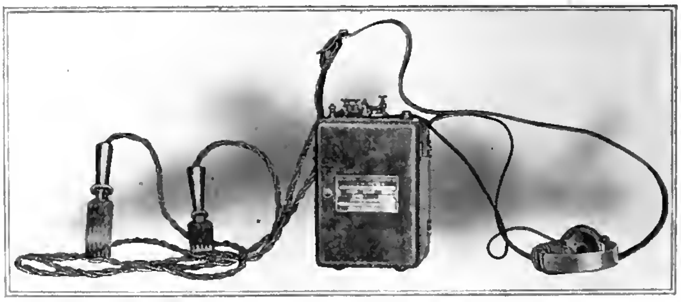

Fig. 1. Device for Detecting Faults in Electrical Connections.

ness of the surroundings) fitted with a head piece so as to leave both hands free for testing. The rheostat may be adjusted to give a sound of any magnitude from a very loud one, more than a normal ear can stand, down as faint as may be desired. Leads extend from the box also to the two test terminals.

This device is inexpensive, small and portable, and requires no outside current to operate it. But one man is needed to operate it under any conditions, so there is no excuse for the tester's desiring a helper. The manufacturers have prepared a neat booklet describing the instrument and giving instructions for its use; this will be sent on request to interested persons.

BLISS TRIPLE-ACTION DRAWING PRESS.

We show herewith a drawing press, placed on the market by the E. W. Bliss Co., 5 Adams St., Brooklyn, N. Y., in which three sliding motions and a knock-out arrangement are so combined that work formerly done in two operations may now be done in one. This does away entirely with rehandling and annealing first operation shells, inasmuch as the second operation immediately follows the first, making the second draw while the metal is still warm.

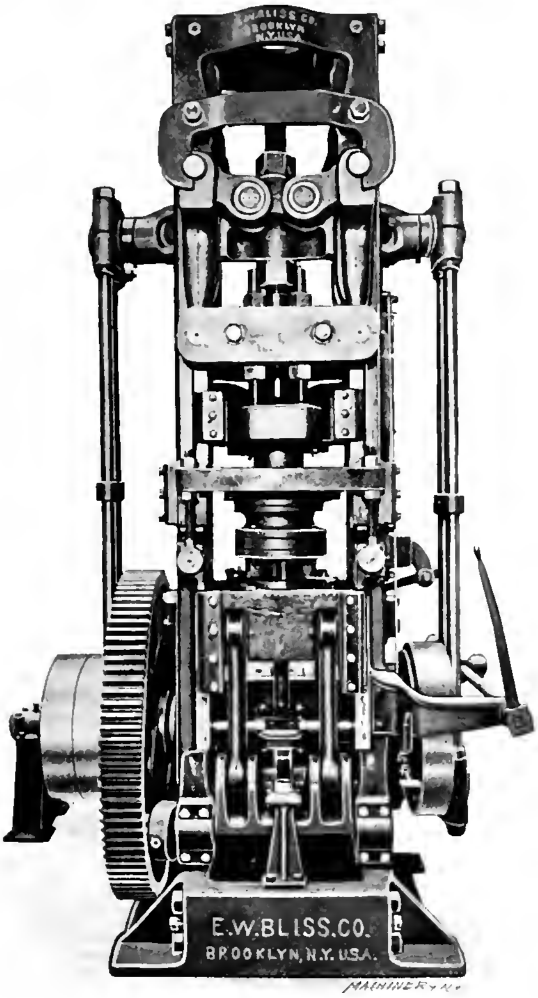

Fig. 1. Triple-action Prese by means of which Two Drawing Operations are performed at Each Stroke of the Machine.

In this press, the dies and the blank placed on them are carried by the lower table, which is raised by the toggle movement shown at the base of the machine to meet the stationary blank holder, supported by the sides of the press frame. Projecting through this stationary blank holder are two plungers, one within the other, of which the outer or first operation plunger is operated by a lever movement which gives it a dwell, independent of and succeeding that given to the lower table, while the inner or second operation plunger is operated by the cranks and connecting-rods shown at the sides of the machine.

In performing a drawing operation, the movements are as follows: The blank is laid on the die carried by the lower table. This is raised by the toggle movement, holding the blank between the die and the stationary blank holder, dwelling there while the first operation punch (the outside plunger) comes into action and makes the first draw. This plunger is then given a dwell by the lever mechanism which operates it, so that it acts as a blank holder for the shell in the second operation. This second operation is performed by the smaller inside plunger, which redraws the shell through a second opening in the die. The parts now all separate, and the knock-out comes into action, ejecting the blank so that it may be easily removed.

This press is of very compact construction, and occupies no more room than any double action machine of the corresponding size for second operation work. The floor space occupied over all is 9 feet 3 inches from front to back, and 10 feet 11 inches from right to left. The height from the top of the frame to the floor is 15 feet 9 inches. The machine is geared in the ratio of 21½ to 1. The fly-wheel is 54 inches in diameter and 8 inches face, weighing 2,300 pounds, while the weight of the whole machine is 60,000 pounds. This machine is another evidence of the tendency in sheet metal working to combine operations, and reduce the number of handlings and annealing required for doing a given piece of work.

THE VIXEN MILLING FILE.

In the March, 1907, issue of MACHINERY, was published a brief description of a file of European origin, in which the teeth were of circular shape, and were cut out of solid metal, instead of being raised by chiseling as with the usual process of file cutting. This file is now introduced to the American market as a commercial product under the name of the "Vixen" patent milling file. It is sold by the National File & Tool Co., 205-206 The Bourse, Philadelphia, Pa.

As may be seen in the half-tone, the teeth have a circular form and are cut unusually deep. This form makes them self-clearing—a great advantage, especially on soft metals. The file cuts equally well on soft or tool steel, cast or wrought iron, bronze and other hard metals, and, in addition, will cut brass, lead, aluminum and other soft metals without clogging. It is also useful as a wood or farrier's rasp, as well as for slate, marble, etc. Although its capacity is higher than even a tool of the rasp or bastard order, it does its work with such smoothness and precision that in spite of its great capacity for removing metal, it is adapted to the finest work as well. This is largely owing to the manner in which the teeth are cut, they being left with true, even cutting edges, which leave a smooth surface, producing curling chips more like that resulting from a true cutting action, than that of the ordinary file. The shape of the teeth is such that the file works as well on a greased surface as on a dry one.

Fig. 1. A Smooth Free-cutting File in which the Teeth are cut out of Solid Metal.

The first cost of the Vixen file is somewhat greater than that of the older variety, but it is asserted that on account of the enormuos amount of work it will do and its long life, it is very much the cheapest file on the market. Besides this, it may be resharpened four times, each operation costing about half that of the re-cutting of the ordinary file, and after each resharpening the file is again quite as good as new. In addition to the special shape of the teeth, the capacity of the file is increased by the special process of hardening which is followed, as well as by the high quality of the steel from which it is made. This steel is a special preparation, obtained after exhaustive experiments. The file is made with 9 teeth to the inch for regular work and

12 teeth to the inch for fine work. The latter ranks with the "smooth" file in the matter of finish, though it greatly exceeds it in the ability to remove metal.

WALCOTT 16-INCH ENGINE LATHE.

The new engine lathe built by the Walcott & Wood Machine Tool Co., of Jackson, Mich., is intended to be a plain manufacturing tool, in which the points specially looked out for are stiffness and cutting power. The accompanying halftone illustration, and the line drawing showing a section through the head, and feed mechanism, will enable the reader to judge as to how nearly these requirements have been filled.

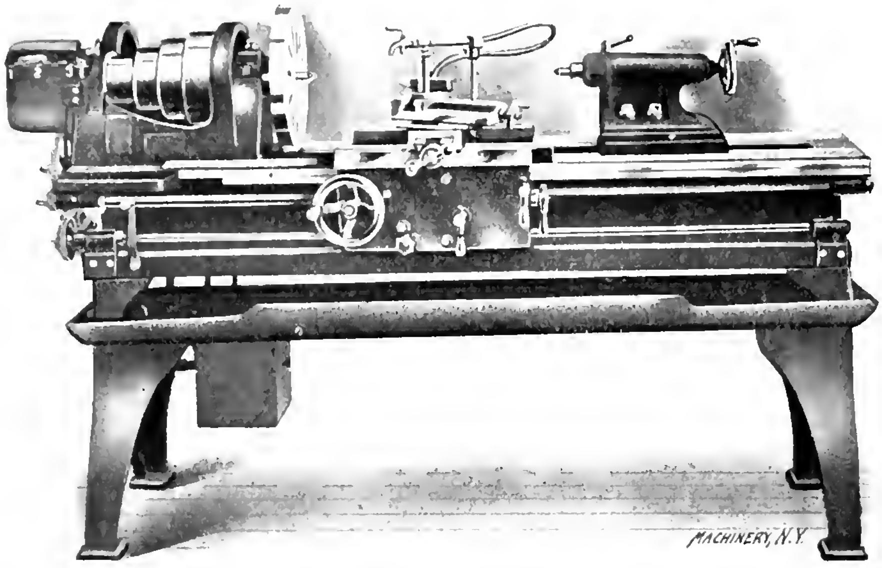

Fig. 1. The Walcott 16-inch Engine Lathe.

As is required for modern conditions, the bed is deep and cross-ribbed at short intervals throughout its entire length. The head-stock is of heavy section, and is rigidly bolted to the bed. A 4-step cone is used, the largest step being 9⅜ inches in diameter and 2 9/16 inch face. The spindle is of high carbon steel, ground, and with a 1 1/16-inch hole through its center. The bearings are of the best phosphor bronze, provided with ample oiling facilities and adjustable for wear. The thrust is entirely taken up at the rear bearing.

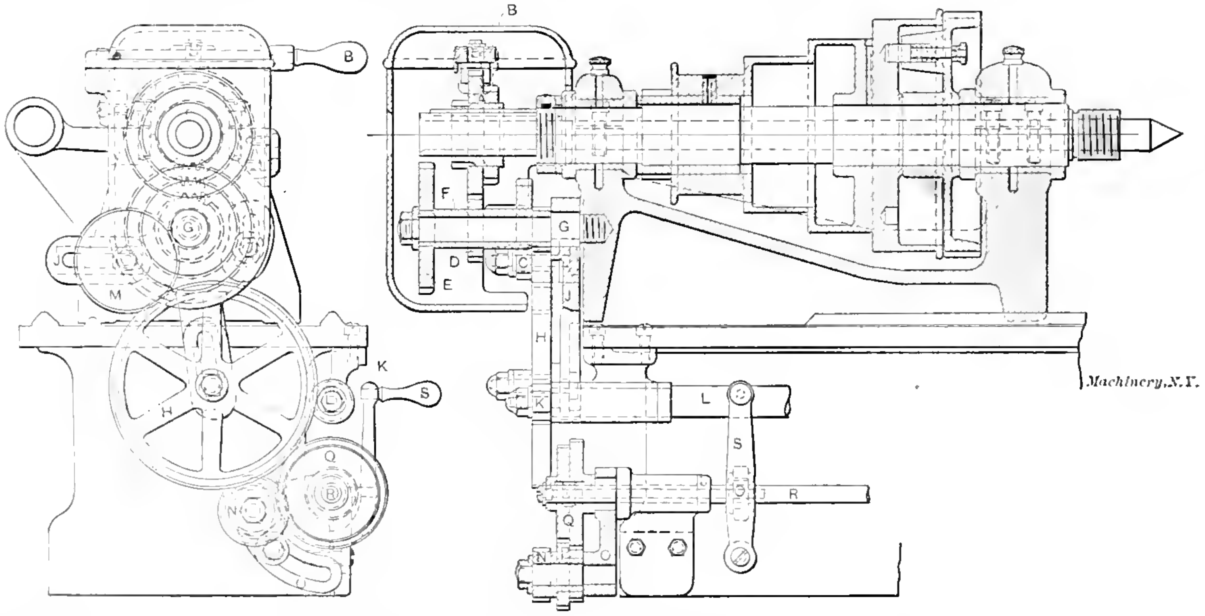

Fig. 2. End View and Section through Head-stock, showing Feed Connections.

Perhaps the principal feature of interest, so far as mechanism is concerned, is the arrangement of the feeds. As may be seen in Fig. 2, the rear end of the spindle is extended to support the triple sliding gear *A*, which, by means of lever *B*, may be shifted to either one of three positions to mesh with gears *C*, *D* and *E*, respectively. These last gears are keyed to sleeve *F*, which runs loosely on stud *G*. For screw cutting, the intermediate gear *H* on quadrant *J* is engaged with pinion teeth cut on the inner end of sleeve *F*, and with the proper change gear *K* on lead-screw *L*. For left-hand threads, intermediate gear *M* is interposed between *F* and *H*. There is nothing to correspond to the tumbler gears of the usual lathe, as the changes for direction of feeds are effected in the apron. For any given change gear at *K*, three threads are available, depending on which of the three positions handle *B* occupies. The thread cutting index provided indicates the position of *B* as well as the change gears used.

While this quick-change apparatus extends the range of screw cutting, it was not primarily designed for this being intended rather for giving a quick control of the feed. When feeding, gear *N* on lower quadrant *O* is thrown into mesh with intermediate gear *H*. To the inner hub of *N* are keyed two gears *P*, meshing with corresponding gears *Q*, which run loosely on the splined feed rod *R*. In recesses in the hubs of gears *Q* are formed clutch teeth, which may be engaged by a clutch blade between them, and manipulated through a sliding collar and an internal rod by hand lever *S*. Two changes of feed are thus obtained, which, combined with the three controlled by lever *B*, gives six in all. This is sufficient for the ordinary range of manufacturing, and makes the machine well adapted to the general run of work, quick change of feeds being much more important in this respect than quick changes for screw cutting.

The carriage is strongly constructed, and has a bearing 22 inches long on the ways. It is securely gibbed to the bed. The longitudinal and cross feeds are driven as explained by the feed rod, independently of the screw. The apron, which is securely bolted to the carriage, is provided with gearing of ample face and pitch to withstand coarse feeds. There is no friction engagement, the drive being positive. Both the longitudinal and cross feeds are reversed in the apron, and the mechanism is so interlocked that the two cannot be thrown in together. The handles and hand-wheels for controlling these, together with those for the clamping arrangement and the throwing in of the half nut for thread cutting, are all on the front of the apron, within easy reach of the

operator. The gearing of the apron is so arranged that one turn of the hand-wheel moves the carriage approximately one inch. This is very convenient in thread cutting, as the lathe can be stopped and the carriage moved back by hand a suitable number of whole turns of the hand-wheel. This being done, the lead-screw nut can be thrown in with the assurance that the threads will match up in the right place.

Special attention is given to the workmanship of these machines, and they are sent out guaranteed to show correctness of alignment within 0.002 inch, in both cross and longitudinal feeds. The beds are made from 6 to 10 feet long, as desired. The 6-foot bed will take 3 feet 3 inches between the centers. The regular equipment includes large and small face-plates, steady and follow rests, compound rest, full set of change gears for cutting threads from 3 to 36 per inch, counter-shaft and wrenches. At extra cost, the lathe will be furnished with an oil pan and pump (as shown in the engraving), or with a taper or relieving attachment.

KIRK STOVE-PIPE ELBOW MACHINE.

The three half-tones shown herewith illustrate an ingenious machine invented by Mr. N. C. Kirk, of Chattanooga, Tenn. The purpose of the machine is the forming of elbows in stove-piping by the crimping process. Unlike other machines for the same work, there are no reciprocating movements whatever in the mechanism, the whole process being a rotary one. This makes possible an exceedingly rapid production, with an almost absolute absence of noise and vibration in the action, which is smooth and continuous.

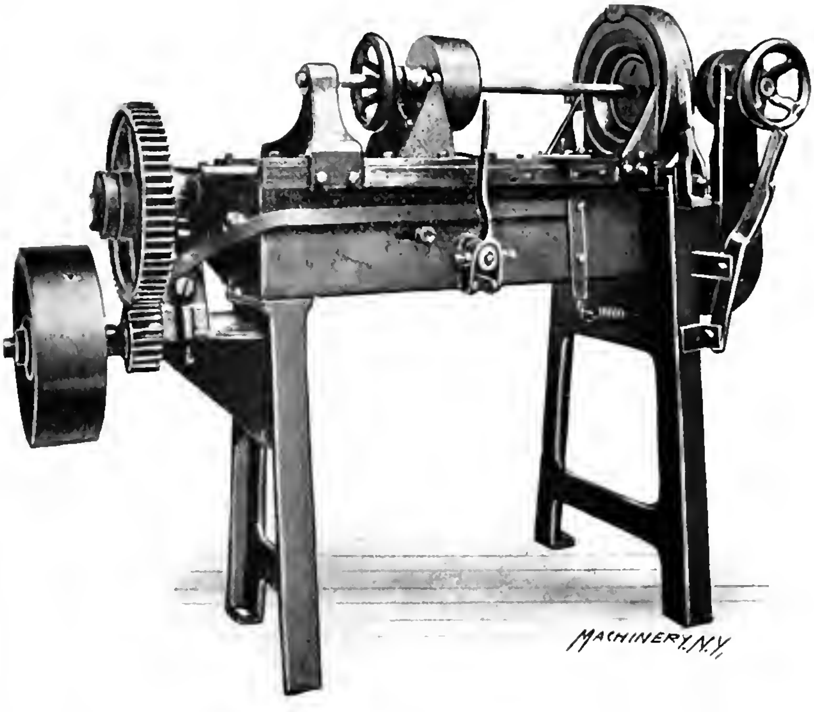

Fig. 1. A Machine for Forming Ribbed Stove pipe Elbows by the Rolling Process.

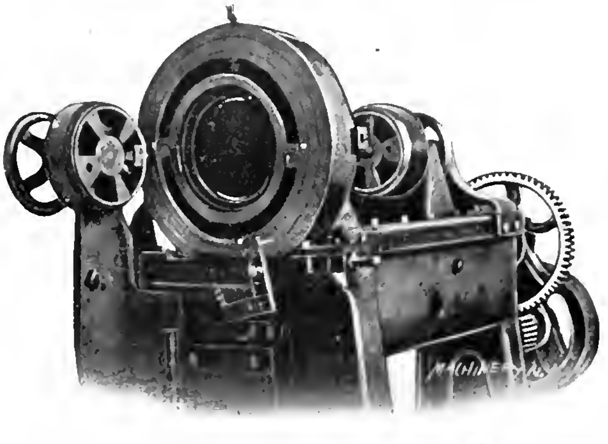

Fig. 2. The Machine Open, ready to receive the Work.

Fig. 1 shows a general view of the machine, Fig. 2 shows the machine with the work in place ready to commence the operation, and Fig. 3 shows the work completed. The power is applied to the pulley shown at the rear of the machine, which, through suitable shafting and gearing, drives a spur gear mounted in the head. This spur gear has an eccentric seat, in which is mounted, on roller bearings, the ring which forms the grooves, the position of this ring being eccentric to the outside of the gear wheel by the depth of crimping required. At each revolution of the gear a crimp is formed. The fact that the crimping ring is mounted on roller bearings, allows it to roll in contact with the work instead of rubbing over it, preventing the shearing action that would otherwise take place.

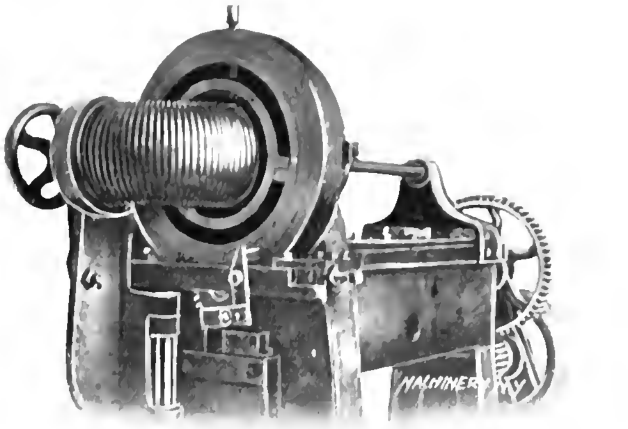

Fig 3. Appearance of Work at the Completion of the Operation note the Swinging Chuck which forms the Elbow to the Desired Radius

The work itself, as shown in Figs. 2 and 3, is held at each end by conveniently operated chucks, so that it does not revolve. The inner chuck is mounted on the sliding bar, while the outer one moves on a swinging support whose radius is equal to that it is desired to give the completed elbow. During the feeding of the pipe, the rear chuck slides on the bar, and the outer chuck swings about its pivot. The feeding is accomplished by the action of the crimping ring, whose axis is set in a position out of parallel with the axis of rotation of the gear which drives it. This angular setting, combined with the rotation, causes the rolling to take place in a helical line around the pipe, advancing the latter a uniform amount for each revolution.

To form an elbow, the operator swings the hinged support with its outer chuck and hand-wheel around in position to receive the end of the blank pipe, which has been slipped through the housing and into the chuck. The two ends are then made fast in inner and outer chucks (the latter being swung in for the purpose) by a slight turn of the hand-wheels. The machine is now started up, and the continuous helical crimp is formed, the pipe being fed out along the desired curve as the operation proceeds. When the correct curvature has been formed, the machine stops automatically with the crimping ring in position to receive another blank, in which position the finished elbow may be easily removed.

DRESES 48-INCH RADIAL DRILL.

The 48-inch radial drill built by the Dreses Machine Tool Co., of Cincinnati, Ohio, has been redesigned throughout, but with particular reference to the driving mechanism. The back gears and clutches for stopping and reversing are now mounted on the spindle head instead of on the arm at the back of the column. This makes it possible to arrange the controlling handles in considerably more convenient locations for machines of different sizes than was previously possible,

and at the same time permits the use of high-speed shafts with low torque to a point in the drive very close to the drill itself. Other features of the machine are the double column with the stationary stump carried very nearly to the top of the outer sleeve, and the gear box which, in combination with the back gears, gives 14 rates of speed, and may be changed with ease while the machine is running. This is due to the fact that the variable speed shaft, if not connected with a higher speed, runs constantly at a speed determined by the lowest ratio of the change gears. The pilot wheel for the quick return movement has four handles, any one of which may be used as a lever for operating the clutch connecting the worm-wheel with the pinion shaft. The machine gives a general appearance of ruggedness and extreme simplicity, especially when the number of movements and adjustments provided, is considered.

LANCASTER OVAL TAPER DRILL SOCKETS, AND LATHE ATTACHMENT FOR PRODUCING THEM.

The Lancaster Machine & Knife Works of Lancaster, N. Y., is selling a new style of twist drill socket which, it would appear, overcomes most of the difficulties met with in driving taper shank twist drills. The great difficulty in doing this, as is well known, is in preventing the tang of the drill from twisting off under the heavy service to which these drills are subjected under modern conditions and with modern tool steels. In the case of the Lancaster socket, the taper shank of the twist drill is oval in section throughout its length, and approximately a corresponding taper oval hole in the socket. When so made, there is no way for the drill to slip, the only possible accident being the breaking of the drill itself, due to an over strain.

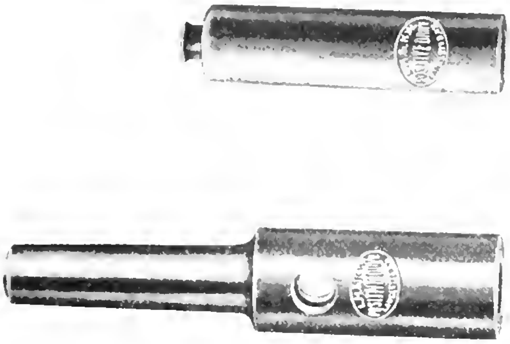

Fig. 1. Lancaster Oval Taper Drill Sockets, which obviate the Use of the Tang

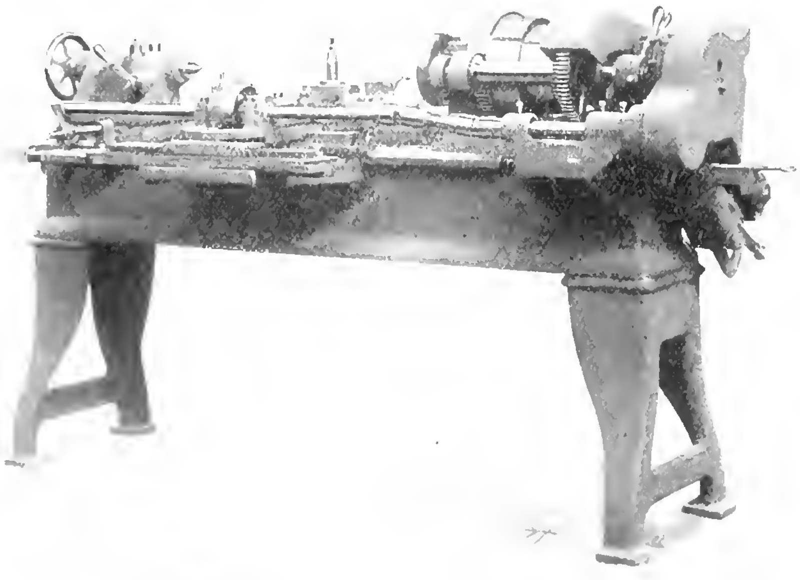

Fig. 2. Lodge & Shipley Lathe fitted with the Lancaster Attachment for Turning and Boring Ovals and other Irregular Shapes.

In the upper part of Fig. 1 is shown a reducing socket with an external and internal taper, both oval in section. A knock-out pin is provided, as shown, for forcing out the drill from the socket without injuring it by raising a burr or otherwise. The lower socket is provided with a shank and is of the usual form, the drill being removed by a drift inserted in the cross hole.

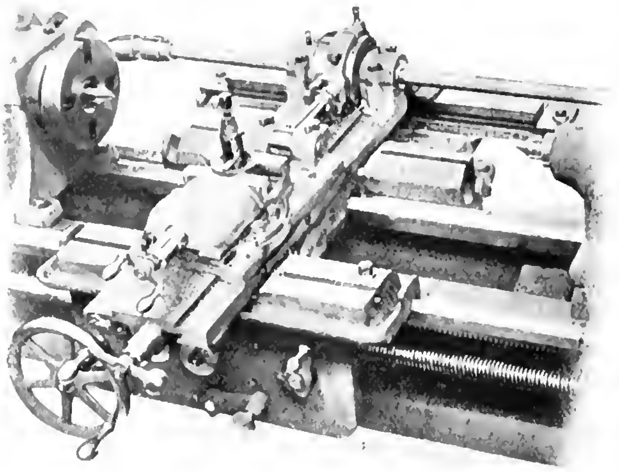

Fig. 3. Rear View of Lathe fitted with Irregular Turning and Boring Attachment.

A lathe built by the Lodge & Shipley Machine Tool Co. and equipped with a Lancaster attachment for turning ovals and other odd shapes, is shown in Figs. 2 and 3. The taper sockets are produced on lathes so arranged. The device consists essentially of a shaft carried in bearings at the rear of the bed, connected on one side by change gearing to the spindle, and on the other by a telescopic shaft to an eccentric on the cross-slide, the eccentric being arranged to reciprocate the tool-post in unison with the rotating of the spindle, thus producing the form desired. The change gearing between the lathe spindle and the attachment may be arranged in the ratio of 1 to 1 for eccentrics, 2 to 1 for ovals, 3 to 1 for 3-lobed cams and 4 to 1 for square sections. Increased ratios may be used for polygons of greater numbers of sides. The eccentric is double, the inner and outer members being rotatable on each other so as to vary the throw at will from zero to ½ inch. A graduated disk is provided showing the throw obtained. For special work special eccentrics may be provided for any desired travel of the slide. Solid eccentrics (not adjustable) may be substituted for the arrangement described above for producing duplicate work in quantities.

The tool-post is mounted on a supplementary slide, dovetailed to the carriage, and under the control of the taper attachment. This supplementary slide has cast to it brackets for the bearings of the sleeve on which the eccentric is mounted. The eccentric rod reciprocates the tool-slide, on which the tool-post may be adjusted to the diameter of work required. The main cross-slide screw operates the supplementary slide.

The lathe shown is equipped with a taper attachment. For round taper turning, the driving shaft of the attachment on the back side of the lathe is disconnected from the spindle, while for plain straight turning the block is disconnected. When this is done the lathe may be run as an ordinary engine lathe. When boring or turning to shape, and using the forming device with or without the taper attachment, the work is done with the same precision and with as little extra care is in turning or boring round surfaces, the whole mechanism being positive and taking care of itself without attention. All the wearing surfaces of this attachment are provided with ample oiling facilities. A depth gage is fitted to the compound rest screw, so that all diameters can be easily and positively duplicated in boring or turning. A gage is furnished for locating the point of the tool for all cutting conditions.

Besides the sockets shown in Fig. 1, other examples of the use of the attachment are shown in Fig. 4. These examples include a series of oval taper shank sockets, inserted one within the other, and a 3-lobed coupling joint, which may be used in the same way as the universal joint common in rolling mill practice. The builders claim that the device is applicable to the making of drives of all kinds, doing away with keys, set-screws, splined shafts and other holding devices. By using the squared design with the ends of the shafts tapered, a square positive coupling drive is procured, free from projecting set-screws and other objectionable features, and one that can be separated quickly and put together again without the necessity of re-facing. The hubs of gears may be bored to a square outline to fit correspondingly square turned shafts. Milling cutters, shell reamers and other tools at present held in place by keys, may also be fastened to their arbors in a similar way. This will avoid much loss from cracking in hardening, due to the weakness in this respect of the sharp corners of the key-way, as at present used.

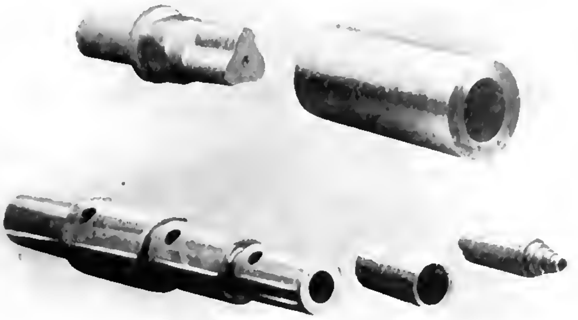

Fig. 4. Samples of Turning and Boring produced by the Attachment.

KEUFFEL & ESSER TAPES WITH KECO FINISH.

The Keuffel & Esser Co., 127 Fulton St., New York, has recently applied a new finish to its line of steel tapes. The illustration shows their Liliput steel tape photographed to show the excellent contrast given by this new finish, known as the "Keco." It will be seen that the figures may be plainly read, the numerals and graduations standing out brilliantly and clearly upon a jet black background. Another advantage of the finish is the fact that it is not injured by exposure to moisture, as rusting is impossible. Its brilliancy is also not marred by handling with moist hands, as is the case with many other methods of finishing.

Fig. 1. The "Liliput" 25-foot Steel Tape; note the Legibility of the Graduations.

The tape shown gives a length of 25 feet in an exceedingly small space. It is known as the "Liliput." It is provided with the maker's compensating centers, which may be adjusted for wear after long use, so as to give just the friction required for the proper winding and unwinding of the tape. This results in materially longer life for the latter.

POWER FEED FOR HOEFER 16-INCH DRILL.

The Hoefer Mfg. Co., Freeport, Ill., has recently designed a power feed for its line of 16-inch drills. This power feed is shown attached to one of these drills in the accompanying engraving. As will be seen the arrangement adopted is rather original and very simple.

The proper ratio for reducing the movement given by the driving shaft to that required for the feed, is obtained by two sets of worm gearing in series. The worm mounted on the driving shaft engages the worm-wheel keyed to the upper end of the vertical shaft, which is supported in a bearing fastened to the upper tie-bar of the frame. The lower end of this shaft carries a 3-step cone, which is belted to a corresponding cone, supported on an arm pivoted to the frame. This second cone is keyed to the shank of a worm, which engages the worm-wheel on the rack and pinion shaft. The engaging or disengaging of the worm is effected by swinging the arm on which it is mounted in towards the worm-wheel or away from it. In the engaged position it is held by a catch operated by a lever, which may be automatically released by an adjustable stop on the spindle sleeve; the depth drilled with the power feed is thus automatically gaged. The tension of the belt on the cone pulleys pulls the worm out of engagement as soon as the trip is released. The rates of feed given with this arrangement for the 16-inch drill are 0.005, 0.008, and 0.012 inch per revolution of the spindles. This has proved to be a suitable range for this size of machine. The convenience of the lever feed has not been sacrificed in attaching this power connection, as the right hand is free to use the lever as before.

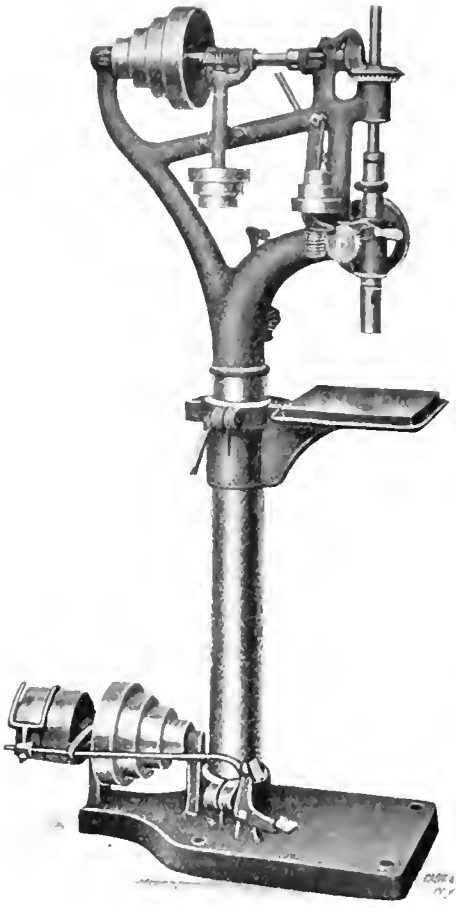

Fig. 1. Hoefer 16-inch Drill arranged with Power Feed.

NOYES VERTICAL T-SQUARE.

The Emmert Mfg. Co., of Waynesboro, Pa., has undertaken the manufacture of the Noyes vertical T-square, which is shown in the two accompanying illustrations. This instrument, which is very well described by its name, comprises a T-square, guided at the top of the board, and provided with a protractor adjustable to any position along its blade. The protractor is arranged with right-angle graduated arms, so as to avoid the necessity for loose scales, thus making the device especially convenient for vertical use.

A round steel track is fastened to the top of the drawing-board. The head of the T-square forms a truck, provided with a set of four rollers which run on and are guided by this track. One pair of the rollers is beveled, and runs on ball bearings, so arranged that the weight of the head holds it down on the track with no lost motion, making possible a

very free and sensitive movement. The head also carries a spring balanced drum to which is attached a cord supporting the vertical sliding protractor, holding the latter to the blade and counterbalancing it. As the protractor is also guided by rollers, it thus has a very sensitive vertical movement. It will be seen that this combination of protractor and T-square makes provision for motion in accurate horizontal and vertical lines.

Pivoted to the sliding protractor is a forked arm, to which interchangeable scales are attached at right angles to each other. This arm is provided with a worm, which engages notches cut on the rim of the protractor, and which can be quickly pressed out of engagement therewith. These notches are spaced 3 degrees apart, thus making possible instantaneous setting of the protractor to any multiple of 3. This includes all the most commonly used angles as 0, 15, 30, 45, 60, 75, and 90 degrees. This 3-degree angle is convenient also in that it is a common draft to give to patterns, and is suitable for the conventional angle used for showing screw threads. For the finer adjustment, the neck of the worm has a graduation of 12 divisions, each of which represents $\frac{1}{4}$ of a degree. Thus, readings are easily made to as fine a scale as $\frac{1}{4}$ of a degree, which is as close as is ever needed in drawings. Interchangeable scales are provided which may give any desired graduations.

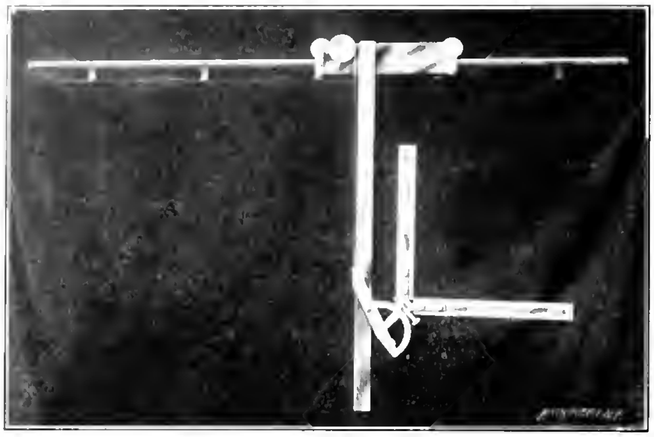

Fig. 1. A T-square which is guided from the Top of the Board and is provided with an Attached Protractor having Adjustable Scales.

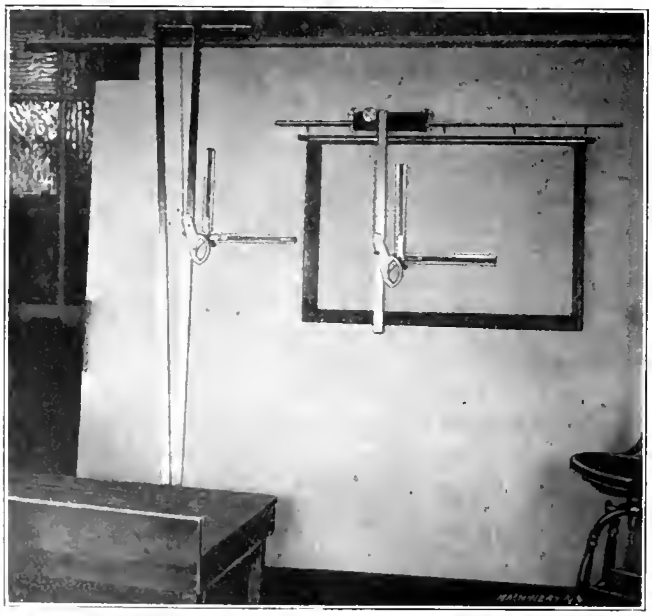

Fig. 2. Two Sizes of the T-square, showing the Application to Small Drawing Boarda, and to Vertical Boards of Great Size.

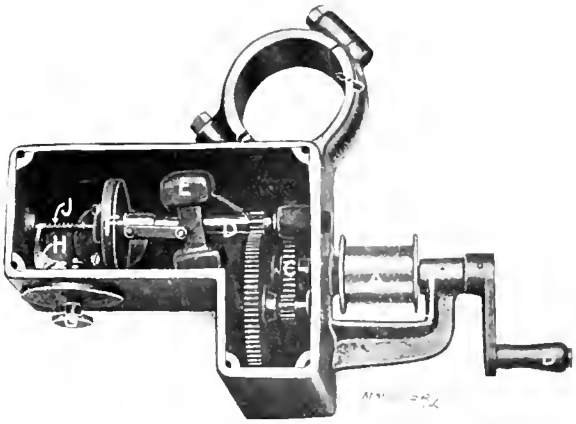
Fig. 1 shows the instrument itself, which may be seen applied to the smaller board in Fig. 2. In the latter illustration is also seen a modification of the T-square for use with boards of large size, that in question accommodating a drawing 6 x 10 feet. The use of such boards is a great convenience, as it is possible to make full-sized drawings of a large machine with the same ease, accuracy and speed as on a 24 x 36-inch board. Full sized assembled drawings, with each part standing in its natural and normal life-sized position, furnish almost the same advantages as a model. With such a layout the location of the operating mechanism and the handles can be tried, and their convenience and accessibility can be determined. A more accurate scale layout is always possible also when a full-size scale is used.

The use of the instrument is by no means confined to the vertical position, it being equally suitable for use on smaller boards in the ordinary horizontal or inclined position. One of its greatest conveniences, however, is the fact that it may be so readily used on the vertical board as to do away with the inconvenience of holding triangles, scales, etc., on the awkward vertical surface, all these instruments being combined in this one. The advantages of the vertical board are thus made available. Owing to the vertical position of the T-square, it may be made much shorter than when it is guided from the left-hand side of the board, thus resulting in greater accuracy. The device does not take up much room outside of the board, it being necessary to extend the track beyond its ends but a few inches.

GOVERNOR FOR BUCKEYE BLUE-PRINTING MACHINE.

The Buckeye electric blue-printing machine manufactured by the Buckeye Engine Co., Salem, Ohio, is of the type in which the tracing to be copied and the blue-print paper are wrapped around a stationary vertical glass cylinder and held there by a convenient rolling curtain while an arc lamp is lowered through the center of the cylinder at the proper rate to give the length of exposure required to make the desired print. In the older machines, with which most of our readers are familiar, the rate of descent of the lamp and the consequent length of exposure of the sensitized paper was regulated by an adjustable pendulum controlling an escapement, the whole being operated by the weight of the lamp. This device has been superseded by the mechanism shown in the accompanying engraving, which employs a governor to give the speed of descent required.



Blue-printing Machine Governor for Controlling the Movement of the Lamp.

The cord which supports the lamp is wound around drum *A*, which, with the attached crank, serves as the means for raising the lamp at the conclusion of the exposure, in preparation for a new one. Inside of the casing shown, and mounted on the same shaft which carries drum *A* and crank *B*, is a gear *C*. This, through the intermediate gearing, rotates governor spindle *D* at a considerable velocity, the ratio of the geared connection being high. The governor *E* consists of a double weight, connected with arms, and pivoted at center of the spindle. Normally the spring at the right of *E* draws the governor to the outward position, pressing disk *F* (by means of the links shown) down against a bearing in a stationary bracket at the left, which also serves as the outer bearing for the shaft. Disk *F* being splined to the shaft, the friction between it and the stationary surface, under the influence of the spring, is sufficient to prevent the rotation of *D*. The lamp is thus held in a stationary position. On the front of the case is a knob *G*, provided with a pointer indicating graduations on the circular dial shown. *G* is connected to a small worm which meshes with seg-

mental worm-wheel teeth cut in the lower arm of lever *H*. The upper arm of this lever encircles a push-rod *J*, and bears on the lower end of the coiled spring shown mounted on it. *J* passes through the stationary friction bracket into a hole in spindle *D*, where it bears against the cross-pin by which the links are fastened to *F*, and by which *F* is keyed to *D*.

It will be seen that the spring on *J* tends to force *F* away from its stationary seat against the influence of the spring attached to *E*, and that this pressure may be varied by the manipulation of knob *G*. When the pointer on *G* is set at zero, the spring on *J* is released, and that attached to *E* has its full effect in preventing rotation of the parts. As the pointer is turned around to increase the pressure of spring *J*, *F* is raised further from its seat, allowing the spindle to revolve until it has attained such a speed that the governor again forces the disk down to its bearing.

The rate of movement of the lamp will thus be maintained at a point corresponding with that position of the governor balls which just barely allows the friction surfaces to rub on each other, with the spring pressure provided. This spring pressure may be varied by knob *G*, which consequently furnishes a means of adjusting the speed. The dial permits the determination of the proper rate of printing for any given paper and given conditions. This rate may be duplicated with certainty at any time without having to go to the trouble of making trial printings.

This device gives a greater variety of speeds than the older method, being capable of the most minute adjustment. It is noiseless and eliminates all jerk and jar from the lamp, thus greatly increasing the life and efficiency of its mechanism. The whole apparatus is enclosed, free from dust and dirt, in an iron box, which is clamped to the frame of the blue-printing machine at any height to suit the convenience of the operator.

AN ADDITION TO THE SLOCOMB LINE OF MICROMETERS.

The accompanying illustration shows six new micrometers which have been added to the line made by the J. T. Slocomb Co., Providence, R. I. They measure all sizes from 13 to 19 inches, inclusive. The heads are provided with the well-known adjusting arrangement provided with all of this line of micrometers.

Set of Slocomb Micrometers, measuring from 13 to 19 Inches.

The six instruments are furnished with the stand shown, which will be found very convenient for use in the tool-room, a board being provided with hooks for checks, to indicate the numbers of the workmen who borrow them. The base of the board forms a compartment for a set of end measures from 13 to 18 inches, increasing by 1-inch steps. They are 7/16 inch in diameter, and are fitted with rubber grips to avoid changes in length due to the heat absorbed from the hands in making measurements.

AMERICAN GAS FURNACE CO., 24 John St., New York. Gas furnace for hardening with barium chloride. This furnace is especially adapted to the use of this form of hardening bath. The crucible is set into the furnace and sealed, in such a way as to prevent the gas flame from attacking the liquid in the crucible, and thus generating noxious fumes.

JOHN H. DORMAN, 1 Bethune St., New York City. Tapping attachment for use in sensitive drill presses. It will drive taps up to and including 3/8 inch in diameter. A stop is provided which, when the desired depth of tapping has been reached, reverses the spindle and backs the tap out. A friction device has been incorporated in the attachment.

CLEVELAND AUTOMATIC MACHINE CO., Cleveland, Ohio. Motor drive for screw machines. This company provides its screw machines, if required, with motor drives entirely self-contained. The motor is placed at the end of the machine, four posts extending upward from the corners of the frame for the support of the counter-shaft to the machine, which is thus independent of any hangers on the ceiling.

WESTERN RAIL SUPPLY CO., Chicago, Ill. Pneumatic vise of simple and rigid construction. On account of its quick and reliable control it can be used not only as a vise, but as a metal former, punch or forcing press, shear, riveting machine, or bull-dozer. The air-cylinder is cast solid with one jaw and the base of the vise. The piston rod is a solid casting carrying the other jaw of the vise.

THE CINCINNATI SHAPER CO., Cincinnati, Ohio. Heavy 24-inch crank planer. This machine is driven by a positive crank motion of Whitworth type so as to secure a quick return. The cross rail is provided with a head which swivels on each side of the vertical, the angle being read from graduations in degrees. The machine will plane 20 inches high, 20 inches wide and has a 24-inch stroke. It is built with a solid base resting on the floor, and weighs 5,500 pounds.

JOSEPH T. RYERSON & SON, Chicago, Ill. A portable automatic key-seating machine, especially designed for cutting key-ways in locomotive axles, either before or after the engine has been assembled. This machine is operated by an air drill or electric motor, as most convenient. An end mill is used, carried by a slide which reciprocates continuously over the length of the key-way, while the mill is slowly fed in until the desired depth has been reached.

THE WESTINGHOUSE TRACTION BRAKE CO., Pittsburg, Pa. A line of belt-driven air compressors for industrial service. These compressors are made in four sizes, having 15, 26, 44½ and 54½ cubic feet of free air per minute capacity, respectively, at standard speeds. The horse-power for these sizes at 100 pounds pressure is 3, 5, 9 and 11, respectively. They are provided with water jackets, but may be operated without if required. This compressor is of the duplex, horizontal, single-acting type, and is easily portable.

BARDONS & OLIVER, Cleveland, Ohio. Motor driven brass working lathe, in which the motor is mounted directly on the spindle. The controller provided is of the reversible drum type, and has an automatic brake, so that the lathe is brought to rest as soon as the power is shut off, though the controller may be set to allow the spindle to be easily turned by hand when desired. The spindle is reversed by the controller for threading in less time than is possible with a belt. Twenty changes of speed are provided, ranging from 300 to 1,400 revolutions per minute in either direction.

GRAPHLIO A NEW GRAPHITE PRODUCT.

A new form of graphite has been placed on the market by Walter D. Carpenter Co., 39 Cortlandt St., New York. This product is of crystalline structure, but ground to a degree of fineness hitherto unattained except with the amorphous form of the same material. The superior toughness and adhesiveness of the flake or crystalline condition make it very difficult to grind, and it is claimed that until recently it has been impossible to reduce it to the impalpable powdered form which would be most effective for practical application. In grinding the graphite to this condition the operation introduces into the material a considerable quantity of fine grit—waste from the stones used for producing the material. Only a part of this grit could be removed, the process usually adopted being that of "blowing," on the same principle that chaff is separated from grain by winnowing. By a process developed by the manufactnrer of Graphlio, the grit produced by grinding this tough flaked graphite to an impalpable powder is so fully gotten rid of that it is impossible to detect its presence in the finished product, thus making a very superior article for the lubrication of the finest and most closely fitted bearings.

Still another characteristic of Graphlio is the fact that it has been so treated that it will remain suspended in light oil practically indefinitely, and thus may be used in any system of oil piping or lubricators already installed, without requiring any special appliance to be furnished for using it. This permits also the continuous application by sight devices, instead of requiring a troublesome periodical application by force pump or otherwise. It is of the highest commercial purity, containing about 95 per cent carbon and 5 per cent silicate, having thus in a high degree the characteristic advantage of the crystalline over the amorphous form—the latter having usually a large proportion of foreign substances combined with it (such as clay) which it is difficult, if not impossible, to remove. Particular attention is called to its freedom from grit. This may be tested by rubbing a small quantity of it on a hard surface, like a glass plate, with a paper knife or any other convenient implement. The substance is so inexpensive that it adds very little to the cost of a gallon of oil, while it is said that its use will decrease the amount of oil used from 40 to 50 per cent, thus resulting in a marked saving in the cost of lubrication.

* * *

As an interesting example of the working of the true mathematical mind, the case of Prof. Akerlund, of the Boras Technical College. Sweden, who lately died, may be mentioned. In many particulars this man resembled Lord Kelvin, and he was well known in mathematical circles in Scandinavia. His former instructor in mathematics stated that, while at high school, after the first principles and the object of trigonometry and analytical geometry had been verbally explained to him, he worked out and became proficient in the fundamental theories of these two subjects without the aid of any textbooks whatever. While at the university he studied philosophy, but as a true mathematician he would accept nothing which he did not understand, and as he found that the learned text-book in logic used there was beyond his own comprehension, he would not admit that it was founded on real logic, and finally made the professor of the subject himself admit that he, too, did not comprehend the particular subject as tanght. This is the supreme test of the true mathematician. He accepts nothing as fact unless he can comprehend or prove it. In this connection it may be interesting to note that Akerlund, while still at school, constructed an electric motor simultaneously with Gramme. Gramme, however, brought his invention first before the public eye and consequently the credit of being the inventor of the electric motor has been accredited to him.

* * *

Commencing October 1, the postage rate on letters mailed in the United States addressed to places in Great Britain and Ireland, will be 2 cents per ounce or fraction thereof. Letters mailed without postage will be forwarded to their destination, but double the deficient postage calculated at the 2 cent per ounce rate will be collected from the recipient upon delivery.

AN AMERICAN MECHANIC IN EUROPE—6.

A SERIES OF LETTERS FROM OSKAR KYLIN ON THE EDITORIAL STAFF OF MACHINERY.

STOCKHOLM, SWEDEN, August 12th, 1908.

The commercial situation in Sweden at the present time appears to be somewhat discouraging. The wave of industrial depression which began last fall in the United States, reached Sweden later than the larger European countries, and consequently the improvement in conditions will doubtless commence somewhat later as well. The machinery dealers who handle largely foreign machines—American, English or German—feel the depression most keenly. The Swedes are patriotic by nature, and, therefore, prefer to buy the products of home industry, other conditions, such as price, quality, etc., being about equal; as a consequence, the importers of foreign products received the first and hardest shock in the financial and industrial depression. The greater number of the works visited here are still working full time, though some of them are building for stock.

The industrial depression in Sweden has, however, also a local cause. The labor unions have during the last few years become very powerful and have time and again, with more or less success, tried to better the conditions of the working people. This summer a dispute arose between the men and employers in some shops, and a strike was declared. The questions involved were rather complex and it appeared at one time as if all the Swedish industries would be drawn into the conflict, and the Employers' Association threatened a general lockout affecting the whole organized force of labor of the country. At the very last moment, however, this extreme step was prevented, and temporary peace, at least, restored. The feeling of unsafety which this state of affairs naturally brought about, had a very demoralizing influence on industry in general, and firms neither dared to take or place an order. The restored peace, however, it appears, has also restored confidence, and already signs are visible of a considerable revival in the industries.

The sales of American machine tools in Sweden are stated to be on the decrease as compared with the sale of other machine tools. Germany, being near to this territory and being in possession of a better knowledge of local conditions, is a very able competitor with America; and the Germans also have the advantage of shorter shipping distances, and can, consequently, deliver their machines more promptly, and, at the same time, the freight charges are smaller. English machinery is also sold to quite a large extent in Sweden, and the competition on the part of the home manufacturers is making itself more and more keenly felt. A few Swedish machine builders are beginning to specialize on standard machine tools to a considerable degree.

Noteworthy Swedish Works.

The largest of the works located in Göteborg is Lindholmen's Mekaniska Verkstad. These works are largely devoted to the shipbuilding trade, and are equipped with some very large docks for the purpose. Many of the vessels for the Swedish navy are built here, and one was under construction at the time of the writer's visit to the plant. The shops are also equipped for building engines and boilers, and for sheet metal work in general. The boiler department is well up to date and equipped with the most modern machinery, but the machine shop is less modern. The most notable work in the hands of the company at this time, perhaps, is the construction of one of the large railway ferryboats ordered by the Swedish government for the traffic between Sweden and Germany. This boat, which is to ply between Trelleborg, Sweden, and Sassnitz, Germany, a distance of some 65 miles, has a capacity of from 15 to 18 railway cars in addition to spacious accommodations for the passengers. The length of the ferryboat is 348 feet, the width being 48 feet.

One of the best-known of the Swedish mechanical works is that of Nydqvist & Holm, Trollhättan. This firm has gained a high reputation in locomotive building, most especially for the high quality of workmanship and careful design of its product. A large number, perhaps, in fact, the largest number of all the locomotives used by both the state

railways and the private roads in Sweden, are made by this concern. For some years past, the firm has also made a specialty of air compressors and pumping machinery, and is, at the present time, starting out in still another line of machine building—that of building gas engines. Sweden has no coal deposits worth mentioning, but is instead in possession of large quantities of peat. The company is now carrying on extensive experiments with a view to using peat in gas producers for the motive power of gas engines. It is stated that there have been some difficulties in connection with these experiments in regard to the gas purifying apparatus, but it is said that the company has been able to eliminate all the difficulties which have arisen; the results of the experiments, however, are still kept secret. A large new machine shop has recently been erected by the firm, which is to be used in addition to the old shops, the latter being too small for the growing business. The new shop is splendidly lighted, and equipped with up-to-date heavy-duty machine tools and large electric traveling cranes. The electric welding process is employed in these works and gives very satisfactory results. It is used largely for mending and welding castings, and it is stated that the welded joint is as strong as the unbroken piece. On account of the large amount of current consumed by the process, it is only run during the night, when there is but little load on the generators.

A remarkable piece of work now in course of construction in these works, is one of the two large water turbines, each of 12,500 H. P., for the government power generating station at Trollhättan. The utilization of the Trollhättan falls by a large government power station, which will ultimately also furnish power for part of the electrified state railways, has previously been, from time to time, referred to in MACHINERY. When complete, the present station will have 8 turbines, each of 12,500 H. P., or a total of 100,000 H. P. Only four units are, however, to be installed at the present time, and the others will be installed as the demand for power increases. The required canal, the tunnels and the buildings, are at the present time built large enough to take care of the ultimate capacity. The energy is transformed by exceptionally large generators into three-phase, 25 period, alternating current of 50,000 volts tension. The current is to be utilized partly by factories within easy reach of the power station, and partly by neighboring cities and towns for lighting purposes. In the future, of course, when the electrification of the state railroads has been carried through, the greater part of the power will be consumed by these. The power plant is planned to be ready January 1, 1910.

A concern which for some time past has been devoting itself exclusively to the building of machine tools, is Lidköpings Mekaniska Verkstad, Lidköping. While this firm largely specializes on lathes, it does not devote itself exclusively to this one line in the American sense of the word specialization, but builds also a large number of other types of machine tools, such as drills, planers, boring mills, etc. This firm's machines, although not of so highly developed design as American machine tools, are strong and powerful, and, apparently, of good workmanship.

The Motala Mekaniska Verkstad, Motala, is one of the largest works in the country, employing about 1,000 men. These works are equipped principally for the making of marine engines, boilers and locomotives, and for bridge building, and have recently commenced to develop a line of oil engines. The concern is old and well established, and commands a skilled and well-trained staff of officers and men, and to the skill of the workmen, rather than to the employment of high-grade tools, must be credited the high class of work produced. Besides the regular machine shops, there is also a small rolling mill plant largely for the individual needs of the shop, and a well-equipped forging shop for heavy forgings. The company also makes the larger portion of its own locomotive accessories.

Without question, the best and highest developed of the Swedish machine tool firms is the Köpings Mekaniska Verkstad, Köping. This is a medium-sized concern which during the course of the last few years has specialized on lathes of large and small types. The largest types of machines are usually built to order, but medium sizes are often built lots of from six to twelve and smaller ones in lots of twenty at a time. Following the practice of most other European works, the company, however, makes also a few other machine tools, such as planers milling machines, drills, etc. but the building of these machines is more or less spasmodic depending upon the variations of demand in the lathe business. A very high class of machine tools is employed in these shops, and the works are conducted according to the most modern methods. Recently some of the latest styles of American grinding machines were bought and introduced into the shops, and the company is commencing to use the latest American methods in grinding; electric chucks are used to a large extent in connection with the grinding machines. An increase in trade is expected by the company in the near future, and an enlargement of the works is therefore contemplated.

A firm which is known outside of Sweden as a machine tool building firm of repute, is Nya Aktiebolaget Atlas, Stockholm. This firm has developed a number of original designs of machine tools, such as drills, milling machines, boring mills, gear-cutting machinery, etc. During the last few years, however, its manufacture of machine tools has gradually diminished, partly because of the keen German competition. The firm is still engaged in this work, but only to a small extent, its efforts being directed toward the locomotive and railway car building industry. The firm is also building steam engines, air compressors, pneumatic tools, railroad bridges, etc. On account of the high price of land in Stockholm and the consequent high living expenses and high wages, the company is contemplating moving the works to a town a few miles out from the city. The first portion of the shops will probably be moved in about a year, and the remainder later, according to the conditions of the trade.

* * *

FIRE RISK IN LOWER NEW YORK CITY.

Owing to the concentration of enormous buildings, the lower end of Manhattan Island is regarded by insurance experts as a very dangerous fire risk. Mr. William McCarroll, president of the New York Board of Trade and Transportation, has published a letter from Mr. P. F. Schofield, in which the danger is vividly pointed out. Mr. Schofield states that the area of Manhattan Island between 14th St. and the Battery is about equal to the area of Chicago, swept by the fire of 1871 in which the property loss was $170,000,000. The assessed valuation of the improvements on this section of New York is over $400,000,000, and the merchandise housed in these buildings brings the valuation up to more than $1,000,000,000. One warehouse alone in this district is said to have stored at one time merchandise valued at more than $50,000,000. It is no wonder then that the wholesale dry goods district of Manhattan is the "nightmare of the insurance world." A conflagration in this section of New York, on the scale of the Chicago fire, would wipe out property values unparalleled, and the effect of such a disaster would not be limited to the metropolis or to New York State. It would be felt in every city of the union, and in the Old World as well. The geographical situation of Manhattan Island, between two rivers, and the narrow cross streets, make the condition very favorable to the spread of a fire, especially when it is considered that winds attaining velocities of forty to fifty miles an hour in combination with a temperature below the freezing point, are not unknown. Take such a situation, with insufficient water pressure, and the possibility of a fire that would be unparalleled in property destruction in the world's history is not so remote as it might be. Should such a fire gain headway, the towering piles of architecture that dominate Broadway, and which are considered impregnable to fire would, in no small measure, add to the conflagration. The streets would be converted into artificial tunnels and canyons, acting like funnels or blow pipes to fan the flames when they had once gotten beyond the control of the fire department, and the flames would leap from building to building far above the puny streams that the fire engines and water towers could throw.

OBITUARY.

Harris Tabor.

Harris Tabor, of the Tabor Mfg. Co., died July 29, 1908, at his home in Philadelphia, his death being the result of an automobile accident which occurred on July 4 of last year. He was on his way to visit friends when the heavy machine in which he was riding was overturned by the shifting of the soil of the narrow hillside road they were following. He was caught beneath the overturned machine and seriously injured, and was confined to his bed until the first of September, shortly after which he resumed his duties at the Tabor Mfg. Co. His improvement was slow, and in March he contracted a severe cold which early in May forced him to again take to his bed. This, together with his weakened condition, brought about his death.

He was born in Clarence, Erie County, New York, on January 26, 1843. At the age of 21 he enlisted as a private in the Civil War for a term of two years. He was honorably discharged and mustered out of service at Elmira, N. Y. He began his mechanical training as an apprentice in the shop of his brother, Leroy Tabor, Sr., at Tiago, Pa., where he remained two years previous to his enlistment. After leaving the army he went to work as a machinist with S. Payne at Troy, N. Y. From there he went to B. W. Payne & Sons, Corning, N. Y., and when this company moved to Elmira, he was made superintendent. In the early 80's he moved to Hartford, Conn., to assume the position of superintendent of the Hartford Steam Engine Works. After a year here he went to Pittsburg as superintendent of the Westinghouse Machine Co., where he remained for three years. During all this time his work had been specialized in the line of steam engineering. The well-known Tabor governor and Tabor steam indicator were invented and placed on the market during this period The former was sold to, and is now being manufactured by, the Ashcroft Mfg. Co.

While with the Westinghouse Machine Co. he became interested in foundry work, and conceived the idea of a power operated molding machine. For furthering the development of this idea, he associated himself with Manning, Maxwell & Moore, and later resigned his position in Pittsburg and took up quarters in New York, where he could give the development of the molding machine his full attention. In 1888 he placed on the market the first successful power molding machine, operated by steam, through an over-head cylinder In the fall the manufacture of the machine was transferred to the Pond Tool Works, Plainfield, N. J., and continued there until the early 90's when the Tabor Mfg. Co was organized, and the manufacture of the machine transferred to Elizabeth, N. J., where the vibrator system of molding and the first compressed air machine were brought out. In 1900 the greater portion of the interest of the company was sold to Mr. Wilfred Lewis, and in September of that year the plant was transferred to Philadelphia. Up to this time he had been president of the company. From 1900 to 1906 he was occupied in looking after his various interests, and acting in the capacity of consulting engineer of the Tabor Mfg. Co. In June, 1906, he moved to Philadelphia, where he again took active part in the affairs of the company up to the time of his illness. Mr. Tabor is survived by a wife.

* * *

PERSONAL.

W. E. Farrel has been elected president of the Stoever Foundry & Mfg. Co., Myerstown, Pa., succeeding Ralph McCarty, who has resigned.

Walter J. Friedlander has been made general manager of the Hisey-Wolf Machine Co., Cincinnati, Ohio, manufacturer of electric drills, grinders, etc.

Walter S. Lang, of the Glasgow branch of Charles Churchill & Co., Ltd., sails for Great Britain September 8. He has spent considerable time in this country studying American methods in a number of the prominent machine tool manufacturing shops.

Forrest E. Cardullo, an occasional contributor to MACHINERY, who was instructor of practical mechanics at Syracuse University, has resigned his position and has been made professor of mechanical engineering at the New Hampshire State College, Durham, N. H.

Edward R. Euston has been elected vice-president and general sales manager of the Stoever Foundry & Mfg. Co., Myerstown, Pa. He will have offices at 140 Cedar Street, New York City. Mr. Euston has been manager of the company's New York office for the past six years.

R. B. Anthony, graduate of University of Wisconsin; E. L. Moreland, graduate of Johns Hopkins University, and F. W. Willey, graduate of Purdue University, have received the degree of master of science from the Massachusetts Institute of Technology for post graduate work done in the electrical engineering department.

S. Coulange, for the past twelve years designer for the Fabrique Nationale d'Armes de Guerre, of Herstal, Belgium, and representative of Fenwick, Freres & Co., has opened an office in Rue Louvrex, Liege, Belgium, as a consulting, inventing and constructing mechanical engineer of machine tools and special machinery. American and foreign manufacturers are requested to send Mr. Coulange their catalogues.

B. B. Quillen, secretary and treasurer of the Cincinnati Planer Co., Cincinnati, Ohio, and Alfred Marshall, president of the Marshall & Huschart Machinery Co., with their wives and a party of friends, left Cincinnati on August 13th in automobiles for a tour through the East, and will travel through Maine, New Hampshire, Vermont, Massachusetts, Rhode Island, Connecticut, New York, New Jersey, visiting New York city, Philadelphia, Atlantic City, etc. The party expects to be on the road four weeks.

Arthur D. Dean has been appointed chief of the division of trade schools of New York State, the appointment taking effect September 1. This appointment is made in accordance with an act passed by the New York legislature this year authorizing the establishment of industrial and trade schools in cities and union free school districts. Mr. Dean will do much traveling throughout the State to meet boards of education and gatherings of citizens interested in promoting local trade schools and industrial education.

* * *

NATIONAL MACHINE TOOL BUILDERS' CONVENTION.

The National Machine Tool Builders' Association will hold its regular annual convention at the Hotel Imperial, corner of Broadway and 32d Street, New York, Tuesday and Wednesday, October 20th and 21st. Further information may be obtained from the secretary, Mr. P. E. Montanus, Springfield Machine Tool Co., Springfield, Ohio.

* * *

Never forget that you must begin at the bottom and not at the top if you desire results. Scattering seeds over an unprepared surface is a waste of time. You must plow first. Then the results will be in direct proportion to the persistence with which the work is followed up.—*Geo. G. Yeomans before the Railway Storekeepers' Association.*

BROWN & SHARPE MFG. CO.

PROVIDENCE, R. I., U. S. A.

A BUYER OF DISCRETION

Will concern himself only with cutters of a recognized standing and quality, for he feels that true economy is only effected by using the best obtainable.

And to find out what make of cutters is most economical, he need look no further than to that make stamped **B. & S. MFG. CO.,** whose reputation for quality was established over 45 years ago, and is still maintained to no less a degree today.

It requires no argument on our part, for the merit of a cutter is in its capacity, that those stamped **B. & S. MFG. CO.** give entire satisfaction.

Write for cutter list.
Sent free to any address.

ADVANCED DEGREES IN ELECTRICAL ENGINEERING, MASSACHUSETTS INSTITUTE OF TECHNOLOGY.

The demand for young men with a more extended and a deeper training in electrical engineering theory than can be obtained in an undergraduate engineering course has led the Massachusetts Institute of Technology, Boston, Mass., to emphasize its graduate courses. These graduate courses lead either to the degree of master of science for young men who propose to spend one year of advanced study of electrical engineering, or to the degree of doctor of philosophy or doctor of engineering for young men who are able and propose to spend longer periods in their advanced study and research. The degrees of master of science and doctor of engineering are particularly applicable to students following electrical engineering studies, and lectures, seminars, and other advanced instruction for students who are candidates for the doctor's degree will be well under way in the electrical engineering department during the next school year. In addition to students who will follow the course leading to the degree of master of science, candidates who will follow the works leading to the degree of doctor of engineering have already arranged to begin this work at the Institute next fall. The advanced work leading to the doctor's degree may follow in its major part either the lines outlined by Professor Jackson's lectures on the organization and administration of public service companies, or by Professor Clifford's advanced course on alternating currents, as the individual student may choose, and it is expected to be accompanied by such other work as may be chosen by the individual student (subject to faculty approval) from other departments of science and engineering. It is believed by the faculty of the Massachusetts Institute of Technology, that engineering students of particular ability can well afford to spend from one to three years of special advanced study under competent instructors along the lines of engineering theory and practice, and that such students will profit largely from the results of such study. Indeed, this seems to be proved by the experience of numbers of engineering students who have gone through courses of advanced study in engineering or scientific schools either in this country or abroad. The schools of foreign countries were doubtless formerly in advance of the American schools, for the purpose of advanced study in engineering and applied science, but it is believed that this condition no longer prevails. The advanced courses in electrical engineering at the Institute are planned particularly with a view to meeting the needs of such students as have hitherto found it necessary to go to foreign countries for advanced engineering instruction.

* * *

LUDWIG LOEWE & CO.'S SCHOOL FOR APPRENTICES.

The machine tool building firm of Ludwig Loewe & Co., Berlin, Germany, has installed in its shop a very complete apprenticeship school. There are seven different courses for apprentices, according to the work for which the young man wants particularly to fit himself. The time of apprenticeship for all-around machinists is four years, divided up between nine different departments in the shop. For tool-makers, molders, pattern-makers, lathe hands, planer and milling machine hands, and blacksmiths, the apprenticeship time is three years. The apprentices are given a rather thorough all-around experience, the lathe hands, for instance, spending three months in the tool grinding department and three months in the hardening department; the pattern-maker apprentices spending six months in the foundry, etc. Besides the practical training, the boy attends an apprentice's school within the shop in which he spends eight hours a week the first year (in the case of a four year's apprenticeship eight hours for the first two years), seven hours for the second year (or third) and six hours for the third (or fourth) year. The curriculum is made up not only of purely mathematical subjects, such as geometry, algebra, drawing, strength of materials, etc., but a general course is also included, giving the rudiments of business law, civics and political economy. Besides this two hours a week are devoted during the last two years to the study of German. It appears that the idea of this apprenticeship school is not only to train good workmen, but also to produce men who have a broadened view of their work and their duties, and who will, if successful in their mechanical work, be able to take any kind of a responsible position around the shop that may fall to them. There is no doubt that an apprentice training planned broadly will give more satisfactory results in the long run than one planned along too narrow and specialized lines.

* * *

ASHES FOR PILLARS IN COAL MINES.

In some of the anthracite coal mines of northeastern Pennsylvania, ashes are being used as pillars to prevent cave-ins. Flushed in the spaces formerly occupied by coal, the ashes form a solid mass when the water drains off, capable of holding up the earth and rock above. Thus they enable the miners to "rob pillars"—to take out coal which they had been forced to leave as supports. A mine just outside of Scranton, Pa., is near a big boiler plant which consumes three hundred tons of coal daily. Naturally, a large supply of ashes is created in the fire boxes beneath the boilers. It is estimated that about fifty tons of ashes a day are sent down into the mine. Water pumped from a nearby mine is used for the flushing. Running through a wooden trough, it reaches a tunnel that passes beneath the ashpits. This tunnel slopes at a grade of three-eighths inch to the foot. At intervals the ashes are shaken into it from above. The flow of the water carries the ashes to a borehole leading down through the ground to the mine. At the bottom are pipes leading to the worked-out places which are to be filled. Through the pipes goes the torrent of ashes and water, and the ashes are piled into the abandoned "breast" or gangway, while the water seeps and drains away. Gradually the pile of ashes grows, until it reaches from floor to roof. Then it becomes hard and firm. Nearby have been left pillars containing hundreds of tons of coal. When the new ash-pillars are large enough to be safe supports, the coal can be taken out. The piping is worn out very rapidly by the sulphur which is always present in mine water and therefore has to be replaced frequently.

* * *

INTERNATIONAL CONGRESS OF INVENTORS.

In view of the discussion that has been carried on in the columns of MACHINERY and elsewhere regarding the status of inventors and their relation to the U. S. Patent Office, it is interesting to know that an organization known as the International Congress of Inventors was established in 1906 and incorporated in 1907 for correcting present abuses and furthering the interests of inventors. Its object is to secure legislation which shall insure to the inventor the services of the patent office which his application fees should provide and protection for his inventions which a government guarantee should give. It was largely through the efforts of this association that Congress this year provided for an increased force of examiners and for an advance in the salaries of the patent office employees. An important matter now under consideration by the association is the establishment of a standard for a United States patent. The patent system purports to be a system for insuring a reward to inventors for their efforts and for stimulating the production of inventions of value to the public, but patentees and holders of patents have found that a United States patent has no definite standing until it has been passed on by the courts. Further information regarding the objects of the association can be obtained from Mr. Ralph T. Olcott, secretary, International Congress of Inventors, Rochester, N. Y.

* * *

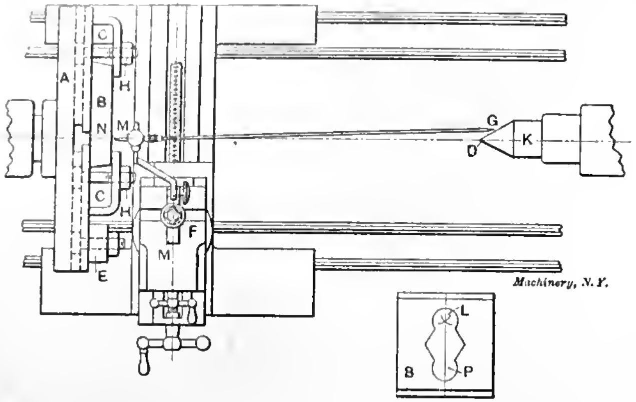
Experiments carried out at the testing plant of the United States Geological Survey, regarding the fuel value of Florida peat, indicate that in a gas producer plant this peat produces gas having a thermal value of 175.2 B.T.U., compared with 149.6 B.T.U. for West Virginia coals and from 141.6 to 153.2 B.T.U. for Pennsylvania coals. The amount of peat consumed per brake horse-power was 2.08 pounds as compared with 1 pound of West Virginia coal, and 1.12 pounds to 1.47 pounds of Pennsylvania coals.

Supplement to MACHINERY, October, 1908.

Operations for the Article in this number entitled "Machine Shop Practice—Machining the Hole for the Punch and Finishing a Blanking Die."

SHOP OPERATION SHEET NO. 76.

C. F. Emerson. MACHINERY, October, 1908.



To True Up on the Face-plate of a Lathe a Prick-punch Mark that has been Spotted on the Face of a Die Blank.

NOTE.—The die blank is assumed to have been planed, laid out, and the centers of the holes to be bored or drilled prick-punched, previous to this operation. The die blank, as laid out, is shown in the lower right-hand corner of the sketch. The prick-punch center *L* is to be trued up with the center of the lathe spindle.

1. Strap die blank *B* on the face-plate *A*, by the aid of the straps *C* and the bolts and nuts *H*. Bring the tail-stock forward, close to the face-plate, and move the tail center *K* forward, so that the point almost touches the die blank *B*.

2. Remove the belt from the head-cone, and let it hang loose.

3. Turn the lathe spindle by hand, and true up the prick-punch mark by lightly tapping die blank *B* until the mark is apparently true with the point *D* of the tail center.

4. Strap weight *E* to the face-plate, to counter-balance the weight of the die blank *B*, which is eccentrically clamped on the face-plate.

5. Revolve face-plate by hand to see if it has been counter-balanced correctly. If not, replace *E* with a heavier or lighter weight, as required.

6. Place the indicator *M* in the tool-post *F* and bring the centering point *N* of the indicator forward so as to enter the prick-punch mark on *B*.

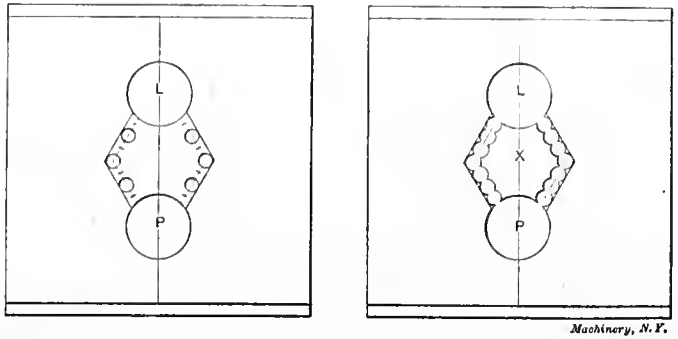
7. Revolve the face-plate *A* and see if the rear end point *G* of the indicator moves. If it does, the prick-punch mark does not run fully true.

8. Turn the face-plate by hand, letting *G*, which will move in a circle, come as close to tail-center *K* as possible. Then tap die blank *B* lightly at a point in a straight line with the center of the lathe spindle, until point *G* remains perfectly motionless when the spindle is revolved.

NOTE.—After having trued up the prick-punch mark, spot and drill hole *L*, and then bore it with an inside turning tool to a taper of 1½ degree on each side, for clearance. Repeat the operation of truing up, drilling, and boring for the hole *P*.

SHOP OPERATION SHEET NO. 77.

C. F. Emerson. MACHINERY, October, 1908.



To Drill Out the Core in a Die, Eliminating the Necessity of Broaching Out the Web of Stock between the Hole.

NOTE.—Previous to this operation the die blank has been planed and holes *L* and *P*, drilled and bored. The core should be drilled out so that the drilled holes incline about 1½ degree with the perpendicular to the face of the die, for clearance.

1. Place a drill in a drill chuck, and tighten the chuck jaws.

2. Lay the die on the drill press table, and proceed to spot every alternate prick-punch mark with the drill.

3. When spotting the holes, care should be taken to see that the drill does not run into the scribed outside lines. Where the drill shows a tendency to do so, draw the spotted hole over towards the inside with a small chisel.

4. Place a thin piece of sheet steel under the corner of the die directly opposite the holes to be drilled. The sheet steel piece is put in so that the holes will be drilled at a slight angle with the bottom of the die, to make unnecessary the operation of reaming the holes from the back with a taper reamer, in order to save time in filing out the die, which is filed to an angle of 1½ degree for clearance.

5. Proceed to drill a hole at every other prick-punch mark all around the inside of the scribed line, as shown to the left in the engraving.

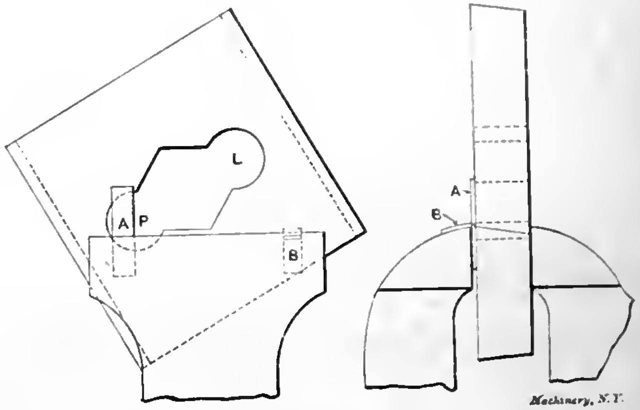
6. After having drilled every other hole, proceed to drill the holes indicated by the prick punch marks between the holes already drilled. When all these holes are drilled, as shown to the right in the engraving, core *X* falls out.

7. With a sharp chisel chip out the remaining projecting points, almost down to the scribed line. In chipping, begin at the face of the die and chip through. If the start is made at the bottom of the die, the stock is apt to break off below the scribed line on the face of the die when the chisel comes through.

NOTE.—When the shape of the opening in the die does not permit the chipping all the way through from the face of the die, chip through as far as the open space will permit, and then begin chipping from the bottom of the die, to meet where the chisel left off when entering from the top.

SHOP OPERATION SHEET NO. 78.

C. F. Emerson. MACHINERY, October, 1908.



To File Out a Blanking Die to Fit a Sample Blank or Templet.

NOTE.—It is assumed that, previous to this operation, the die has been planed, the shape of the opening laid out, the holes *L* and *P* drilled and bored, and the core in the center of the opening removed by drilling around the scribed outline of the core as shown in Shop Operation Sheet No. 77.

1. Place the die in a vise with the face of the die towards the back of the vise.

2. Place pieces *A* and *B* in the vise as shown. Piece *A* prevents the edges of hole *P* in the die from coming in contact with the edge of the file when the die is filed out. Piece *B* simply serves the purpose of permitting the die to be held parallel in the vise.

3. A coarse file is first used for rough filing the opening, filing down to the inside of the lines scribed. File to a clearance of about 1½ degree.

4. Insert the sample blank or templet from the bottom of the die, pressing it lightly forward as far as it will go into the opening in the die.

5. Remove the die from the vise, and hold it up to the light, and mark with a lead pencil those parts of the die where the sample blank bears against the sides of the opening in the die.

6. Remove the sample blank, place the die in the vise, and file out the lead pencil marks. Insert the blank once more, and repeat the operation described in steps 4 and 5 until the blank will pass through the opening. When the die is nearly filed out to the required size, use a fine file for finishing.

NOTE.—In filing out the die opening, care should be taken to see that the clearance is filed straight, and not rounded, as in the latter case, the die will not cut the stock properly and the blanks will not readily drop through the opening. The clearance angle may be made correct and uniform by the use of a die-maker's square, which differs from other squares in that the blade is set at an angle of 90 degrees plus the clearance angle, with the stock.

Tables for the Articles in this number entitled "Band and Block Brake

FORMULAS FOR BLOCK BRAKES.

F = force in pounds at end of brake handle,

P = tangential force in pounds at rim of brake wheel,

μ = coefficient of friction between the brake block and brake wheel.

(1) Block brake (Fig. 1)

For rotation in either direction:

$$F = P\frac{b}{a+b}\times\frac{1}{\mu} = \frac{Pb}{a+b}\left(\frac{1}{\mu}\right)$$

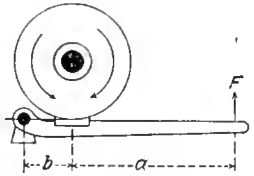


Fig. 1.

(2) Block brake (Fig. 2)

For clockwise rotation:

$$F = \frac{\frac{Pb}{\mu}-Pc}{a+b} = \frac{Pb}{a+b}\left(\frac{1}{\mu}-\frac{c}{b}\right)$$

For counter clockwise rotation:

$$F = \frac{\frac{Pb}{\mu}+Pc}{a+b} = \frac{Pb}{a+b}\left(\frac{1}{\mu}+\frac{c}{b}\right)$$

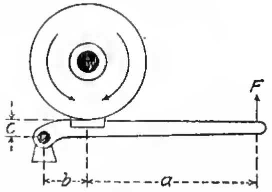

Fig. 2.

(3) Block brake (Fig. 3)

For clockwise rotation:

$$F = \frac{\frac{Pb}{\mu}+Pc}{a+b} = \frac{Pb}{a+b}\left(\frac{1}{\mu}+\frac{c}{b}\right)$$

For counter clockwise rotation:

$$F = \frac{\frac{Pb}{\mu}-Pc}{a+b} = \frac{Pb}{a+b}\left(\frac{1}{\mu}-\frac{c}{b}\right)$$

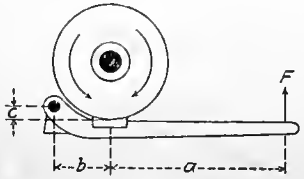

Fig. 3.

The brake wheel and friction block of the block brake are often grooved as shown by Fig. 4. In this case substitute for μ in the above equations the value $\frac{\mu}{\sin\alpha+\mu\cos\alpha}$ where α is one half the angle included by the faces of the grooves.

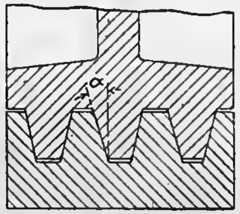

Fig. 4.

Contributed by A. L. Campbell.

FORMULAS FOR SIMPLE AND DIFFERENTIAL BAND BRAKES.

F = force in pounds at end of brake handle,

P = tangential force in pounds at rim of brake wheel,

e = base of natural logarithms = 2.71828,

μ = coefficient of friction between the brake band and the brake wheel,

θ = angle of contact of the brake band with the brake wheel, expressed in radians (one radian = $\frac{180^\circ}{\pi}$ = 57.296 degrees),

$$T_1 = P\frac{1}{e^{\mu\theta}-1}, \qquad T_2 = P\frac{e^{\mu\theta}}{e^{\mu\theta}-1}.$$

(1) Simple band brake (Fig. 1)

For clockwise rotation:

$$F = \frac{bT_2}{a} = \frac{Pb}{a}\left(\frac{e^{\mu\theta}}{e^{\mu\theta}-1}\right)$$

For counter clockwise rotation:

$$F = \frac{bT_1}{a} = \frac{Pb}{a}\left(\frac{1}{e^{\mu\theta}-1}\right)$$

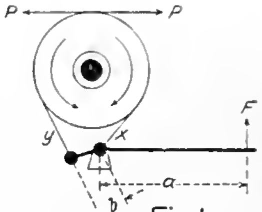

Fig. 1.

(2) Simple band brake (Fig. 2)

For clockwise rotation:

$$F = \frac{bT_1}{a} = \frac{Pb}{a}\left(\frac{1}{e^{\mu\theta}-1}\right)$$

For counter clockwise rotation:

$$F = \frac{bT_2}{a} = \frac{Pb}{a}\left(\frac{e^{\mu\theta}}{e^{\mu\theta}-1}\right)$$

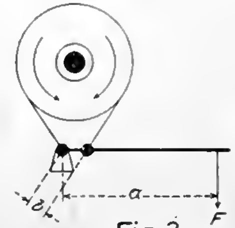

Fig. 2.

(3) Differential band brake (Fig. 3)

For clockwise rotation:

$$F = \frac{b_2T_2-b_1T_1}{a} = \frac{P}{a}\left(\frac{b_2e^{\mu\theta}-b_1}{e^{\mu\theta}-1}\right)$$

For counter clockwise rotation:

$$F = \frac{b_2T_1-b_1T_2}{a} = \frac{P}{a}\left(\frac{b_2-b_1e^{\mu\theta}}{e^{\mu\theta}-1}\right)$$

In this case, if b_2 is equal to, or less than, $b_1e^{\mu\theta}$, the force F will be 0 or negative and the band brake works automatically.

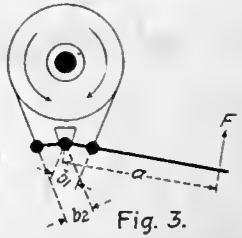

Fig. 3.

(4) Differential band brake (Fig. 4)

For clockwise rotation:

$$F = \frac{b_2T_2+b_1T_1}{a} = \frac{P}{a}\left(\frac{b_2e^{\mu\theta}+b_1}{e^{\mu\theta}-1}\right)$$

For counter clockwise rotation:

$$F = \frac{b_1T_2+b_2T_1}{a} = \frac{P}{a}\left(\frac{b_1e^{\mu\theta}+b_2}{e^{\mu\theta}-1}\right)$$

If $b_2 = b_1$, both of the above formulas reduce to $F = \frac{Pb_1}{a}\left(\frac{e^{\mu\theta}+1}{e^{\mu\theta}-1}\right)$. In this case the same force F is required for rotation in either direction.

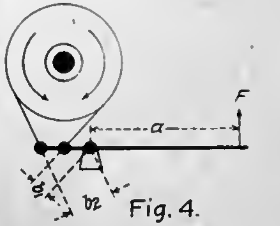

Fig. 4.

October, 1908.

DESIGN AND CONSTRUCTION OF METAL-WORKING SHOPS—2.

W. P. SARGENT *

IN the previous article of this series, the author dwelt at length on the controlling influence of the engineer in the planning of extensive improvements. In order to maintain the personal tone, the following observations, while of general interest, will be addressed to the engineer in charge.

It is highly improbable that a corporation, with the wisdom and caution acquired by successful growth, will expend large sums of money for improvements without having at hand information covering "the existing state of the art." The engineer, therefore, should spend considerable time visiting the best and largest examples of recently built plants for metal-working, and also, from the first moment that extensions are considered, gather together all information possible bearing on the subject from technical papers. It is well to formulate an outline of the essential points affecting, first, the efficiency of the plant; second, the adaptability for systematic extension; third, the expense attending the operation; fourth, the construction of buildings; and fifth, the cost of plant.

The following points are suggested as covering such information as will be of use in planning new shops. Other things will suggest themselves if some particular branch of the manufacturing is "lame" in the shops for which improvements are under consideration, as, for instance, the forge shop or power plant, which are often neglected in shops otherwise highly efficient. Under the head of efficiency, look for the adaptability of the buildings to the equipment within them; as to whether or not there is sufficient height and span of cranes over the erecting space, as often provision is not made for increase in size of the product; and in the machine shop space, look at the reservation of space near machines for work in progress, so that expensive machines may not be held up waiting for castings to be brought from some remote part of the works. Such provision well justifies the cost of the additional width of bay required. Then, as to shipping, look out for space and handling facilities that will obviate the use of the valuable productive erecting space for tracks and boxing. The handling of work affects the productive efficiency according to the amount of non-productive time spent by producers in waiting for cranes and getting work on and off machines; therefore, attention should be given to the number of traveling cranes in relation to the floor space served by them, to the use of industrial tracks and column jib-cranes, and to the operating speeds of the various handling apparatus. This question of handling work may perhaps be considered a question of equipment, but it is involved in the arrangement of space and affects the amount of space and dimensions a great deal.

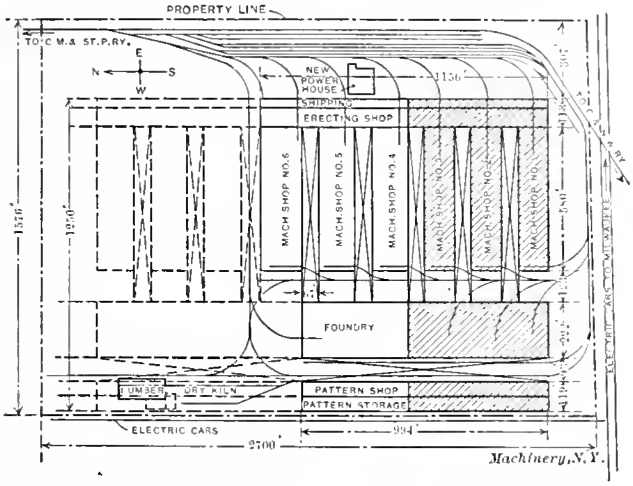

Fig. 4. Plan of Allis-Chalmers Co.'s Plant at West Allis, Milwaukee, Wis.

Under the head of future extension, observe the area of the site in relation to space covered by the buildings, and how the works' system of trackage is planned in connection with the trunk lines of the various railroads serving the city where the site is located. Observe the points that bear on the labor supply; such as homes, street-car facilities, and the proximity to large manufacturing sections from which the better class of workmen can be drawn.

Under expense of operation, study the arrangement of space and the length of haul within the works of the bulk of the material handled, the rapidity of handling, and the course of the product through the works; also the arrangement of trackage, and facilities for storage and unloading which tend to keep down demurrage charges. The type of buildings has also a bearing on the expense factor through the variation of insurance rates. The length and efficiency of power transmission lines, and the efficiency of the power plant and heating apparatus, are large factors in the expense of operation.

The details of building construction, when brought together for comparison, show the trend of the best thought, inasmuch as particular features that may be found in *all* or *nearly all* of the later plants, and which also conform to the recommended standards of the underwriter's and fire-protective associations, certainly are good examples to follow. The writer has almost come to regard the recommendations of the factory mutual fire insurance companies as axioms, and to judge building construction accordingly. The fact that the fire losses for the past ten years in plants insured in the older factory mutual companies, and conforming to their standards, has been but four cents per hundred dollars annually compared with sixty cents in other properties, seems sufficient justification for this opinion. The framing, walls, roofs, floors, galleries, fire-proofing, and lighting should all be studied, and their relative costs. Railroad shops should not be neglected in one's investigations, as the size of some of the latest shops is such that almost all of the problems that arise in planning any metal-working shop have been handled on a large scale in planning them.

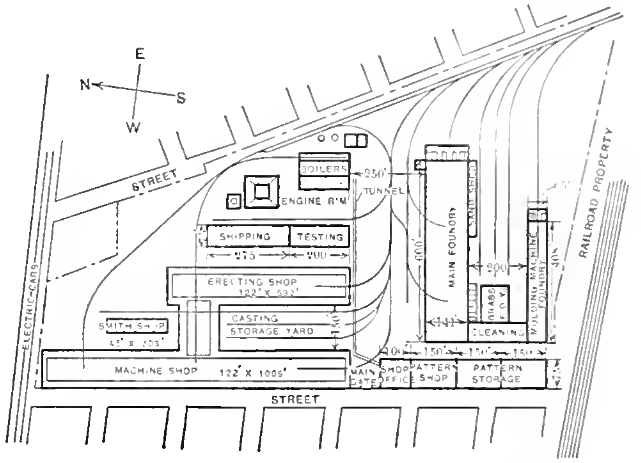

Fig. 5. Plan of Worthington Shops, Harrison, N. J.

The points outlined above will aid in getting at the meat of many published articles, and in gathering definite facts, rather than general knowledge without a definite application in mind. The following resumé of the leading features of some of the later plants will emphasize the bearing of these points on various factors affecting the planning of new shops.

Study of Recent Plants.

A site for a new plant may be selected from a number of sites by its preponderance of advantages affecting the following heads: Adaptability for future extensions; railroad facili-

---

* Address: 948 Campbell Ave., Hamilton, Ohio.

ties; labor supply; water supply; cost of foundations; cost of power.

The West Allis plant of the Allis-Chalmers Co. at Milwaukee, Wis., is pre-eminent in meeting the requirements under most of these heads. Fig. 4 shows the general plan. The original buildings are shown by the shaded portion, the recent additions by the full lines, and the possible limits of extensions in conformity with the predetermined plan, by the dotted lines. The arrangement and type of buildings are such that this layout of extension can be followed even if the nature of the product should be entirely different from the present lines. This plant is served by two railroads, and the activity of the rival freight agents in endeavoring to secure the lion's share of the business naturally tends toward a liberal supply of cars even when there is a general car shortage. As regards the labor supply, Milwaukee is the principal manufacturing city in this section of the country. Locally, the site is in a recently improved community, just outside of the city limits.

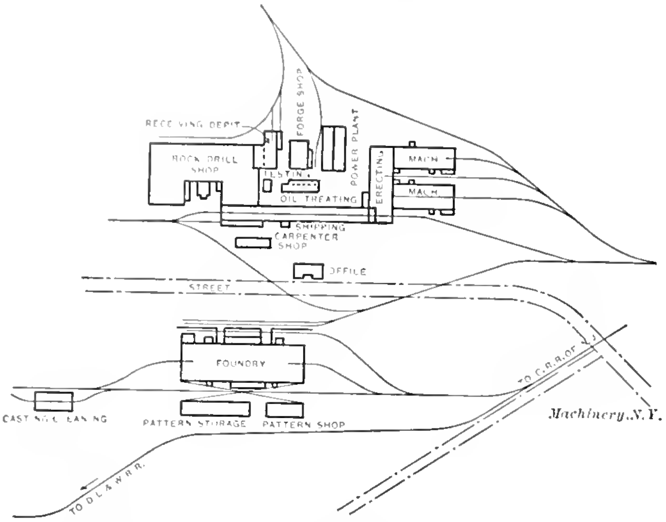

Fig. 6. The Ingersoll-Rand Plant, Phillipsburg, N. J.

TABLE V. COMPARISON OF PLANT ARRANGEMENTS.

	West Allis Works, Plant No. 6.	Worthington Works, Plant No. 7.	Ingersoll-Rand Works, Plant No 8.
Rectangular space, sq. ft.	1,445,000	1,000,000	1,562,500
Covered by buildings	746,000	450,000	400,000
Percentage covered by buildings	51	45	26
Yard space under cranes	305,000	None	25,000
Percentage	21	None	1.6
Percentage remaining	28	55	72.4
Minimum distance between foundry and machine shops.	123 ft.	250 ft.	560 ft.
Maximum distance between extreme points of foundry and machine shops	1,500 ft.	1,750 ft.	2,000 ft.
Average haul of castings	810 ft.	1,111 ft.	1,280 ft.
Maximum distance of power transmission (electric)	1,500 ft.	1,100 ft.	1,600 ft.
Distance of transmission when ground floor space was 400,000 square feet	600 ft.		

The well lighted and well ventilated shops, together with these other advantages, make the plant attractive to a high class of mechanics. The site chosen was a nearly level field of two hundred acres, and as a good bearing soil lay within a few feet of the surface, very little grading was necessary, and the foundation cost was relatively low. The item of foundation cost as effected by a proposed site is important, as the cost of one foot of foundation in depth will pay for two or more feet of brick wall above the foundation.

Referring to Fig. 4, the great area of yard space served by yard cranes will be noticed, as shown by the diagonal lines between the various buildings, and this space is as effectively used as if under roof; the storing of castings inside the shop long in advance of the time when the machines are ready for them is avoided.

Arrangement of Buildings.

It has previously been stated that the arrangement of departments is one of the major factors affecting shop efficiency, and the facilities for handling materials another. The more effective use of space at the West Allis plant (Fig. 4) compared with the Worthington Works at Harrison, N. J. (Fig. 5), and the Ingersoll-Rand Works at Phillipsburg, N. J. (Fig. 6), is shown by the following: The rectangle formed by the buildings indicated by the dimensions 1,156 feet north and south, and 1,250 feet east and west contains 1,445,000 square feet; the buildings in Fig. 5 are contained in a rectangle 1,550 by 800 feet, and deducting east of the smith shop leaves approximately 1,000,000 square feet. The buildings in Fig. 6 are contained in a rectangle 1,250 by 1,250 equaling 1,562,500 square feet. The ground space covered by buildings within these areas is 746,000 square feet for Fig. 4 or 51 per cent, 450,000 square feet, or 45 per cent for Fig. 5, and 400,000 square feet, or 26 per cent for Fig. 6. Then again, Fig. 4 has 21 per cent of the remaining space within the rectangle under yard cranes, Fig. 5 is without yard cranes, and Fig. 6 has but 25,000 square feet or less than 2 per cent under yard cranes. These percentages with other items pertaining to the handling of materials are compared in Table V.

TABLE VI GENERAL DIMENSIONS AND DESCRIPTION OF RECENTLY BUILT PLANTS.

Building.	Plant No. 6.		Plant No. 7.		Plant No. 8.
Erecting Shop—			High.	Low.	
Crane-track span	70′		58′	59½′	112′
Crane-track, height	60′		62′		35′
Floor to roof truss	72′6″		72′		44′
Width of building	72′		126′	122′	
Machine Shop.					
Large work—	Nos. 1-2.	Nos. 4-5.			
Width of building	122′	145′	122′		100.
Width of bays	26′-69′-26′	69′-71′	30′ 62′-30.		30′-40′-30′
Crane-track span	67′	67′	59½′		38′
Crane-track, height	26′	44′6″	30′		25′
Floor to truss	34′	52′	50′		
Under gallery floor—					
Crane track span	25′6″	38′6″	28′		No galleries.
Crane track, height	13′	17′	13′		
Floor to ceiling.	18′	21′3″	15½′		
Gallery Floor—					
Above main floor.	21′4″	26′2″	18′4″		
Head-room	14′8″	16′	12′		
Machine Shop.					No galleries.
Small work—	4 Stories.		Galleries in shops.		Saw-tooth roof.
Width of floors	53′ Inside		31½′		18 bays 25′ wide.
Head-room—					
1st story	21′4″		15′6″		13′6″-16′6″
2d story	14′2″		12′6″		Ventilating bays run N. and S. 20′ wide, 29′ high. See Fig. 15.
3d story	14′3″		12′6″		
4th story	12′8″				
Roofs	Flat pitch. Center skylights. No monitors. Wood sheathing. Tar and gravel.		Flat pitch. Center skylights. No monitors. Wood sheathing. Composition.		Pitch 1 in 5. Center skylights. Monitors.
Framing	Steel.		Steel.		Steel.
Walls	Brick.		Brick.		Brick.
Pattern Shop.	One story brick. Steel frame fireproofed. Flat pitch concrete roof. Wire-glass windows with metal frames. Fire-doors automatic.				Slow-burning mill construction. Wood floors with asbestos paper between. Plank roof covered with 4-ply slag roofing.
Pattern Storage.	Four stories. Same construction as pattern shop.				Four stories. Pattern shop is a part of this building.
Foundry.	Brick and steel. Roof—Flat pitch, plank covered with tar and gravel.		Brick and steel. Flat pitch.		Brick and steel. Pitch 1 in 5.
Width of building	222 feet		141 feet.		160 feet.
Width of main bay	80 "		60 "		69 "
Crane track span	78 "		58 "		65 "
Crane track, height	28 "				32 "
Floor to roof truss	49 "		38 "		46 "
Side bays	Center skylights. One 68′ wide. Two 32′ wide. Skylights.		Center skylights. Two 40′ wide. Skylights.		Side skylights. Two 46′ wide. Skylights.
Height of charging floor	23 feet.		21 feet.		18 feet.
Sand and supply storage	On sand floor at level of charging floor inside of building.		In lean-to outside of main space.		Outside storage bins.
Cleaning	No separate building.		Large work inside. Small work separate building.		Separate building.
Moulding machine foundry	Part of main foundry.		Separate building, sand-mixing below.		Part of main foundry.

A visit to the West Allis plant will dispel any doubt, because of the compact arrangement of space, as to there being sufficient yard room. The sectional book-case idea is noticeable in the lay-out of the Ingersoll-Rand plant as well as the West Allis works, and the relation of departments will be unchanged despite additions that may be made.

An advantage peculiar to the layout of wing machine-shops at right angles to the erecting shop with yards between lies in what may be called the side-feed of unfinished materials to the machine-shops. Castings are stored in these yards adjacent to the door nearest the interior point where they will be machined. This side-feed requires the least amount of crane and truck handling and provides the shortest possible inside route to the erecting floor, and eliminates in a measure the well known scene in end feed shops when all of the cranes are tied up at one end while the furthermost crane is getting a large casting for transportation to the other end of the shop.

The future methodical extension of all the departments does not seem to have been considered necessary for Plant No. 7, Fig. 5, as only the smith shop, low erecting shop, and molding machine foundry have lee-way.

These three plants have the problem in common of the economical production of large, medium and small work in large quantities, and the Table VI indicates the manner in which different designers have met the conditions.

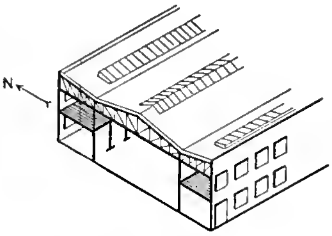

Fig. 7

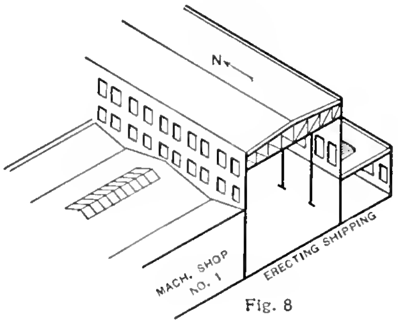

Fig. 8

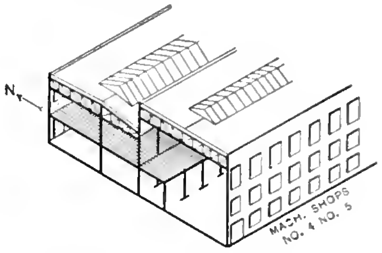

Fig. 9

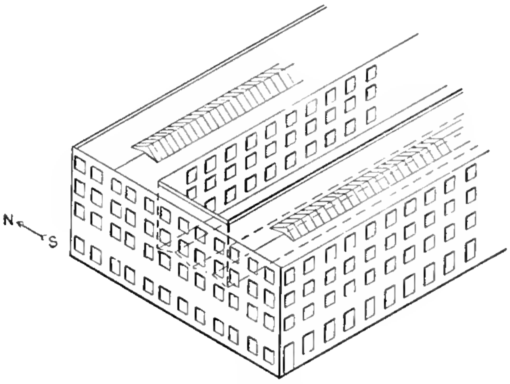

Fig. 10

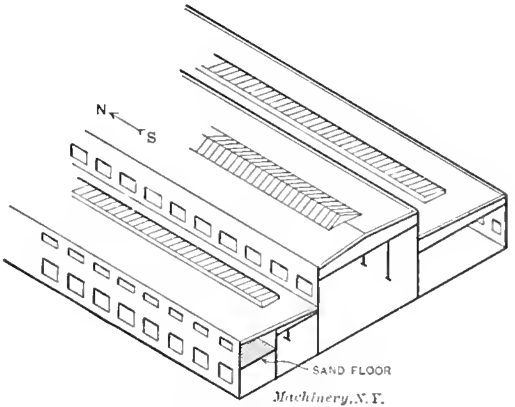

Fig. 11

Fig. 7. Machine Shops Nos. 1 and 2 of the Plant shown in Fig. 4. Fig 8. Erecting and Shipping Department. Fig. 9. Machine Shops Nos. 4 and 5. Fig. 10. Machine Shop No. 6. Fig. 11. Foundry.

The heating of these three plants is through the medium of hot water under forced circulation, the heaters being in series with regular condensers, the vacuum on the engines being broken in proportion to the temperature of the outside atmosphere. The relative areas of departments and the power requirements of these and other large plants will be given later.

The following information is derived mainly from articles in past issues of Machinery. The Hooven-Owens & Rentschler Co. works at Hamilton, Ohio, was described in the January, 1904, number. This firm builds vertical and horizontal Corliss engines. The plant is exceptionally well equipped as the maximum size of work is limited only by the machine tools, of which the 20 x 20-foot boring-mill and a planer 14 x 12 x 35 foot traverse are the largest. The shops are of brick and steel, and the lighting and ventilation are good. The main erecting bay is 75 feet wide and 57 feet from floor to lower chord of roof truss. The main machine bay has the same dimensions. The roofs of the two bays are of one-sixth pitch, of plank and slate, and with skylights except on the slope next the west wall, the skylight area being approximately 5 per cent of the slant area. The machine bay at right angles to the main bay is 73 feet wide and 34 feet to the roof truss, and the machine bays parallel with the main bay are 44 feet and 35 feet wide and 22 feet to the trusses. The foundry main bay is 75 feet wide and 40 feet to roof truss; the roof is slate on plank and pitched 1 in 6. The lean-to bay is 39 feet wide and 24 feet to the truss, roof slope 1 in 10, and of plank covered with tar and gravel.

The Ball Engine Works, Erie, Pa., is interesting in the comparison of the buildings with those of the Hooven plant. Fig. 16 shows the erecting shop, 200 feet long, 74 feet wide, 44 feet to trusses; roof slope, 1 in 4, of plank covered with slate. The machine shop bays are at right angles to the erecting space and consist of alternate flat and pitch roofs 20 feet wide, forming a unique type of saw-tooth roof. This form of saw-tooth, supplemented as it is by the windows in the walls, has a more pleasing architectural effect than the severely plain type of saw-tooth roof shown in Fig. 17 which represents the erecting shop and machine bays of the Ridgeway Machine Tool Co. at Ridgeway, Pa. These latter shops are without side-wall windows except in the north wall. The roof of Fig. 16 is far superior as regards ventilation on account of the opportunity for using movable sash in the vertical frames; and the elimination of gutters and consequent freedom from troubles, caused by melting and freezing of snow, common to the cheaper forms of the regular saw-tooth, is a strong point in favor of this modified type. The crane tracks project into the erecting space in both the shops shown in the two figures.

The B. F. Sturtevant Shops.

The new B. F. Sturtevant plant at Hyde Park, Mass., has many interesting features in the composite type of buildings. New England mill construction forms the base and is modified by the use of steel interior columns for the first story, a 20-foot column spacing, steel main girders and 12 x 16-inch wood floor beams on 4-foot centers for gallery floors, and by the transverse saw-tooth skylights over the high erecting floor and inner portions of the galleries. The erecting bay is 40 feet wide and 30 feet from floor to truss. The galleries on either side are 40 feet wide and have 15 feet head-room under and over the gallery floor. The ground floor is of 3-inch hemlock on tar concrete; the gallery floor for 250-pound load is of 2½-inch hard pine with 1-inch maple top floor, and of 2-inch pine and 1-inch maple for 200-pound load. The roofs

are ½-inch pitch, 3-inch hard pine planking covered with tar and gravel. There are no wall columns as the walls of brick are 20 inches thick to the gallery floor and 16 inches thick from there to the roof.

The Jones & Lamson Shop.

An excellent example of economical fire-proof construction is afforded by the machine shop of the Jones & Lamson Company at Springfield, Vt. The product of this shop is the well-known flat turret lathe. The building is three stories high, 150 feet long, 75 feet wide, with 14 feet headroom for first floor, 11 feet for second floor, and 11 feet for the third or top floor. A monitor 25 feet wide assists in lighting this floor. About 60 per cent of the wall area is glass, which is the same percentage as the window area of the new Pratt & Whitney machine shop at Hartford. The frame is of steel fire-proofed with concrete, floors and roof are of reinforced concrete, and the curtain walls are of brick.

The Pencoyd Works of the American Bridge Co.

This shop is remarkable for its massive construction as evidenced by the loads for which the gallery floors are designed: the first gallery for 500 pounds per square foot, and the second for 300 pounds per square foot. The central bay is 60 feet wide and the gallery bays 25 feet wide. Concrete is used for walls and extends from web to web of the columns. The window area is 60 per cent of the wall area, and all but the lower sash are glazed with ribbed glass. The headroom under the first gallery is 13 feet, under the second, 12 feet, and 11 feet under the roof. The crane arrangements are most unique. Over the 25-ton crane of 56-foot span in the main bay are two 10-ton cranes of 30-foot span running parallel, the trucks of these cranes away from the columns running on tracks supported from the roof trusses. Under each gallery are two parallel runways suspended from the main floor girders and on these runways are electrically operated jib cranes with 5-foot radius arms. These cranes pick up work from trucks in the gangways and swing it over into the machines. Tar concrete is used under the wood block top floor for the first story under the gallery, the tar being used for its preservative effect on the wood.

Pratt & Whitney Shop.

A shop that is representative of many of the recently constructed New England factory buildings for light and medium work is that of the Pratt & Whitney Company at Hartford, Conn. It is an extremely rigid building with brick walls having about 60 per cent window area, steel frame, and concrete floors with the concrete of the floor slab-haunched down to the lower flange of the supporting I-beams, thereby fireproofing them partly and adding about 50 per cent to their strength.

The roof is nearly flat, of plank covered with tar and gravel roofing. Top floors are of clear 1⅛-inch maple laid on sleepers which are embedded in the concrete. The ground floor consists of 3 inches of concrete, then a damp-proof course of tarred felt, then 9 inches of concrete in which are embedded the 4 x 4-inch sleepers as in the upper floors, and between the concrete and maple there is a stratum of asphalt composition applied hot, thus giving the wood flooring a solid bearing.

The building is very rigid, as the steel work is designed sufficiently strong for an additional story. It is a five-story L-shaped building, one wing being 65 feet wide and the other 75 feet wide, with a double row of interior columns giving a center passage-way 25 feet wide for cranes. The first story has a clear headroom of 18 feet 4 inches and all of the other floors have a headroom of 13 feet 4 inches (considerably more than in most other multi-storied shops), and as the windows come up to the under side of the floors the lighting is excellent. A comparison of this shop with a single-story saw-tooth shop will be given later. As the benches, offices, and toolrooms are next the walls, and sprinklers are installed, the noticeable absence of wooden cupboards and other combustibles near the interior columns will lead an unbiased observer, I am sure, to pronounce this shop sufficiently fireproof to compare with, and in details to be of a higher class than, a reinforced concrete structure.

The foundry is situated across the tracks of the New York, New Haven & Hartford Railroad, and is connected with the machine shops by a concrete tunnel which has the double function of affording a passageway protected from the weather for castings and for the distribution of heat, light, and power between the various buildings.

Hoefer Manufacturing Company.

The machine shop of the Hoefer Mfg. Co., described in MACHINERY December, 1905, is three stories in height, of modified mill construction with wooden columns spaced on 20-foot centers each way, and with wood floor beams. The floors consist of a ⅞-inch maple top floor laid on 3-inch yellow pine under planking; the walls are of brick, 17 inches thick for the first story and 13 inches thick for the two upper stories. The cost is given as $22,000, or a little less than $1.00 per square foot of floor space.

Colburn Machine Tool Co.'s Machine Shop, Franklin, Pa.

This shop is typical of many of the medium-sized plants making machine tools and requiring traveling cranes. The shop is of brick and steel with a slate roof laid on plank. The main bay is 37 feet wide and 31 feet to the roof truss; the side bays are each 30 feet wide and 14 feet to the trusses. The glass surface is about 65 per cent of the area of the side walls. This shop was described in MACHINERY, February, 1906, and details and specifications were also given. The machine shop portion of Fig. 13 illustrates this type of shop.

United Shoe Machinery Co.'s Plant, Beverly, Mass.

The designers and owners of this plant have adopted a purely reinforced concrete construction. The floor space covered is about 17 acres, and the floors, roofs and columns of all buildings are of concrete. About 90 per cent of the entire wall area is of glass. There should be some great advantages in this exceptionally large glass surface to justify the greatly increased cost of heating, but these advantages are too deeply hidden to be excavated by the author. Sprinklers are installed only where combustibles are used or stored, and no insurance is carried.

The Aiken Roof Type of One-story Shop.

This peculiar type of roof construction is shown in Fig. 18. The advantages possessed by this form over the ordinary saw-tooth roof for buildings of very large areas are found in low first cost and maintenance. The lighting is not so uniform, but is very good. The shops of the Standard Steel Car Company at Butler, Pa., are of this type, the main building being 400 feet by 1,612 feet. The National Malleable Castings Company shop of this type is 225 feet wide and 750 feet long. In this type of roof, sections are almost flat, the high sections being carried on the upper chord members and the lower sections attached to the bottom chord members of the trusses. The writer believes that even the strongest advocates of saw-tooth construction will admit the lower cost and superior natural ventilation of this type, at least on single buildings of large area.

Multi-storied and Saw-tooth Roof Shops Compared.

The Pratt & Whitney machine shop compared with a saw-tooth shop of equivalent floor area (125,000 square feet) has better natural ventilation, is cooler in summer, has 25,000 square feet of the simplest form of roof against 125,000 square feet of skylights, and has 80 per cent less underground piping to maintain. Heat, light, and power distribution is more economical both in first cost and in transmission losses. The greatest distance that a truck-load of material would traverse on elevator and floor from the receiving point in one corner to the extreme corner of the upper floor is 300 feet against 450 feet from corner to corner of a one-storied structure.

As regards lighting, the saw-tooth shop undoubtedly possesses an advantage in the better diffusion of light, and consequently the strain on the eyes is greatly minimized. This advantage may be offset in a degree by the use of ribbed glass in the upper sash or windows and by the necessary window shades on east and south sides of a five-story building. The writer has yet to find that the productive efficiency in any saw-tooth shop is greater than in the many two or more storied shops in the manufacturing cities throughout the country. The writer recently has had experience in handling a maze of fine cotton yarns in a side-lighted shop and can fully appreciate the necessity of a soft, even light for textile work, but cannot see the necessity for better lighting in machine shops than can be obtained by side lighting.

Comparative Cost.

The cost of saw-tooth shops may be 40 to 50 cents less per square foot of floor space than the high-class Pratt & Whitney shop described, but not less than a shop of slow-burning mill construction. The cause of this 40 or 50 cents difference per square foot is partly shown by the Table VII. These items, of course, do not make up the entire cost. The column *A* is for a high-class five-story machine shop for light and medium work and with a floor space of 125,000 square feet, gravel roof on plank sheathing on wooden purlins supported by steel roof beams. Column *B* is a saw-tooth shop of 125,000 square feet, roof slopes covered with slate.

Much of this apparent saving on buildings may be offset by the extra cost of sewers, piping and wiring, so that a fair comparison of cost cannot be made except for shops for manufacturing like products, and ready for operation.

Reinforced Concrete as a Building Material

For underground work reinforced concrete is unsurpassed, for instance for tunnels, foundations, retaining walls, and vaults. Pattern shops and pattern storage buildings should be of real fire-proof construction and therefore concrete is an ideal material for their construction. Concerns making light work are as well housed in one type of construction as another, but for machine shops and foundries necessitating high roofs and wide spans, brick and steel construction is better suited. Despite their strongly presented claims of low cost, leading concrete construction companies in New England and the Central West, in 1906, could not meet the steel companies on cost and time of erection, but undoubtedly concrete construction methods have been very much perfected since then. As the allowable stress per square inch of section in columns of reinforced concrete and steel is in the ratio of one to thirteen, a concrete column occupies twice as much space as a steel column, and by casting broader shadows affects the lighting adversely. The writer is loth to believe that concrete should be adopted as the sole material of construction for large plants. As to cost, Mr. Leonard C. Wason writing in the *Engineering Magazine*, June, 1907, states that reinforced concrete construction will cost 10 to 25 per cent more than mill construction, and 20 to 30 per cent less than fire-proofed steel frame buildings. On account of the great variation of bids on reinforced concrete construction, the writer is unable to give reliable information on cost.

TABLE VII. COST IN CENTS PER SQUARE FOOT OF FLOOR AREA.

	A	*B*
Land—based on $435 per acre..........	0.2	1.0
Floors	26.0	22.0
Steel work	65.0	16.0
Walls and foundations	31.0	8.4
Roofs	3.6	40.0
	125.8	87.4

Conclusions.

The engineer before commencing work on tentative plans should visit the West Allis plant, even if he never investigates another large works, as he will find that the problems here have been well thought out and logically handled. It will be difficult to find another plant (having so few buildings) capable of turning out a million dollars' worth of work per month within a year after the buildings were completed. The arrangement of space is most excellent, the work is handled economically and expeditiously, the power transmission is economical, and the interior equipment is in keeping with the high class character of the buildings.

For light work, not requiring traveling cranes to serve many of the machine tools, a three-, four-, or five-storied shop with a light court, as shown in Fig. 10, is recommended where compactness of plant is desired or necessitated through lack of ground space or high cost of land.

Mill construction is cheapest for multi-storied shops, and if built to comply with the rules of the factory mutual companies will cost from $1.00 to $1.10 per square foot of floor area. Steel frame construction, not fire-proofed, will cost from $1.40 to $1.60 per square foot, and reinforced concrete will cost from $1.30 to $1.50 per square foot. If the nature of the contents is combustible, automatic sprinklers should be provided, and the insurance rate will be from 20 to 35 cents per $100 per annum on either of the three classes of buildings. Corrugated iron or steel covered buildings are naturally eliminated from consideration for these buildings, because they are not sufficiently warm or permanent except at a high cost of maintenance.

For light and medium work, saw-tooth single-story shops of 40,000 square feet area and an average height of 25 feet can be built for approximately $1 per square foot, but one must be content with a severely plain building, forbidding in appearance.

For medium and heavy machining, or for light and medium machining and erecting, the gallery type shown in Figs. 7, 9,

and 12, is common to most large plants. For building machines up to 15 tons weight the type of building shown in Fig. 13 houses all departments of many plants of 25,000 to 50,000 square feet of floor space. For heavy work, demanding separate machine and erecting shops, the best results are obtained when the machine shops are at right angles to the erecting shop with the cranes projecting into erecting space as in Figs. 8, 13, 16, and 17.

Very high shops of wide span, and with galleries, are uniformly of brick and steel and cost from $1.60 to $2.00 per square foot according to the crane capacity and the gallery floor loads for which the buildings are designed.

Pattern storage buildings are generally 2, 3, or 4 stories in height with fire-walls dividing the space into compartments. Slow-burning mill construction, fire-proofed steel, and concrete are all used, the wooden construction leading; as in all such buildings, automatic sprinklers are the main reliance for the protection of the contents, and given that they protect the contents they will protect the buildings. The writer believes that concrete with metal window frames and wire-glass windows will be the standard construction in the future. In that event no insurance need be carried on the buildings. One very important thing should be remembered in designing pattern storage buildings and that is to design the shelving and racks first, and then determine the window spacing and column spacing.

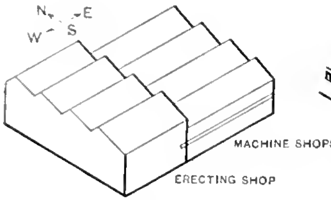

Fig. 17

Fig 17 Plain Saw tooth Roof.

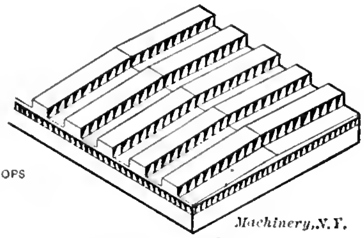

Fig. 18

Fig. 18. Aiken Roof.

Another thing that has been impressed on the writer's mind very strongly is to avoid outside down-spouts. This is best accomplished by extending the walls above the roof in the "parapet wall construction" recommended by the insurance companies, at the same time securing a more finished appearance. The down-spouts should have copper wire strainers at least 10 inches high and saddles should be built against the parapet avoiding sharp bends in the roofing felt, and the counterflashing should be built into the brickwork. Down-spouts inside will not freeze, and may be of galvanized iron to within about eight feet of the floor, where they should enter heavy cast-iron piping which should continue to the horizontal drains. The writer has seen, during the past winter, gangs of men with steam hose and fires, engaged in almost futile attempts to thaw out the outside spouts around a large plant.

Roofs of large areas generally require a great deal of attention, and the roofs giving the least trouble are of very flat pitch and covered with tar and gravel or with tar and slag.

Floors in single-story shops are now mostly laid on concrete with a coating of coal tar between the concrete and the planking, and maple top floors are laid on the under planking to give a hard wearing surface and to facilitate repairs. Monolithic concrete floors are fast superseding other kinds for galleries and upper floors, as they add much to the rigidity of a building and can be built to stand heavy loads at a low cost.

Books that are most in demand for information pertaining to the design and construction of shops are: Cambria Steel Company's, Jones & Laughlin's or Carnegie Steel Co.'s handbook, Kidder's "Architects' and Builders' Handbook," and Ketchum's "Mill Buildings."

The preceding matter throughout is written with the dominant idea in mind that the difference between cost and selling price is the principal object in manufacturing, and the writer has endeavored to present principally the points affecting this difference, rather than those tending toward artistic perfection.

DIAGRAMS FOR DESIGNING SPIRAL GEARS.*

FRANCIS J. BOSTOCK †

Great difficulties are usually experienced in designing spiral gears, and these difficulties are greatly accentuated when one has to design them for two shafts whose center distance cannot be altered to suit the gears, and also when the angle between the shafts is not a right angle, and the speed ratio is not equal. The general practice is to work out the gears by lengthy mathematics, and should the answer not come out as desired, then a new trial is made, varying either one or the other factor, until the angles and diameters are correct. This method of "cut-and-try" entails a great deal of work and waste of time. The following method, together with the diagrams used with it, will remove some of the difficulties, and enable one to arrive at the data required in a very short time. The method adopted is graphical, but the results may be checked by simple figuring.

As the pitch diameter, spiral angle, and circular pitch are interdependent, they cannot be considered as a starting point in solving the problem, because they are not known. The starting point, therefore, must be the speed ratio, and some idea of the strength required, together with the center distance. These factors, as a rule, can easily be ascertained. As it is common usage to employ ordinary spur gear cutters of regular diametral pitches for cutting spiral gears, the normal pitch, or distance from one tooth to the next, measured at right angles to the tooth, must be the same as the pitch of a spur gear for which the cutter to be used is intended; therefore, the corresponding diametral pitch and the speed ratio must be the initial data, all others being obtained afterwards.

Three diagrams are given for the graphical solution of spiral gears. The diagram in Fig. 1 shows the relation between the quotient of number of teeth ÷ diametral pitch, spiral angles, and pitch diameters. The quotient $\frac{\text{number of teeth}}{\text{diametral pitch}}$ is commonly termed "equivalent diameter," and will be so referred to in the following. The diagram in Fig. 2 shows the relation between the diametral pitch, the number of teeth, and the equivalent diameter. Finally, the diagram in Fig. 3 shows the relation between the pitch diameter, the spiral angle, and the lead of the helix. We will now proceed to give some typical examples illustrating the use of the diagrams.

Example 1. Given a gear having 24 teeth, 6 diametral pitch, and a spiral angle of 40 degrees. Find the pitch diameter.

First obtain the value of the ratio, number of teeth ÷ diametral pitch, which, in this case, can be obtained without referring to diagram Fig. 2, being simply $24 \div 6 = 4$. Locate 4 on the horizontal line in diagram Fig. 1, and project vertically until the line from figure 4 intersects the line for 40 degrees spiral angle. Then follow the circular arc from this point, either to the right or downward, reading off 5.22 on the corresponding scale, this being the pitch diameter. Should the diameter be required accurately, we can figure it by the formula

$$\text{Pitch diameter} = \frac{\text{No. of teeth}}{\text{Diametral pitch}} \times \frac{1}{\text{cos spiral angle}}$$

$$= 4 \times \frac{1}{\text{cos 40 deg.}} = 5.222 \text{ inches.}$$

This also gives a check of the result obtained by means of the diagram. The lead of the helix is now obtained from Fig. 3, by projecting the pitch diameter 5.22 horizontally to the radial line for the spiral angle, and then, following the vertical line to the lead scale at the bottom of the diagram, we find, in this case, a lead of 19.6 inches. Of course, the outside diameter of the blank would be $5.222 + 2 \times 1/6 = 5.555$ inches, which is the pitch diameter + 2 times the addendum.

Example 2. Required two gears which are to be equal in all respects, the diametral pitch being 8, and the centers to be approximately 4 inches apart.

As the centers are not fixed, the gears in this case may be

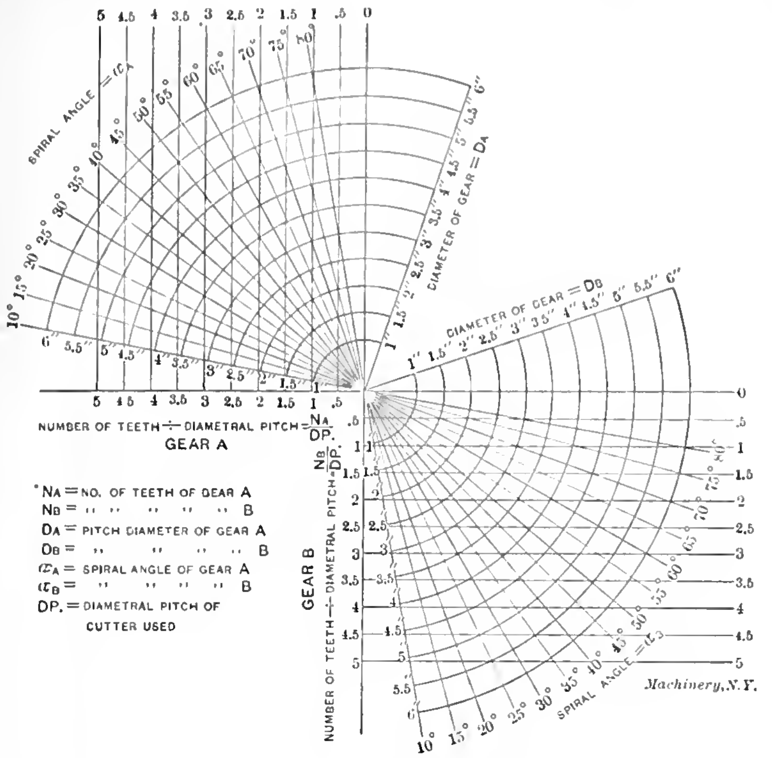

Fig. 1. Diagram for Solution of Spiral Gears.

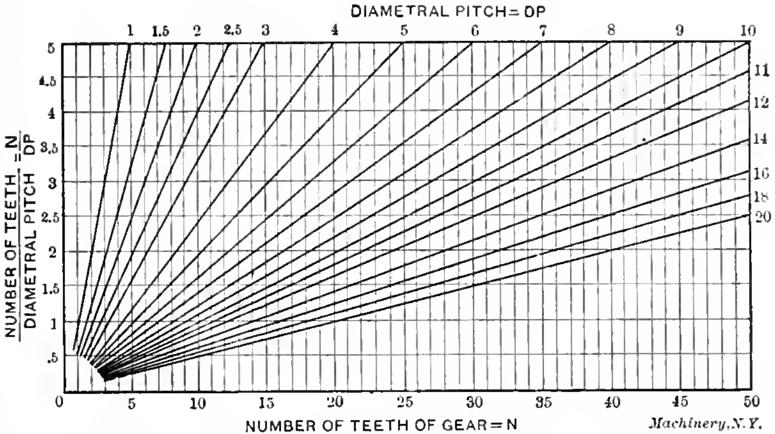

Fig. 2. Relation between Pitch, Number of Teeth, and Equivalent Diameter

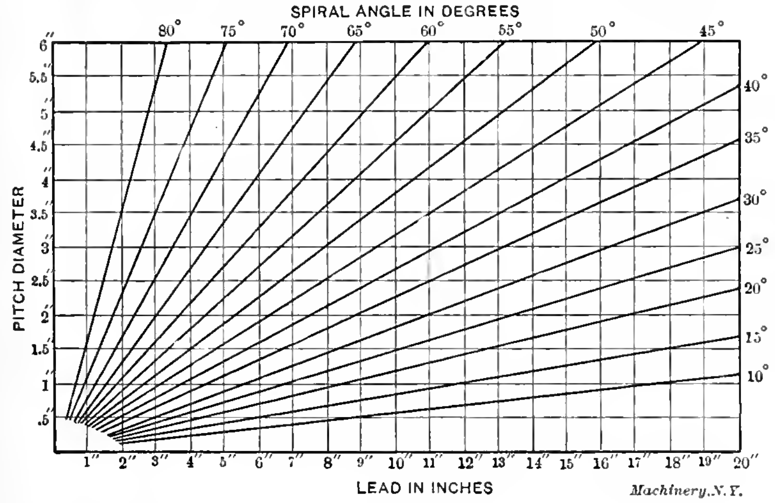

Fig. 3. Relation between Pitch Diameter, Spiral Angle, and Lead of Helix.

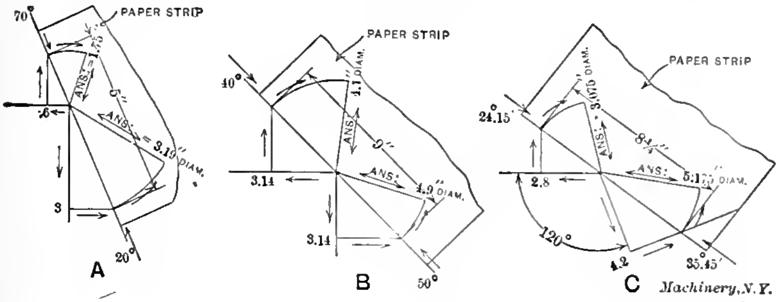

Fig. 4. Separate Diagrams for the Solution of some of the Problems Presented.

made with 45 degrees spiral angle, and the center distance may be slightly adjusted to suit the pitch diameters. Referring to Fig. 1, follow the circular arc from diameter of gear = 4 inches, until it intersects the radial line for 45 degrees spiral angle; then follow the vertical line down to the scale of the ratio between the number of teeth and diametral pitch, which is found to be 2.82. Then, from Fig. 2, we find that with this ratio and 8 diametral pitch, the number of teeth is not a whole number, but the nearest number is 23, giving a ratio of 2.875 instead of 2.82, which, by reversing the process and referring to diagram Fig. 1, gives a pitch diameter of 4.07 inches. These results may be checked as follows

$$\text{Pitch diameter} = \frac{\text{No. of teeth}}{\text{Diametral pitch}} \times \frac{1}{\cos 45 \text{ deg}}$$

$$= 2.875 \times \frac{1}{0.707} = 4.07 \text{ inches.}$$

The outside diameter is $4.07 + 2 \times 0.125 = 4.32$. The lead, as obtained from diagram Fig. 3, in the same way as in Example 1, is 12.8 inches.

Example 3. Required a pair of spiral gears having a normal pitch corresponding to 10 diametral pitch, having a given center distance of 2½ inches approximately, the sum of the spiral angles being 90 degrees, and the speed ratio equal to 5 to 1.

In this case both portions of diagram Fig. 1 are used, the upper part being employed for one gear and the lower part for the other, the easiest way being to get a strip of paper with two lines marked on its edge 5 inches (twice the center distance) apart, drawn to the same scale as the diagram. Move this strip of paper on the diagram (so that the edge of the strip passes through the center), as indicated at *A*, Fig. 4, until the lines marked coincide with points where the ratio of the equivalent diameters equals 5 ÷ 1, and then determine from Fig. 2 that these diameters also give whole numbers of teeth with 10 diametral pitch. We find that 0.5 and 2.5 at 78 degrees and 12 degrees are two such positions, and also 0.6 and 3.0 at 70 degrees and 20 degrees. If we use the latter values, we will have 6 teeth and 30 teeth at 70 and 20 degrees angle, respectively. The exact diameters can now be determined, as in our previous problem, and are 1.75 and 3.19 inches, respectively, the outside diameters being 0.2 inch larger, or 1.95 and 3.39 inches, respectively. This gives the center distance 2.47. These values can now be figured from the formulas as before, and the leads obtained.

Example 4. Required a pair of spiral gears, having a fixed center distance of 4.5 inches, running at equal speeds, the diametral pitch being 7.

The method of procedure is similar to that of the last example, using a strip of paper having a distance of 9 inches marked on the edge in the proper scale, as indicated at *B* in Fig. 4. At about 40 degrees spiral angle we find in Fig. 1 the ratio of number of teeth to diametral pitch to equal 3.14. This ratio is adjusted on diagram Fig. 2, as previously shown, so as to enable one to get a whole number of teeth with 7 diametral pitch, this number being in this case 22. The ratio is then 3.143, and following from this in Fig. 1 to the 40-degree line, one obtains a pitch diameter of about 4.1 inches for one gear, and at 50 degrees, about 4.9 inches for the other. The spiral angles should now be carefully checked mathematically as follows:

cos spiral angle (first gear)

$$= 3.143 \times \frac{1}{4.1} = 0.766; \text{ spiral angle} = 40 \text{ deg.}$$

cos spiral angle (second gear)

$$= 3.143 \times \frac{1}{4.9} = 0.642;$$

spiral angle = 50 deg., nearly.

Now obtain the leads from diagram Fig. 3 in the same way as before, giving the leads of the gears 15.4 and 12.9 inches, respectively.

Example 5. Required a pair of spiral gears, the axes of which are at an angle of 120 degrees; center distance, 4.125; the ratio of equivalent diameters should be as 2 to 3, and the diametral pitch 5.

We require first of all two numbers representing the equivalent diameters, these two numbers bearing the ratio to each other of 2 to 3, and giving a whole number of teeth with 5 diametral pitch. These two numbers, when projected onto two spiral angle lines in a diagram made up as in Fig. 1, the sum of the angles of which lines equals 120 or 60 degrees, give two diameters whose sum equals the center distance multiplied by 2, or 8.25. In this case we cannot use both parts of the diagram Fig. 1, as it is made up for shafts at 90 degrees angle, and for this reason we must take the two readings from the same part of the diagram. The ratios 3 and 4.5 at 30 degrees give corresponding diameters of 3.5 and 5.2, the sum being 8.7. The ratios 2.8 and 4.2 giving 14 and 21 teeth at 25 and 35 degrees, respectively, have diameters of 3.1 and 5.15 (equals 8.25). From this we see that we can use 14 and 21 teeth and the ratios 2.8 and 4.2. The diameters and spiral angles can now be obtained graphically, and more accurately in this manner:

Draw two radial lines, as shown at *C* in Fig. 4, at 120 degrees angle, on a separate piece of paper, and lay off on these to some scale the equivalent diameters, marking the end points 2.8 and 4.2 as shown at *C*, Fig. 4. From these points draw lines at right angles to the radial lines. It is now necesssary to find the position of a line 8.25 inches long, terminating upon these perpendicular lines, and passing through the center. A strip of paper is used in the same manner as before, and upon careful measuring of the respective distances from the center to the lines, one obtains the distances 3.075 and 5.175 inches, which represent the respective diameters, the sum being 8.25. The spiral angle is obtained by measuring or calculating as follows:

$$\text{cos spiral angle of first gear} = 2.8 \times \frac{1}{3.075} = 0.910;$$

$$\text{spiral angle} = 24 \text{ deg. } 15 \text{ min.}$$

$$\text{cos spiral angle of second gear} = 4.2 \times \frac{1}{5.175} = 0.812;$$

$$\text{spiral angle} = 35 \text{ deg. } 45 \text{ min.}$$

The above examples will show the careful student the manner of working out each kind of gear required, and if the directions are properly followed, this method will be found to be a great time-saver. It may be mentioned that it is advisable to keep the spiral angle as nearly equal in the two gears as possible in order to obtain the greatest efficiency of transmission. It should be noted that when diagrams of this type are to be used for practical calculation of spiral gears, they should be laid out in much larger scale than that shown in the engravings, and it would be advisable to lay out radial lines in Fig. 1 for every degree, and vertical and horizontal lines for every tenth of an inch, and circular arcs for equally fine subdivisions. The same is true of the diagrams in Figs. 2 and 3. In Fig. 2, horizontal lines should be laid out for every tenth of an inch, and vertical lines should be laid out for all whole numbers of teeth. In Fig. 3, the horizontal lines should be laid out for every tenth of an inch, vertical lines for at least every 0.2 of an inch, and radial lines for every degree. This diagram should also be laid out so that leads over 20 inches may be read off, as well as those below this figure.

* * *

Some manufacturing concerns, because of general excellence of product in years gone by, have acquired so great a reputation that they have capitalized their reputation, as it were, using the name to bolster up an output that no longer has superlative merit. So marked is this condition with certain concerns to-day that one whose conversation is marked by greater forcefulness than elegance, remarks: "So-and-so's capitalization of good will and mechanical excellence has a h—— of a lot of water in it."

INSTRUMENTS FOR MEASURING TEMPERATURES.

In an article in *The Engineering Review*, September, 1907, entitled "Practical Pyrometry," the author gives a comparative table of the various types of thermometers and pyrometers in use, explaining the general principles upon which each depends for its working, and stating the limits of temperature between which each type may be used. This table, particularly valuable on account of the concise form in which the information it contains has been put, is reproduced below. At the present time pyrometry is becoming an important subject in industrial life, and is not any longer confined to the scientific laboratory only. It would be difficult to mention many industrial operations that do not involve, during some stage or other, an accurate measurement of temperature. To the engineer, power station manager, foundry operator, metallurgist, and, last but not least, the tool hardener, particularly when he deals with high-speed steel, the judgment of temperature has become of the first importance, as upon it depends the maintenance of efficiency in the highest possible degree, or the perfection of the material under treatment. Guess-work—concomitant with costliness—is now being gradually replaced by scientific thermometry, and manufacturers are realizing the assistance that the physicist is capable of affording them in the vital matter of accurate high temperature measurement.

TYPES OF THERMOMETERS IN GENERAL USE.

Class.	General Characteristics of Action.	Type.	Range in degrees Fahrenheit over which they can be used.
Expansion	Change in volume or length of a body with temperature.	Gas..............	32 to 1800
		Mercury, Jena glass and nitrogen......	—40 to 900
		Glass and spirit or petrol.......	—350 to +100
		Unequal expansion of metal rods...........	32 to 900
		Contraction of porcelain......	32 to 3250
Transpiration and Viscosity	Flow of gases through capillary tubes or small apertures.	The Uehling.....	32 to 2900
Thermo-electric	Electromotive force developed by the difference in temperature of two thermo-electric junctions.	Galvanometric..	32 to 2900
		Potentiometric.	32 to 2900
Electric Resistance	Increase in electric resistance of a wire with temperature.	Direct reading on indicator or bridge and galvanometer. ...	32 to 2200
Radiation	Heat radiated by hot bodies.	Thermo-couple in focus of mirror.	32 to 18,000
		Bolometer.......	32 to 18,000
Optical	Change in brightness or in wave-length of the light emitted.	Photometric comparison........	32 to 3600
		Incandescent filament in telescope	32 to 3600
		Nicol with quartz plate and analyzer.............	32 to 3600
Calorimetric	Specific heat of a body raised to a high temperature.	Copper or platinum ball with water vessel...	32 to 2700
Fusion	Unequal fusibility of various metals or earthenware blocks.	Alloys of various fusibilities.....	32 to 3600

THE DESIGN OF JIB CRANES.*

R. W. VALLS.†

R. W. Valls.‡

Among the various types of jib cranes employed for different services in the industrial field, the simple underbraced type is most common, and has been selected for analysis in this article. In the investigation, the method of design, and all the possible stresses to which this type of crane may be subjected, are considered. The treatise may appear somewhat lengthy for such a simple machine, and although some of the stresses discussed are frequently disregarded in actual practice because of the employment of large factors of safety, yet all stresses should be investigated and provision made for them, especially in cranes of abnormal capacities or proportions, or both, which are frequently met with in practice.

As has often been said, sound judgment is a requisite of a successful designer. No precise rules can ever be formulated to cover all cases as they arise in practice, and the judgment of the designer is called upon repeatedly to decide the correct proceeding where there is no precedent.

The following discussion is of a typical crane, and is treated from a theoretical as well as a commercial standpoint, such as would be followed in the engineering office of a manufacturing company.

The type considered consists essentially of a structure in which *GF*, a mast, rests on a foundation (see Fig. 1), and is supported at the top by a suitable connection. *AE* is a member secured to the mast, and supported at *D* by a strut *DC*, which is bolted or riveted to a gusset plate on the member and mast, or connected to these members either with angles or castings as in Fig. 4. Let us first investigate the stresses produced in these members composing the frame, by the external forces acting on the crane. The member *AE*, commonly called the jib, is subjected to stresses produced by the loads concentrated at the wheels of the trolley, and the weight of the members themselves, which stresses we will proceed to find. The trolley carrying the load is supported by four wheels traveling the length of the jib and producing the loads *p*, *p*, placed at a distance *d* from each other. The constant distance *d* is known as the wheel base. These wheel loads *p*, *p* are equal to the sum of the net load to be lifted, *P*, plus the weight of the trolley, ropes and bottom block, divided by the number of wheels supporting trolley, usually four.

The jib is considered as a beam supported at the joints *A* and *D*, having a cantilever end *DE*, and subjected to axial tensile, eccentric tensile, eccentric compressive, and flexural stresses. The length of the cantilever end from *D* to center line of load, when the load is at extreme outer end of the jib, is frequently made about one-fourth the distance between supports *A* and *D*, since, in general, the maximum bending moment produced by loads *p*, *p* when at the end of the cantilever, and that produced when the load is midway between *A* and *D* are about equal. But, more accurately, this ratio should be proportioned so as to obtain equal maximum fiber stresses in both cantilever and span, and thus a jib having a constant cross-section, such as a rolled beam or channel, can be economically employed. When loads *p*, *p* are acting between *D* and *E*, the maximum reaction *R* at *D*, when the trolley is at the extreme end of the cantilever, is the sum of the products of each of the wheel loads multiplied by the ratio of the long levers *AE* and AE_1 to the short lever *AD*. Expressing *AE*, AE_1, and *AD* in terms of the dimension letters, we have (see Fig. 1) *b*, $(b - d)$, and *l*, respectively. Then taking moments about *A*, the fulcrum of the lever, we have

$$R = p \times \frac{b}{l} + p \times \frac{(b - d)}{l} \qquad (1)$$

This reaction *R* produces a direct tensile stress between the points *A* and *D* of the jib, and a compressive stress in strut *CD*.

Let side *AC* of the triangle *ADC* in Fig. 1 represent the magnitude of this reaction *R*; then side *AD* represents the value of the tensile stress, or

$$\text{Stress in } AD = \frac{\text{side } AD}{\text{side } AC} \times R,$$

and, employing dimension letters *l* and *g*, we obtain

$$\text{Stress in } AD = \frac{l}{g} \times R.$$

Substituting the value of *R* of formula (1) for *R*, we have

$$\text{Stress in } AD = \frac{pb + p\,(b - d)}{l} \times \frac{l}{g} = \frac{pb + p\,(b - d)}{g} \qquad (2)$$

Before the section of the jib can be determined, it is required to find the maximum flexural stresses due to the live and dead load bending moments, and combine them with the axial or direct tensile stresses acting on span *AD*, when the absolute maximum bending moment occurs, that is when the wheel loads *p*, *p* are so placed that the center of the span is midway between the center of gravity of these loads and one of the trolley wheels. They must also be combined with the stresses produced by the eccentric pull of the ropes holding the load.

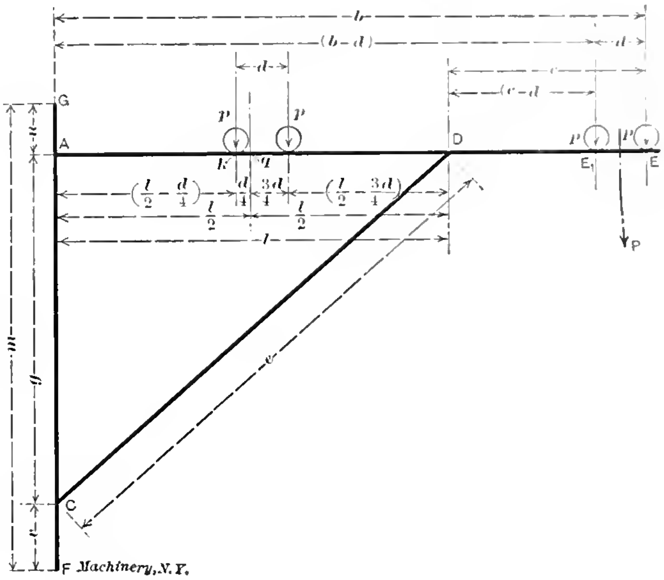

Fig. 1. Diagram of Type o Jib Crane selected for Analysis of Stresses

The direct tensile stress in the jib to be so combined is then not the maximum one just found by formula (2), but that due to the reaction R_1 when the trolley is at the position in the span producing the greatest bending moment, and the value of that reaction R_1 at *D* is found by taking the moments about support *A*, or,

$$R_1 = \frac{p\left(l + \frac{d}{2}\right)}{l}$$

Value of R_2 at *A* is found by taking moments about support *D*,

$$R_2 = \frac{p\left(l - \frac{d}{2}\right)}{l}$$

To obtain the maximum live load bending moment we take

---

† Address: 754 Hoover St., Columbus, Ohio.

‡ R. W. Valls was born at Ponce, Porto Rico, 1880. He is a draftsman and designer, and has been employed at the Deely Iron Works, New York City; Bethlehem Steel Co., South Bethlehem, Pa., and the Case Mfg. Co., Columbus, Ohio.

moments about point k under one of the wheels (as shown in Fig. 1); then we have

$$\text{Maximum bending moment} = R_2 \times \left(\frac{l}{2} - \frac{d}{4}\right)$$

But as $R_2 = \dfrac{p\left(l - \dfrac{d}{2}\right)}{l}$, if we substitute this value of R_2 in the last equation, we find the greatest live load bending moment from

$$\text{Live load bending moment} = \frac{p}{2l}\left(l - \frac{d}{2}\right)^2 \qquad (3)$$

$$\text{Dead load bending moment} = \frac{wl}{8} \qquad (4)$$

$$\text{Approximate total bending moment} = \frac{p}{2l}\left(l - \frac{d}{2}\right)^2 + \frac{wl}{8} \qquad (5)$$

where d = wheel base,

w = weight of jib between supports A and D, which weight must be assumed,

$l = AD$, or span.

In regard to formula (5) it may be said that the customary approximate method of adding the maximum live load bending moment to the maximum dead load bending moment is incorrect, except in cases where the maximum live load bending moment occurs at the center of the span. The correct method for this case is to add to the maximum live load bending moment its increment of the dead load moment at that point, and not the maximum value which takes place at the center of the span. The usual method is sufficiently correct for practical purposes, however, as it is on the safe side.

The unit-stress f, due to bending, in pounds per square inch is found from

$$f = \frac{\dfrac{p}{2l}\left(l - \dfrac{d}{2}\right)^2 + \dfrac{wl}{8}}{Z} \qquad (6)$$

The unit-stress due to jib reaction R_1 is found from

$$f_1 = \frac{R_1 \times \dfrac{l}{g}}{a} = \frac{p\left(l + \dfrac{d}{2}\right)}{ag} \qquad (7)$$

Unit-stress f_2, due to tension of rope, is found from

$$f_2 = \frac{T}{a} + \frac{Tz}{Z} \qquad (8)$$

where T = tension in rope in pounds,

R_2 = value of reaction at D when greatest live load bending moment occurs,

z = eccentricity or distance between center line of rope and center line of member, in inches,

Z = section modulus of section,

a = area of section of member in square inches,

w = weight of jib between supports A and D, and

d, g, l, and p designate quantities as indicated in Fig. 1.

The maximum compressive stress in top flange of jib section $= f - f_1 + f_2$, or

$$\frac{\dfrac{p}{2l}\left(l - \dfrac{d}{2}\right)^2 + \dfrac{wl}{8}}{Z} - \frac{p\left(l + \dfrac{d}{2}\right)}{ag} + \frac{T}{a} + \frac{Tz}{Z}$$

or combining

$$f - f_1 + f_2 = \frac{\left[\dfrac{p}{2l}\left(l - \dfrac{d}{2}\right)^2 + \dfrac{wl}{8}\right] + Tz}{Z} + \frac{T - p\,\dfrac{\left(l + \dfrac{d}{2}\right)}{g}}{a} \qquad (9)$$

The maximum tensile stress in the bottom flange of jib when such flange is opposite to the line of action of the rope (see Fig. 3) $= f + f_1 - f_2$ (f_2 in this case being modified to give tensile stress in bottom flange, due to eccentricity of rope loading), or

$$\frac{\dfrac{p}{2l}\left(l - \dfrac{d}{2}\right)^2 + \dfrac{wl}{8}}{Z} + \frac{p\left(l + \dfrac{d}{2}\right)}{ag} - \frac{T}{a} + \frac{Tz}{Z}$$

or combining,

$$f + f_1 - f_2 = \frac{\left[\dfrac{p}{2l}\left(l - \dfrac{d}{2}\right)^2 + \dfrac{wl}{8}\right] + Tz}{Z} + \frac{\dfrac{p\left(l + \dfrac{d}{2}\right)}{g} - T}{a} \qquad (10)$$

These results should not exceed the specified fiber stress for the structure. Before selecting a structural shape to resist these maximum stresses just found, the stresses on the cantilever end should be considered as follows:

f = flexural stress due to bending.

f_1 = tensile stress due to jib reaction,

f_2 = compressive stress due to tension or pull of ropes.

Live and dead load maximum bending moment

$$= (p \times c) + [p \times (c - d)] + \left(w \times \frac{c}{2}\right) \qquad (11)$$

and f, or stress due to bending on cantilever

$$\text{Unit stress } f = \frac{pc + p\,(c - d) + \dfrac{wc}{2}}{Z} \qquad (12)$$

This maximum flexural stress takes place at D, and immediately to the left of D, there exists at the same time the direct tensile stress due to the maximum reaction R, when the trolley is at the extreme end of the cantilever producing this bending stress, found in formula (1), which also must be combined with the stress due to the pull of the rope. Therefore the unit-stress at point $D = f + f_1 - f_2$.

$$\text{Unit-stress } f_1 = \frac{Rl}{ag} = \frac{pb + p\,(b - d)}{ag} \qquad (13)$$

Stress due to pull of ropes $= f_2$.

$$\text{Unit-stress } f_2 = \frac{T}{a} + \frac{Tz}{Z} \qquad (8)$$

Therefore the maximum fiber stress =

$$f + f_1 - f_2 = \frac{pc + p\,(c - d) + \dfrac{wc}{2}}{Z} + \frac{pb + p\,(b - d)}{ag} - \left(\frac{T}{a} + \frac{Tz}{Z}\right)$$

or combining,

$$f + f_1 - f_2 = \frac{pc + p\,(c - d) + \dfrac{wc}{2} - Tz}{Z} + \frac{\dfrac{pb + p\,(b - d)}{g} - T}{a} \qquad (14)$$

where p = wheel load as before,

w = weight of section of jib from D to its extremity (see Fig. 1).

The compressive stress in strut CD is $R \times \dfrac{\text{side } CD}{\text{side } AC}$, of the triangle ADC, or $R \times \dfrac{e}{g}$.

And since R is maximum when the trolley is at the extreme end of the cantilever, or

$$R = \frac{pb + p\,(b - d)}{l} \qquad (1)$$

then the maximum compressive stress in strut =

$$\frac{pb + p\,(b - d)}{l} \times \frac{e}{g} \qquad (15)$$

$$\text{Unit-stress in strut} = \frac{[pb + p\,(b - d)]\,e}{agl}, \text{ (see Fig. 1).} \qquad (16)$$

where a equals area of cross-section of strut.

The allowable unit-stress per square inch of section of this member is found by the usual Gordon formulas

$$\text{for structural steel, } f = 17{,}100 - 57\,\frac{l}{r} \qquad (17)$$

$$\text{for yellow pine, } f = 1{,}200 - 18\,\frac{l}{t} \qquad (18)$$

However, a satisfactory reducing formula of the Rankine type, extensively used by bridge companies, and specified by some railroad companies, is recommended. It is as follows:

$$\text{for structural steel, } f = \frac{15{,}000}{1 + \dfrac{l^2}{13{,}500\,r^2}} \qquad (19)$$

$$\text{for yellow pine, } f = \frac{1{,}200}{1 + \dfrac{l^2}{250\,t^2}} \qquad (20)$$

where l = length of strut in inches,
t = thickness of timber in inches,
r = least radius of gyration.

The stress in the strut due to its own weight is neglected as being very small in most practical cases.

Ordinarily the ratio $\frac{l}{r}$ should not exceed 130; however, this ratio is frequently increased if the fiber-stress is well under the one specified, and as long as its departure from straightness will not subject the strut to an appreciable bending moment.

The stresses that may exist in the mast are as follows: (See Fig. 1.)

(1) Axial compression due to reaction R_3 and weight of structure.

(2) Eccentric stress due to R_3 when trolley is at extreme position on jib next to mast for cranes where jib connects to the face of the mast, and not at the center line of gravity of its section.

(3) Eccentric flexural stress due to tension in ropes.

(4) Flexural stress due to direct tension in jib AE, and to the horizontal component of direct compression in the strut DC.

(5) Eccentric flexural stress due to weight of drum and other hoisting machinery. This last stress is usually disregarded, however, except where the jib and hoisting machinery are of abnormally large proportions.

$$\text{Unit-stress } f'_1 = \frac{R_3}{a},$$

$$\text{but} \qquad R_3 = \frac{pl + p\,(l - d)}{l}$$

$$\text{therefore} \qquad f'_1 = \frac{\dfrac{pl + p\,(l - d)}{l}}{a} = \frac{pl + p\,(l - d)}{al} \qquad (21)$$

$$\text{Unit-stress } f'_2 = \frac{R_3}{a} + \frac{R_3 z_1}{Z} \text{ (see Fig. 3),}$$

$$\text{but} \qquad R_3 = \frac{pl + p\,(l - d)}{l}$$

$$\text{therefore} \qquad f'_2 = \frac{pl + p\,(l - d)}{l}\left(\frac{1}{a} + \frac{z_1}{Z}\right) \qquad (22)$$

$$\text{Unit-stress } f'_3 = \frac{T}{a} + \frac{Tz_3}{Z}\cos\theta \qquad (23)$$

$$\text{Tension in jib} = H = \frac{pb + p\,(b - d)}{g} \text{ (see Fig. 2)} \qquad (2)$$

The horizontal component of stress in strut is equal to the tension H. The mast is then considered as a beam supported by reactions H and r. (See Fig. 2.)

$$r = \frac{p \times b + p\,(b - d) + w_1 \times j}{m} \qquad (24)$$

where w_1 = weight of structural frame,
j = distance from center of mast to center of gravity of frame,
m = distance between centers of bearings.

The quantity $w_1 \times j$ may be omitted when the frame is not very large. The maximum bending moment in the mast is then $r \times u$ or $r \times v$, whichever is greatest. Distances GA and CF, Fig. 1, should be as small as consistent with the design to obtain economy.

$$\text{Unit-stress } f'_4 \text{ at cantilever } GA = \frac{ru}{Z}$$

$$\text{Unit-stress } f'_5 \text{ at cantilever } CF = \frac{rv}{Z} \qquad (25)$$

The axial compressive stress in the mast due to the whole weight of the structure, should be added to the flexural compressive stress f_4' due to bending when the trolley is at the extreme end of the jib, since that part of the mast immediately beneath C is subjected to both at the same time under these conditions.

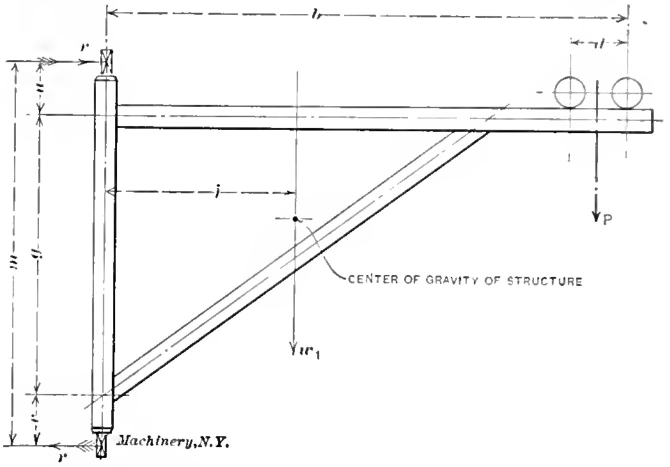

Fig. 2. Outline of Crane for which the Design is Calculated.

The stress f_4' is not added to the stress f_2' as found by formula (22), because they do not take place at the same time, the maximum bending taking place when the trolley is at the end of the jib, and the maximum eccentric compressive stress when the trolley is close to the mast.

It is sometimes required, when long jib members are necessary, to brace the two shapes composing the jib at some intermediate point in order to reduce the ratio $\frac{l}{r}$, and, at the same time, lessen the tendency of the jib members to spread. This is done by securing structural shapes bent clear over the jib trolley. (See Fig. 4.) The ratio $\frac{l}{r}$ should not exceed that above specified.

The pintles at G and F should be made large enough to resist the bending moment on them, and also designed for a safe bearing pressure per square inch of their projected area. This pressure is the quantity r in formula (24).

The jib end connection is subjected to flexural stresses due to the tension of the rope or ropes, which should be taken into consideration. The connection is treated as a beam, and the pull of the rope or ropes as concentrated loads in the middle or at equal distances from the middle, according to the kind of connection employed, the beam in question being supported at both ends.

Example.

Required to design a jib crane of the underbraced type to lift a load of 10,000 pounds at a radius of 21 feet 6 inches; distance between underside of roof truss or top support and floor 13 feet 6 inches; jib to be constructed of two structural steel frames composed of standard size channels and connected together (see Fig. 4); trolley mounted on four wheels running on top flanges of jib member. Maximum fiber-stress 13,000 pounds per square inch, which is allowable for hand-power machines. For a load of 10,000 pounds we will use four parts of 7/16-inch—6 strands of 19 wires—plow steel hoisting rope, having a breaking strength of 17,700 pounds, and will give a factor of safety of $\frac{4 \times 17{,}700}{10{,}000} = 7.08$, which must also take care of the bending stresses in the ropes. This size of rope will require sheaves of 14 inches in diameter, and will allow a wheel base of 36 inches. Two ends of these two lengths of rope will wind on the drum, and the other two ends will be supported at the outer end of the jib by an equalizing beam.

Load to be lifted	10,000 pounds
Approximate weight of trolley, ropes and block	500 pounds
Total	10,500 pounds

which will make the wheel loads $\frac{10{,}500}{4} = 2{,}625$ pounds each.

Distance between mast and joint D, Fig. 3, = 208 inches.

Distance between jib and joint C = 120 inches.

Distance between mast and extreme position of outermost wheels of trolley = effective radius + half the wheel base = 21 feet 6 inches + 1 foot 6 inches = 23 feet = 276 inches.

Let us first assume the trolley at that position in the span AD producing the greatest bending moment (see Fig. 1).

Maximum live load bending moment

$$= \frac{2625}{2 \times 208}\left(208 - \frac{36}{2}\right)^2 = 227{,}793 \text{ inch-pounds.} \qquad (3)$$

By looking at the table of properties of steel channels in any steel company's handbook, we find that a 12-inch channel weighing 20.5 pounds per foot, with an area of 6.03 square inches, has a section modulus about the axis perpendicular to the web of 21.4, and this value divided into the live load bending moment will give a stress of 10,644 pounds per square inch, which leaves us a margin for the other stresses yet to be considered. Therefore, we will temporarily select the above shape for the purpose of finding the bending-moment due to the uniform weight of the member itself.

Weight of channel between A and D $= \frac{208}{12} \times 20.5 = 355$ pounds.

$$\text{Dead load bending moment} = \frac{355 \times 208}{8} = 9{,}230 \text{ inch pounds.} \qquad (4)$$

Approximate total bending moment

$$= 227{,}793 + 9{,}230 = 237{,}023 \text{ inch-pounds.} \qquad (5)$$

Unit stress due to bending

$$= \frac{\frac{P}{2l}\left(l - \frac{d}{2}\right)^2 + \frac{wl}{8}}{Z} = \frac{237{,}023}{21.4} = 11{,}076 \text{ pounds per square inch.} \qquad (6)$$

Unit-stress due to reaction R_1

$$= \frac{2625 \times \left(208 + \frac{36}{2}\right)}{120 \times 6.03} = 817 \text{ pounds per square inch} \qquad (7)$$

$$\text{Tension in ropes} = \frac{10{,}000}{4} = 2{,}500 \text{ pounds.}$$

Unit-stress due to tension in rope

$$= \frac{2{,}500}{6.03} + \frac{2{,}500 \times 8}{21.4} = 1{,}348 \text{ pounds per square inch.} \qquad (8)$$

Total stress on top flange $= f - f_1 + f_2 = 11{,}076 - 817 + 1{,}348 = 11{,}607$ pounds per square inch (9), which stress is under the one specified; the shape tentatively selected may therefore be used for this member of the crane.

Weight of cantilever end of jib $= \frac{93}{12} \times 20.5 = 159$ pounds.

Unit stress due to bending

$$= \frac{2{,}625 \times 68 + 2{,}625 \times 32 + 159 \times \frac{93}{2}}{21.4} = 12{,}613 \text{ pounds per sq. inch.} \qquad (12)$$

Unit-stress due to reaction R

$$= \frac{2{,}625 \times 276 + 2{,}625 \times (276 - 36)}{120 \times 6.03} = 1{,}872 \text{ pounds per sq. inch.} \qquad (13)$$

Unit-stress due to pull in rope

$$= \frac{2{,}500}{6.03} + \frac{2{,}500 \times 8}{21.4} = 1{,}348 \text{ pounds per square inch.} \qquad (8)$$

Total unit-stress on top flange of cantilever =
$12{,}613 + 1{,}872 - 1{,}348 = 13{,}137$ pounds per square inch, **(14)** which is 137 pounds per square inch more than the specified stress. In practice, this will not be considered of sufficient importance to change the design.

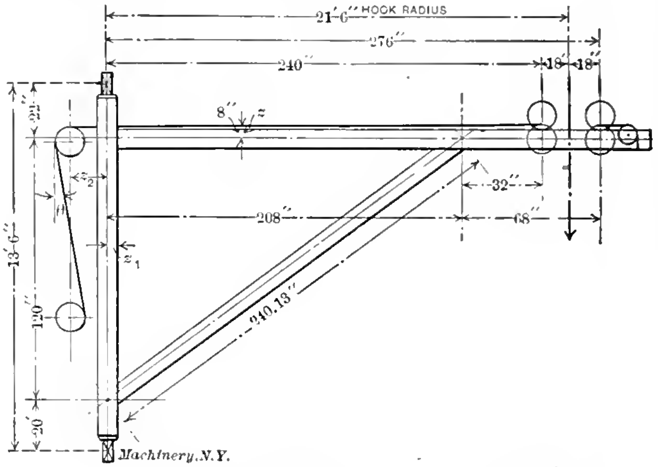

Fig. 3. General Dimensions of Crane to be Designed.

Total length of jib member = 25 feet 1 inch, or 301 inches.

Least radius of gyration of 12 × 20.5 pounds channel = 0.81.

The ratio $\frac{\text{length}}{\text{least radius of gyration}} = \frac{301}{0.81} = 371$, consequently the channels of the two frames should be braced at least at a point midway between the end connection and the mast. (See Fig. 4.)

Length of strut $DC = \sqrt{120^2 + 208^2} = 240.13$ inches. Selecting a 15 × 33-pound channel having a cross-sectional area of 9.9 square inches, and least radius of gyration of 0.91, for strut, we have the compressive unit-stress

$$= \frac{[2{,}625 \times 276 + 2{,}625\,(276 - 36)] \times 240.13}{208 \times 120 \times 9.9} = 1{,}316 \text{ pounds per square inch.} \qquad (16)$$

$$\text{Allowable stress} = \frac{15{,}000}{1 + \frac{240.13^2}{13{,}500 \times 0.91^2}} = 2{,}440 \text{ pounds per sq. inch.} \qquad (19)$$

The ratio of the length of the strut to its least radius of gyration is $\frac{240.13}{0.91} = 264$, which is excessive; the maximum unit-stress, however, is very low, only 1,316 pounds per square inch, or hardly more than half of that allowed by the formula (19). As there is not a channel rolled by any mill with a greater "least radius of gyration" than the one we have employed, we may stiffen the strut laterally by riveting an angle to its web in the inside or back of channel. Unless the ratio 130 must be adhered to, the channel should be left as it is as long as the member shows no great deflection under load.

Let us now investigate the stresses existing in the mast, which we assume is composed of two 12 × 20.5-pound channels. The distance from center of mast to nearest wheel when the trolley is at the extreme position next to mast = 11 inches.

$$\text{Then } R_3 = \frac{2{,}625\,(208 - 11) + 2{,}625\,(208 - 11 - 36)}{208} = 4{,}518$$

pounds.

As the two vertical shapes composing the mast are latticed together, we will take the two equal reactions R_3 (one which acts on one channel and the other on the opposite one) to be resisted by the two shapes combined, therefore the least radius of gyration of the mast as built is then that perpendicular to the web of the channels, whose value is 4.61.

Then the allowable compressive stress

$$= \frac{15{,}000}{1 + \dfrac{162^2}{13{,}500 \times 4.61^2}} = 13{,}761 \text{ pounds per sq. inch.} \quad (19)$$

Unit-stress f'_1

$$= \frac{2{,}625\,(208 - 11) + 2{,}625\,(208 - 11 - 36)}{6.03 \times 208} = 749 \text{ pounds per square inch.} \quad (21)$$

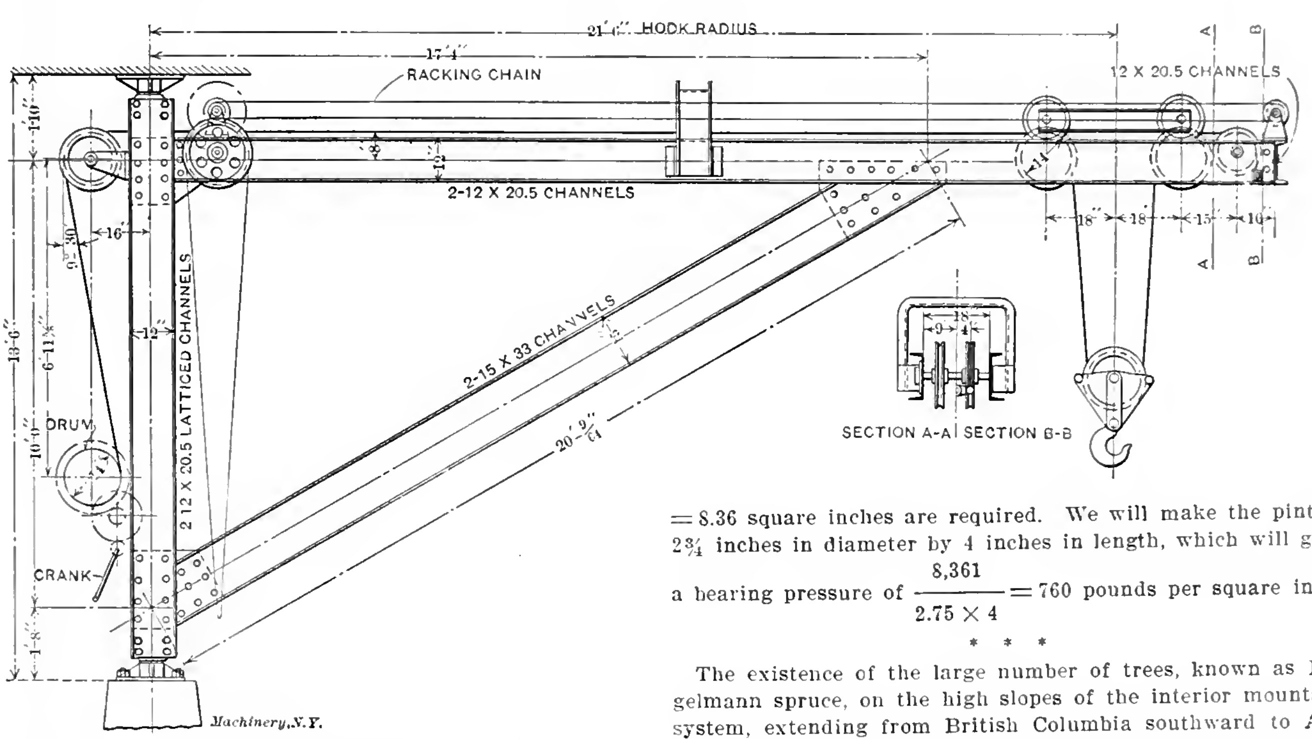

Fig. 4. Crane calculated to lift a Load of 10,000 Pounds at a Radius of 21 feet 6 inches.

Stresses f'_2 do not take place in this gusset-connected frame.

Unit-stress f'_3 due to tension of rope

$$= \frac{2{,}500}{6.03} + \frac{2{,}500 \times 16}{21.4} \times \cos 9 \text{ deg. } 30 \text{ min.} \quad (23)$$

$= 2{,}257$ pounds per square inch. (See Fig. 4.)

Horizontal reaction at top and bottom of mast when load is at extreme outside end of jib =

$$r = \frac{2{,}625 \times 276 + 2{,}625\,(276 - 36)}{162} = 8{,}361 \text{ pounds.} \quad (24)$$

Unit-stress f'_4 due to bending moment at top of mast =

$$\frac{8{,}361 \times 22}{21.4} = 8{,}548 \text{ pounds per square inch.} \quad (25)$$

Maximum unit-stress immediately beneath point A of mast $= f'_4 + f'_3 = 8{,}548 + 2{,}257 = 10{,}805$ pounds per square inch.

For the end connection of the jib at E we select a 12-inch × 20.5 pounds channel for the sake of symmetry, and proceed to investigate the bending stress to which it is subjected due to the pull of the ropes. The distance between the jib members is 18 inches. The pull on the ropes is 2,500 pounds. The section modulus of the channel in consideration about an axis parallel to the web is 1.75. Two ropes, both four inches from the center of connecting channel are used (see Fig. 4).

Maximum bending moment on channel $= 2{,}500 \times (9 - 4) =$ 12,500 inch-pounds

$$\text{Unit-stress} = \frac{12{,}500}{1.75} = 7{,}143 \text{ pounds per square inch.}$$

Horizontal reaction on pintles

$$r = \frac{2{,}625 \times 276 + 2{,}625\,(276 - 36)}{162} = 8{,}361 \text{ pounds.} \quad (24)$$

Assuming the pintles to be 4 inches long, and taking moments about a lever arm from the center of the bearing to the support (= 2 inches), we have, bending moment = 8,361 × 2 = 16,722 inch-pounds. Unit-stress on pintles should not exceed 9,000 pounds per square inch for machine steel.

$$\text{Section modulus of a circular section} = \frac{\pi d^3}{32} = 0.098 d^3,$$

where d = diameter of section.

$$\text{Diameter of pintle} = d = \sqrt[3]{\frac{16722}{0.098 \times 9000}} = 2.66 \text{ inches.}$$

The bearing pressure on pintles should not exceed 1,000 pounds per square inch of projected area. Therefore $\dfrac{8{,}361}{1{,}000} = 8.36$ square inches are required. We will make the pintles $2\frac{3}{4}$ inches in diameter by 4 inches in length, which will give

$$\text{a bearing pressure of } \frac{8{,}361}{2.75 \times 4} = 760 \text{ pounds per square inch.}$$

* * *

The existence of the large number of trees, known as Engelmann spruce, on the high slopes of the interior mountain system, extending from British Columbia southward to Arizona and New Mexico, has induced the U. S. Forest Service to undertake experiments to determine whether this tree, which is comparatively small and which is not considered a very valuable timber tree, can be used for making paper pulp. Samples have been received from the national forests of Wyoming, Colorado and Utah, and these have been treated by the sulphite process, and pulp obtained from which is secured paper fully as good as that made from Eastern spruce. The results of preliminary trials on seasoned wood shows that it gives a fiber fully as valuable as that from its Eastern relative. The fiber of Engelmann spruce seems to be slightly shorter than that of the Eastern spruce, but it is of sufficient length to be used for the latter in nearly all the manufactured products, and there is apparently no reason why it should not be so used provided that other conditions of manufacture and transportation are favorable.

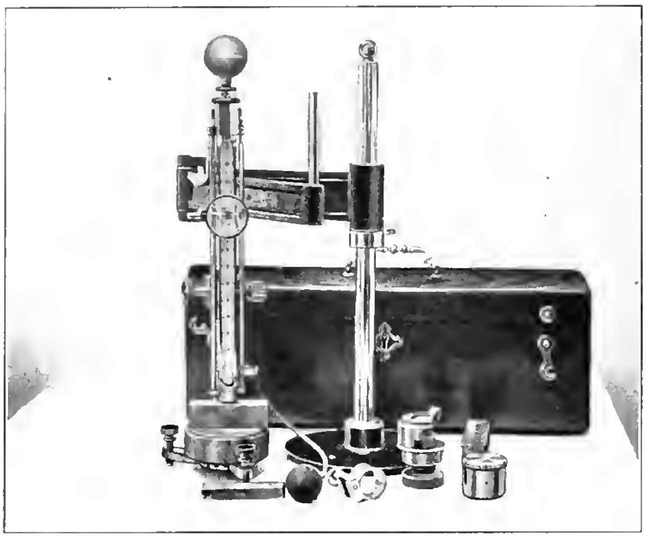
* * *

It is stated in the *English Mechanic and World of Science* that an English company has succeeded in obtaining photographic films where the natural colors of the objects photographed are reproduced. The photographs are obtained by a direct method, and are made for use in a moving picture apparatus. The company has given an exhibition of the results obtained to members of the press, and it appears that this invention marks a decided advance in color photography.

A NEW MECHANICAL TEST FOR HARDNESS.*

J. F. SPRINGER †

Even when men first began to harden steel, they probably sought some method of ascertaining in particular cases whether their object had been accomplished. Perhaps the testing tool was nothing more than a fragment of flint or another piece of steel known to be hard. Certain jewels—as the diamond—are well suited to a process which depends upon scratching. In fact, this process is in common use everywhere even at the present day. The test by filing is not to be despised as it is easily applied, and if the file is a good one, the results are sufficiently accurate and reliable for a considerable class of work. But the file is an instrument inadequate to the requirements of modern metallurgists and manufacturers. This is true for two reasons: First, the alloy steels seem to possess the property of being able to resist a file, apart from hardness. Thus, a piece of manganese self-hardening tool steel may be, in reality, softer than a specimen of a pure carbon steel, and yet resist the attacks of the file equally well. In explanation of this phenomenon, it has been suggested that the hard manganese resists the file while the iron substratum remains soft. The combination as a whole would not be so hard, although able to withstand the file. This, however, seems really to involve the proposition that such steel is not a perfect chemical combination, but that particles of manganese are held imbedded in iron or an iron alloy. Perhaps this may be so; but if it is true, then the action of such steel on the file is very similar to that of an emery wheel. The emery itself is very hard, but is held in a matrix that is soft. However, whether we accept this explanation or not, it is doubtful whether we have good reason to contend that a specimen of alloy steel is as hard as a piece of pure carbon steel, merely because it resists the file equally well.



The Scleroscope—An Instrument for Testing the Hardness of Metals.

The second objection to the file is that it affords no reliable means of making accurate comparisons between different degrees of hardness. It is sometimes of importance in cases where one element of a machine slides against another to ascertain which of the two is the harder. The difference may be very slight, yet it will readily be granted that this difference might become of importance if lubrication failed. For, the harder piece would then cut or wear the softer. If such a contingency is possible, then it is important that the more expensive part shall be the harder. A little reflection will convince one that this principle of associating a harder valuable part with a softer less valuable part, has application everywhere in machine construction; but in order to apply this principle widely, it is necessary to be able to determine differences in hardness where these differences are quite small in amount.

A modern instrumental means of testing for small differences in hardness is that known as the Brinell device. In accordance with this method, a steel ball is pressed against the specimen to be tested. The permanent indentation formed is then measured—say, for depth. Assuming that, with the compression the same and with a ball of the same size and hardness, the variations in depth of indentation furnish a means of quantitatively determining variations in the degree of hardness; it only remains to measure these depths with sufficient accuracy, and we shall obtain, by referring to a previously calculated table, a series of numerical values expressing the variations in hardness. Of course, the deeper the indentation, the softer the substance; so that if it is desired that the numbers increase with the increase in hardness, we have only to take the reciprocals. This mechanical test for hardness has found pretty extended introduction. But it may well be questioned whether hardness is really tested by the slow formation of an indentation. There can be no doubt that resistance to slow penetration is tested by this procedure, but is resistance to slow deformation what we mean by hardness? I scarcely think so.

A piece of sealing-wax resists deformation but feebly if the deforming procedure is applied gradually. We should hardly say that the hardness of this substance is of so low a degree as this slight resistance to slow displacement of its particles would indicate. Then again, it is quite conceivable that toughness might so contribute its assistance in withstanding a slow deformative process that the result could not be looked on as an accurate indication of hardness alone. Now what we call toughness appears to be slow in its operation. That is, at the beginning of a deformative effort there is a yielding of the particles; this is followed by resistance to further displacement. But time seems to be required for the development of this resistance. What we call hardness appears to be, on the contrary, a resistance that is instantly available. That is to say, in hardness there is an instantaneous resistance to displacement of particles. This conception of the difference between hardness and toughness as the difference between an instantaneous and a slower recovery of particles, seems to strike close to the truth. Adopting this distinction as a true criterion, we should derive a test for hardness by testing for the instantaneous recuperative power of metals.

In the process employed by Mr. Shore (Shore Instrument & Mfg. Co., 226 W. 24th St., New York City), carried out by means of the hardness-testing instrument (the scleroscope—see Fig. 1) which he has developed, the energy of resistance at the moment when the elastic limit is exceeded seems to be the thing measured. And this would appear to be just about what we mean by hardness. A tiny hammer, pointed at the lower end, falls from a fixed height upon the specimen, striking a blow exceeding the elastic limit. The rebound is then measured.

In the first experiments, a steel ball was used as the hammer, but the results were only partially satisfactory. In fact, the inventor was well-nigh on the point of giving up when he met a French expert in metals by the name of Dr. Herould. Following out certain of his suggestions, Mr. Shore has succeeded in producing an instrument which apparently gives great promise of solving the problem of the testing of hardness. The difficulty with the ball-shaped hammer was that it was incapable of striking a sufficiently hard blow to get adequate results, especially with hardened tool-steel, so the area of contact was reduced, although the weight was kept large in comparison. In fact, the blow struck by the sharper of the two varieties of hammer used in the scleroscope, is estimated at 75,000 pounds per square inch. The point which strikes is, however, so small on the tip that with a fall of ten inches the weight of the whole hammer is required to be but a small fraction of an ounce.

But the determination of these points, while important, was not by any means a complete solution. A great difficulty arose in connection with the material for the hammer; it was necessary to have extraordinary hardness combined with a non-crystalline structure. The diamond was found unequal to the requirements of the case, and after much investigation in which the scleroscope—although itself still imperfect—assisted, a method of treating tool steel was developed, which

---

* For additional information on this subject, see the article on "The Brinell Method of Testing the Hardness of Metals" published in the September, 1908, issue of MACHINERY.

† Address: 625 W. 135th St., New York City.

produces, under favorable conditions, a very hard steel capable of the exacting duty required. The absolute weight of the entire hammer is little, but relatively to the striking area it is very great. This hammer, having a cylindrical body, is guided in its fall by a glass tube. Great difficulty has been experienced in getting tubes with a sufficiently perfect bore. There seems to be no commercial method of manufacturing such tubes, so the method of test-and-reject is employed, resulting in a very great waste.

The tube is secured to a frame in a vertical position with the lower end open. Upon exhausting the air by means of a rubber bulb connection, the hammer is drawn to the top where it is held by a suitable catch. When it is desired to release the hammer, a hook, seen in Fig. 1 at the top and to the left, is drawn downwards by the left hand while the right compresses a second rubber bulb, seen on the table. Upon releasing the bulb, the hammer drops and its point strikes sharply the piece of metal to be tested. The rebound of the hammer is measured against a scale graduated from 0 to 140, secured in position back of the glass tube. To aid in reading the rebound, a magnifying glass is supplied. After some practice, its assistance may be dispensed with, if desired. However, to use it, it is secured in such position as to cover the possible region of the expected reading. The rod to the left of the tube is the support to which the magnifying attachment is secured and along which it is adjustable. The rod to the right of the tube is a plumb-rod; it swings freely from a point of attachment above, and enables the operator to keep the tube vertical.

Fig. 2. Shaft and Box of a Lathe being Tested to determine the Relative Hardness.

The instrument proper—that is, apart from the supporting stand—may be used to test parts of machinery in position. In this way a shaft and box may be tested to determine the relative hardness. See Fig. 2. In using the instrument with the stand, the specimen is placed on the table or secured in a holder. It is necessary that the actual point tested should be clean and horizontal, and that the piece should be firmly held. If the specimen is quite irregular, it may be held in a support of asphaltum and tar. This combination; while yielding to slow pressures, is quite unyielding when the blow is instantaneous—as with the scleroscope hammer. Of course, the upper part of the specimen at the point to be tested must be horizontal. If necessary to test more than once, the piece should be slightly moved so as to expose a fresh point to the hammer. The indentation made is, however, very minute, so that several are usually unobjectionable.

The scale, as already mentioned, runs from 0 to 140. The hardness of the finest steels ranges from 100 to 110. Porcelain and glass have higher grades, while unhardened steels, brass, zinc, and lead show lower and lower degrees. Unhammered or unrolled lead produces a rebound of but two graduations. The question may arise with some whether the graduations should all be of equal size—whether, in fact, they should not progressively increase as one goes from one end of the scale to another. It seems that there should be no difference. What it is desired to measure is the energy of the rebound. Now the energy of falling (or rebounding) bodies varies with the first power of the space traversed, so that with equal increases of energy we shall have equal increases of the space rebounded. The scale may be regarded, then, as affording readings which are strictly proportional to the energy of resistance of the metal being tested, when the elastic limit is exceeded. If we regard this energy of resistance as indicative of what we mean by hardness, then the scleroscope seems to fulfill the requirements of a scientific measurer of this important property of metals.

One of the great results of the introduction of scientific methods of precise quantitative measurement of hardness, promises to be in the determination of the relation of the cutting tool to the work to be machined. We are all aware that the tool must be harder; but how much harder? And how express this relation in intelligible language? The scleroscope, it is hoped, will afford a pretty definite answer to this problem. The law has been laid down that the comparative hardness between tool and work as determined by scleroscope readings, should be in the ratio of 3 to 1 or 4 to 1, in order to secure the best commercial results. In illustration of this point, we may take the case of work to be machined consisting of a 1 per cent carbon tool steel. Unannealed, such steel is found upon testing to disclose a hardness varying from 40 to 45 points. According to the above law, the cutting tool should be at least about 120 to 135 hard; but the same steel properly annealed, is only about 31 hard. Consequently, it is not at all difficult to find a suitable material for the cutting tools. Thus, a fine quality of pure carbon tool steel, well hardened, has a hardness of 95 to 110, and is consequently suitable to cut material of a hardness of 31. Now if this principle as to relative hardness necessary, can be thoroughly established for all kinds of metals, an element of scientific certainty will be introduced into machine practice. This will make for economy of time and tool.

Again, it is, of course, to be expected that if two metal parts wear or rub against each other, the harder of the two will cut the softer, whether the difference is small or great, so that it is often important to know whether the more expensive part is really the harder. The scleroscope would seem to afford a means of determining with precision slight differences in hardness, thus enabling the manufacturer to assemble contacting moving parts on the principle of a harder expensive piece in association with a softer cheaper one. Thus in an electrical repair shop, instances may readily be found of the steel shaft cut by the brass box, the box cut by the shaft, and a pretty even wear of both. From an economical point of view, it is much better to have the brasses worn than the shaft, and with such an instrument as the scleroscope it would be possible to predetermine this economically better result. It would seem an easy matter for an automobile manufacturer, say, so to specify the hardness of the gear wheels used, that the gear manufacturer could supply him with a uniform product.

A further illustration, which suggests itself, is the possibility of assembling the outer and inner rings of ball bearings so as to equalize the wear of the two raceways. Other things being equal, the inner raceway wears more rapidly because the convex ball contacts with a rather sharply convex raceway (convex as seen transversely), while in the case of the outer raceway the convex ball contacts with a more gradual and concave curve. By adjusting this inequality through association of a hard inner ring with a softer outer ring, the wear may be equalized.

An important application of quantitative hardness tests, would appear to be in connection with high-speed steels. Now such steels disclose upon testing with this instrument, a

hardness varying from 80 to 105. This is at ordinary temperatures, however, and shows scarcely as high a degree as the best of the pure carbon steels. The effectiveness of high-speed steels depends largely upon the fact that at temperatures of 600 to 1,000 degrees, at which pure carbon steels would lose their temper, they retain a high degree of hardness, amounting, say, to 75 on the scleroscope scale. This is sufficient—following the principle of 3 to 1—to do heavy machining on annealed machinery steel measuring 25 on the same scale. But, if the heat developed by high speed and heavy cuts, succeeds in lowering the high-speed steel of the tool much lower than 75, then it is no longer an effective tool. It becomes of importance then to test high-speed steels for their effectiveness under temperature conditions obtaining in actual service. It is a small matter to know that a certain tool of high-speed steel is very hard when cold; what is its condition when hot? By heating the tool to the required temperature, and then testing with the scleroscope, its condition may be determined. It is thought that thus the real effectiveness of the high-speed steels may be determined in advance of their use or even of their purchase.

It is deserving of serious consideration that the scleroscope method is not limited to particular metals. It seems applicable to practically all the metals, not only for comparing different varieties of the same metal, but for comparing specimens of different metals. Thus, as already pointed out, brass may be compared with steel.

* * *

BAND AND BLOCK BRAKES.

A. L. CAMPBELL.*

Formulas for band and block brakes are not easily obtained, because many mechanical hand-books do not give any information on this subject. In order to supply a possible need in this direction, the formulas given in the current supplement have been compiled. These formulas are based on, and agree in form with, the formulas for these classes of brakes given in "Des Ingenieurs Taschenbuch," published by the Hütte Association, Berlin, Germany.

In any band brake, such as shown in Fig. 1 in the Supplement, where the brake wheel rotates in a clockwise direction, the tension in that part of the band marked x equals $P\dfrac{1}{e^{\mu\theta}-1}$; and in that part marked y, the tension equals $P\dfrac{e^{\mu\theta}}{e^{\mu\theta}-1}$. In these expressions,

P = tangential force in pounds at rim of brake wheel,
e = base of natural logarithms = 2.71828,
μ = coefficient of friction between the brake band and the brake wheel,
θ = angle of contact of the brake band with the brake wheel expressed in radians (one radian = $\dfrac{180 \text{ deg.}}{\pi}$ = 57.296 degrees).

For simplicity in the formulas presented, the tensions at x and y (Fig. 1, band brakes) are denoted T_1 and T_2, respectively, for clockwise rotation. When the direction of the rotation is reversed, the tension in x equals $T_2 = P\dfrac{e^{\mu\theta}}{e^{\mu\theta}-1}$ and the tension in y equals $T_1 = P\dfrac{1}{e^{\mu\theta}-1}$, which is the reverse of the tension in the clockwise direction.

The value of the expression $e^{\mu\theta}$ occurring in these formulas may be most easily solved by means of logarithms. The value of $e^{\mu\theta}$ is found by multiplying the logarithm of e by the product of the numerical values of μ and θ, and finding the number whose logarithm is equal to the result of this multiplication. The procedure may be best illustrated by an example.

In a band brake of the type in Fig. 1 in the Supplement, dimension $a = 24$ inches, and $b = 4$ inches; force $P = 100$ pounds; coefficient $\mu = 0.2$, and angle of contact = 240 degrees, or $\theta = \dfrac{240}{180} \times \pi = 4.18$. The rotation is clockwise. Find force F required.

$$F = \frac{Pb}{a}\left(\frac{e^{\mu\theta}}{e^{\mu\theta}-1}\right) = \frac{100 \times 4}{24}\left(\frac{2.71828^{0.2\times 4.18}}{2.71828^{0.2\times 4.18}-1}\right) =$$

$$\frac{400}{24} \times \frac{2.71828^{0.836}}{2.71828^{0.836}-1} = 16.66 \times \frac{2.31}{2.31-1} = 29.4.$$

The formulas given for the brakes in the Supplement are not empirical, but are theoretically correct. They can be mathematically verified. By means of calculus the values represented by T_1 and T_2 for the band brakes may be deduced, while the various expressions for F are obtained by equating the moments of the forces involved about any point of the brake, preferably about its fulcrum, or fixed point. For the block brakes the whole question is one of moments. For example, in Fig. 3, for clockwise rotation, by taking moments about the fulcrum we obtain $F(a + b) - Pc = \dfrac{Pb}{\mu}$,

From which

$$F = \frac{\dfrac{Pb}{\mu} + Pc}{a + b} = \frac{Pb}{a + b}\left(\frac{1}{\mu} + \frac{c}{b}\right)$$

The calculations for determining the value of $e^{\mu\theta}$ are rather cumbersome, and the accompanying table is appended in order to save the computation of this value for certain values of μ, and certain angles θ.

* * *

An interesting little slide rule has been brought out by Kolesch & Co., New York. This slide rule is only about half as long as the ordinary slide rule, and its weight does not exceed 1½ ounce; but it can be used to the same advantage, with equal reliability and accuracy, as the larger rules. The subdivisions are the same as those of the larger instruments, and in order to make it possible for the eye to read off the results with the same convenience as on a larger rule, a magnifying glass is placed in the runner, so that the divisions appear to the eye as clearly as those of larger slide rules.

METHOD OF LAYING OUT AND CUTTING CAMS.*

HERBERT C. BARNES.†

Working by guess, or by the rule of thumb, is practiced quite as much, if not more, in the making of cams as in any other kind of machine work. Possibly this is so because a little leeway is generally given for the action of cams in the design of many machines, and the time-honored cut and try methods are relied on to bring the movements within necessary limits. It is certainly a fact that many a man who has laid out and cut cams does not know just what their performances will be until they are assembled in their machine and tested.

In this article we will consider the method of laying out a cam the requirements of which are as complicated in principle as any ordinarily used. We will then review a process for making the master cam, which is generally used, and also another process not generally employed, but of much greater service.

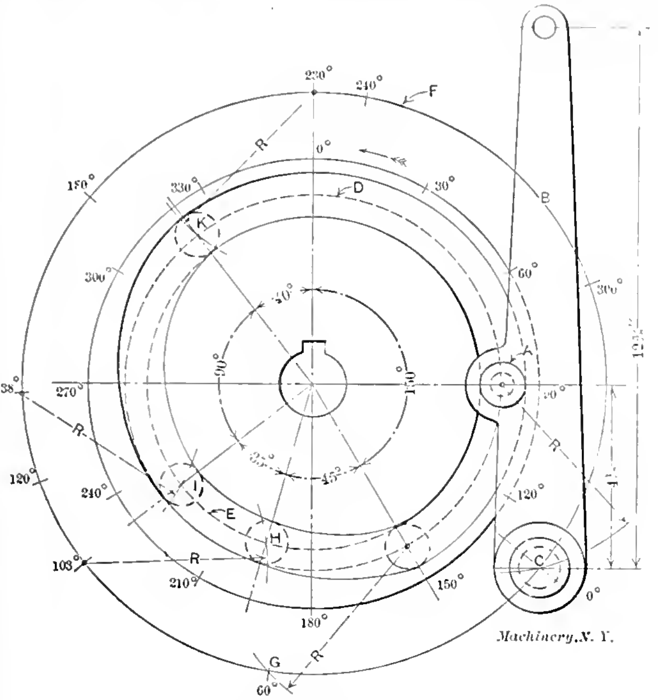

Fig. 1. Layout of Cam.

The cam which we will lay out is seen in Fig. 1. It turns toward the left and moves a 1-inch roller *A* which controls the lever *B* swinging on the stud *C*. The cam is to be keyed to a shaft, together with several other cams, in all of which the keyway is at the beginning of the cycle. The requirements which follow are selected to illustrate as simply as may be the method employed. The head of the lever *B*, which is 12¾ inches long, is to remain at rest until the cam has turned 150 degrees from the zero point or beginning of the cycle; it is then to advance 1½ inch in 43 degrees; then it will dwell for 35 degrees more, and, finally, retreat 1½ inch in 92 degrees, after which it will dwell for the remainder of the cycle. In Fig. 1 it is seen that the roller *A* is located at one-third of the distance from the pivot of the lever to its head. Hence a movement of one-half inch is required of the roller in the cam to move the lever head 1½ inch.

Layout of Cam.

We will now begin the layout. Draw first the circumference of the cam; its diameter we will make 10 inches. With the keyway on the vertical diameter, draw a line through its center. With this line as zero, divide the circumference into 30 degree sections, as shown, and number them. Now draw the circle *D* with a radius of 4 3/16 inches, to show the extreme outer position of the center of the roller, and the circle *E* with a radius of 3 11/16 inches, to show the extreme inner position of the center of the roller. Next, with the center of the cam as its center, draw the circle *F*, so that it will pass through the center of the stud *C*. Beginning with the center of the stud *C* as zero, divide this circle into sections and number them, as shown, for each 60 degrees. Such further sub-divisions as may be needed later may be made when required.

Proceed now with care to place the needle of a pair of good compasses in the center of the roller *A*, and adjust them so that the pencil point will pass through the center of the stud *C*. We will call this radius *R*. Now having in mind the requirements stated above, one being that the cam should turn 150 degrees from its zero before the roller moves place the end of the compasses at 150 degrees on the circle *D*. Holding the needle here, with the radius *R* draw an arc intersecting the stud circle *F* at the point *G*. It is seen that the point of intersection is at 60 degrees on the circle *F*. Now place the needle point 43 degrees further along on the stud circle, or at 103 degrees, and with the radius *R* draw an arc intersecting the circle *E* at the point *H*. The point *H* marks the halt of the advance of the roller, and the beginning of its dwell. Now move the needle 35 degrees further along the stud circle to 138 degrees, and with the radius *R* draw another arc intersecting the circle *E* at the point *I*. This point marks the end of the dwell and the beginning of the retreat. Now move the needle 92 degrees further along the stud circle to 230 degrees and with the radius *R* draw an arc intersecting the circle *D* at the point *K*. This point marks the end of the retreat and the beginning of the dwell for the remainder of the cycle.

The points *H*, *I* and *K* being marked, draw radii through them extending to the circumference of the cam circle. Knowing that the roll begins to advance at 150 degrees on the cam, the advance is seen to continue for 45 degrees. The roll then dwells for 35 degrees and retreats in 90 degrees, after which it dwells until the next advance begins. It is proper that these figures do not agree with the figures for the lever movement stated above. Barring possible slight errors in the layout, they are correct for the cam.

The radius of the inner wall of the raceway or groove is, of course, ½ inch less than that of the path of the cam center. Hence the radius of the inner wall of the outer dwell is 3 11/16 inches, and that of the inner dwell is 3 3/16 inches. This inner wall is the counterpart of the master cam which will be used to cut the cam groove.

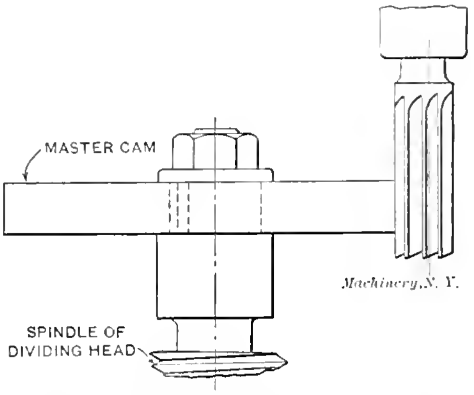

Fig. 2. Common Method of Milling Master Cams.

Common Method of Making Master Cams.

Assuming that the master cam has been properly machined and roughed down, we will consider briefly the generally used method of finishing it. This method comprises mounting the master cam in the dividing head of a universal milling machine, and gearing the head with the feed-screw of the table so that the table will advance in proper ratio with the turning of the work in the dividing head. In Fig. 2 the master cam is mounted as above described, and held against a cutter in the vertical spindle milling attachment on a milling machine. This cutter is of the same diameter as the roll which will be used in the cam.

The process is as follows: Feed the work against the cutter until the cutter is 3 11/16 inches from the center of the master cam. Now, with the key-slot of the master cam which is the "zero" of the cam, directly in line with the cutter, turn the work 150 degrees. This finishes a part of the outer

---

* For additional information on this subject, see "Laying Out Cams for Rapid Motions," February, 1908, and other articles there referred to.

† Address: 158 Underhill Ave., Brooklyn, N. Y.

dwell of the cam. The next operation is to feed the work against the cutter ½ inch while the dividing head turns 45 degrees. Since 45 degrees is ⅛ of 360 degrees, or one turn, we want gears which will turn the work ⅛ of a revolution while the table advances ½ inch. This is equal to one turn of the work while the table advances 4 inches. The gears on a feed-screw with four threads per inch, and 40-tooth worm-gear in the dividing head are,

Gear on worm 36,
First gear on stud 36,
Second gear on stud 28,
Gear on screw 70.

Having connected these gears with care, feed the work against the cutter 0.500 inch. The gears will at the same time turn the work 45 degrees. This will give the advance of the cam. Now, with the table clamped where it is, turn the work 35 degrees further. This will give the inner dwell of the cam. Now change the gears so that the work will turn 90 degrees while the table is backed away ½ inch. This may be done by removing the first gear on the stud with 36 teeth and replacing it with a 72-tooth gear. Having done this with care to avoid disturbing the work during the change, back the work away from the cutter 0.500 inch. The gears will have turned the work 90 degrees more, the intermediate having been properly adjusted. This will give the retreat of the cam. Now, with the table clamped where it is, turn the work until the cutter reaches the part already finished.

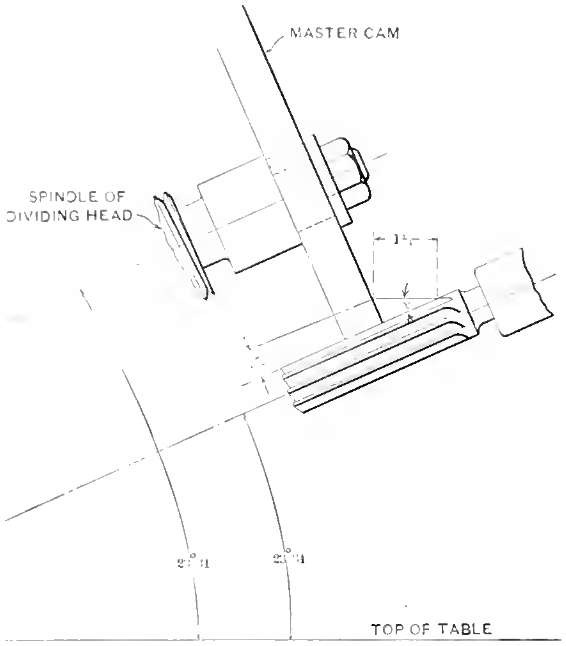

Fig. 3. Improved Method of Milling Master Cams.

This method, which has just been described, is very convenient when the change gears will give the combinations that are necessary, but it will often happen that the desired combination cannot be made with even an approach to accuracy. This difficulty may be overcome, however, by a method which is not in general use, but by which any desired result may be obtained.

Improved Method for Producing Master Cams.

For convenience we will suppose that the master cam could not be cut with the gears named or with any others, in the vertical position. We will proceed as follows: Mount the roughed out master cam as before in the dividing head, and place a 1-inch end mill in the vertical milling attachment, but, instead of setting them in a vertical position, incline each at an angle of 23 degrees 34 minutes, as shown in Fig. 3. The reason for this will appear later.

By inspection we see that if the work be fed against the cutter, Fig. 3, the cutter will enter the work and approach the mandrel. We also see that if the angle of inclination be increased or reduced, the rate with which the cutter approaches the mandrel will vary likewise. A convenient combination of gears to use in this case is one which will turn the work 360 degrees while the table advances 10 inches. This result may be obtained by using four 36-tooth gears to turn the work.

Having milled the master cam for the first 150 degrees to a radius of 3 11/16 as before mentioned, we must find the correct distance to feed the table forward in order to make the cutter approach the mandrel ½ inch while the work turns 45 degrees. The computation is done as follows: Forty-five degrees is ⅛ of 360 degrees. Since the table is geared to advance 10 inches while the work turns 360 degrees, the table will advance ⅛ of 10 inches while the work turns 45 degrees. Thus the advance is 1¼ inch to the 45-degree turn of the work. By inspection we see that in Fig. 3 the cutter and the work-face form two sides in a right angle triangle with a hypothenuse of 1¼ inch and one side of ½ inch. By solving, we find the angle a to be 23 degrees 34 minutes, as mentioned above. Having now properly connected the gears to mill the advance on the cam, feed the table ahead 1.250 inch. As just stated, this will make the cutter approach the mandrel ½ inch while the gears will have turned the work 45 degrees. Now with the table clamped where it is, turn the work 35 degrees more. We are then ready to begin the retreat of the cam. We must arrange gears which will turn the work 90 degrees while the table is backed 1¼ inch. By removing the 36-tooth gear from the screw and replacing it with a 72-tooth gear, we get this result. Carefully make the change so as not to disturb the work, and then back the table 1.250 inch. The gears will have turned the work 90 degrees further. Now, with the table clamped where it is, turn the work until the master cam is completed.

This system for making cams may be used only where uniform movements are required. While we have used it to entirely finish a master plate cam, any part of any cam requiring uniform motion may be milled in this way with a degree of accuracy not readily obtained in any other way. In fact, the work should be as true as the machine on which it is done. The same system may be used to make a master cam for a drum cam, as shown in Fig. 4. Note, however, that the work is set 23 degrees 34 minutes from the vertical position, while the cutter inclines at right angles to, instead of parallel with, the axis of the mandrel. The same combinations of gears would be used if the drum cam action were similar to the one which we have discussed. The exceedingly low cost of making master cams by this method makes it profitable to provide a master cam for cutting the groove in a single cam.

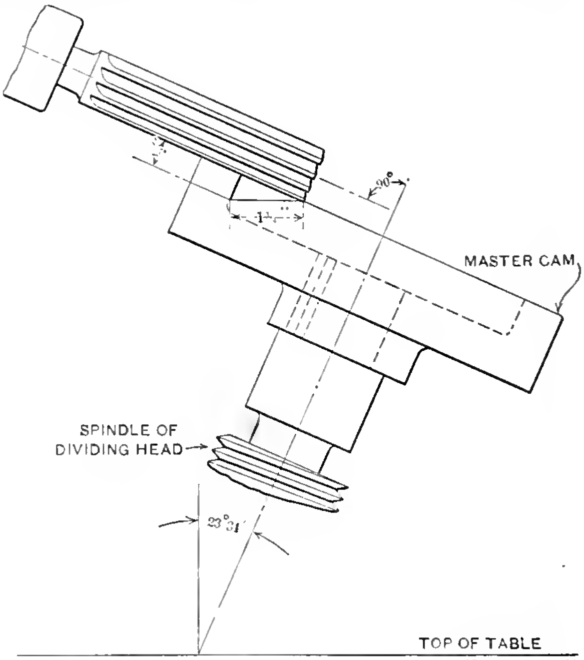

Fig. 4. Milling a Master Cam for a Drum Cam.

Special Cutter for Finishing Grooved Cams.

A source of constant annoyance in milling grooves in cast iron cams lies in the fact that finishing cutters quickly wear and become under size. They must then be laid aside

or used for taking the roughing cuts, while a new cutter of full size is used for finishing. We will not discuss the practice of putting a piece of paper in the collet to make the small cutter run out of true. Another source of trouble, even with cutters with spiral flutes, is the tendency of the cutter to chatter, unless it is perfectly ground and all other conditions are exactly right. Still a third trouble is in the tendency of the cutter to cut more on one side than on the other and to dig out stock in spots in the groove.

In Fig. 5 is shown an extremely simple tool, the usefulness of which cannot be overestimated for finishing grooves in cast iron cams. It is a piece of tool steel, suitably machined to mount on an arbor. It is turned on the outside, with enough stock left on for grinding, after which the spiral grooves shown in the developed surface are milled with an angular cutter. The piece is then hardened and ground to size. The cam groove which we are to finish is roughed out from 0.002 inch to 0.012 inch below size; the roughing cutter is removed from the spindle of the cam-cutting machine, and this special tool is mounted in its place. The cam is then fed against the tool until the tool reaches the bottom, when the cam is turned one complete revolution. The tool will leave a true groove exactly the right size, and without chatter marks or hollows.

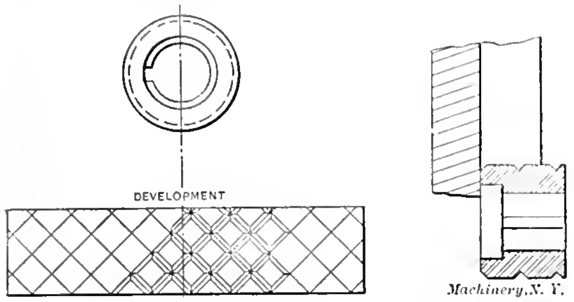

Fig. 5. Special Finishing Cutter for Cam Grooves.

By reason of the form of the cutting or scraping edges, it will outlast many ordinary cutters. Used in connection with it, a single roughing cutter may be repeatedly sharpened before it becomes too small for good results.

TO FIND THE CENTER OF A SHAFT.

The ways of amateurs are interesting—and sometimes instructive. The machinist will find the following question and answer, clipped from the column of a worthy contemporary, whose name we forbear to publish, interesting, somewhat amusing, but scarcely instructive, however—that is from a practical standpoint. Imagine a mechanic with a tool box filled with auger bits of various diameters for boring blocks of wood so that he could center all sizes of shafts likely to come his way! Following is the sketch with the question and answer referred to:

What is a good method for finding the center of a shaft?—A. G.

In a block of wood three-fourths inch thick bore a hole with an augur bit, just the size of the shaft. Allow the point of the bit to just show through the block. Place the block over the end of the shaft, and the center may then be marked with a sharp pointed prick punch.

The Cincinnati Shaper Co., Cincinnati, O., informs us that it has a patent pending on its shaper key-seating attachment illustrated and described in our September issue.

ELECTRO-CHEMICAL CLEANING BATHS.

In a paper presented before the American Brass Founders' Association, by Mr. Charles H. Proctor, Arlington, N. J., the electrolytic process of cleaning metals was described. The process is comparatively new, the first published account of it appearing about three years ago, and, although used by many large concerns, it is not as generally known as it should be considering the good results obtained and the cheapness of the process.

Alkaline substitutes, such as sodium carbonate, potassium carbonate, potassium hydroxide and sodium hydroxide in solution in varying degrees of concentration, and with small portions of potassium cyanide, develop sufficient hydrogen, with a current of 4 to 8 volts, with the bath at nearly boiling temperature, to entirely remove all organic substances from the surface of metal, leaving same chemically clean. The use of this method has been constantly increasing, and at the present time very few large concerns, particularly those engaged in the manufacture of hardware, are without electrochemical cleaning baths.

The action of an electro-cleanser is similar to the action of an electroplating bath. The only difference as far as the development of gases is concerned, is that no metal being in solution and the anode being insoluble, no metal is deposited, but with a strong current a copious evolution of oxyhydrogen gas is developed upon the articles, which attack the organic matter upon the surface, practically lifting it off and by rapid evolution of the gases carries it to the surface. The small quantity of potassium cyanide contained in solution absorbs the slight oxidation that might be upon the surface, and by the combined action produces a surface clean enough, after washing in clear water, for any deposits.

The arrangement of an electro-cleaning bath is very simple. Prepare a wrought-iron tank of proportions best adapted to the amount of work to be cleansed. This should be heated with steam coils of iron. Across the top of the tank an insulated frame should be constructed. Upon this frame place three conducting poles, as on the regular plating bath. To the two outside poles the positive current should be carried direct. This can best be accomplished with at least ½-inch copper wire flexible cables. To the center pole the negative current is connected with a cable of the same dimensions; no rheostats are necessary. The stronger the current the greater the evolution of gases and the quicker the cleansing operation is accomplished.

Although direct contact can be made with the positive current to the tank itself, in practice better results have been obtained with anodes of sheet iron not more than 6 inches wide and of a length in proportion to the depth of the tank.

The electro-cleaning solution should consist (for ordinary purposes) of 3 to 4 ounces caustic potash to each gallon of water, and to every 100 gallons of solution 8 ounces cyanide of potassium. This can be varied according to conditions. It is advisable to add at least ¼ pound of cyanide each week. Where the articles, such as iron or steel, contain much oil or grease upon the surface, the density of the solution can be increased. For articles of brass, copper or bronze that have been polished, use a solution of carbonate of soda in the proportion of 2 ounces soda and ½ ounce caustic potash to each gallon of water, with the addition of 4 ounces of cyanide to every 100 gallons of solution. If much organic matter is upon the surface of the articles to be cleansed, it is advisable, where an air pressure can be obtained from an ordinary blower, to arrange a pipe so that the current of air can be deflected upon the surface of the solution, thus keeping the center of the solution clear of the insoluble substance that arises to the surface. When the cleanser is at rest, as much of this matter as possible should be removed.

It should be the aim of the operator to use the same methods of avoiding all unnecessary contamination as he would in electro-depositing baths. It is obvious even to those who have not practiced this method of cleansing metallic articles that large quantities of work can be treated very rapidly, and this is the case especially where frames or racks are used in the plating operations.

CABLE HAULING ON THE NEW MANHATTAN BRIDGE.

From the windows of the Industrial Press business office the construction of the new Manhattan Bridge, spanning the East River, can be plainly seen. This is the fourth great bridge between Manhattan and Long Island, the others being the Brooklyn Bridge and Williamsburg Bridge, both completed, and the Blackwell's Island Bridge, nearly finished. The latter is of the cantilever type, and the other three are of the well-known suspension form. The towers of the Manhattan Bridge are built of structural steel and were completed a few months ago. At the present time the process of "spinning" or hauling the cables is going on. Preliminary to spinning the cables, temporary foot-bridges were erected, these being suspended on $1\frac{3}{4}$-inch cables. These cables support four foot-bridges on which the workmen stand, and also sustain the hauling rope supports which guide and control the spinning of the wire composing the four main

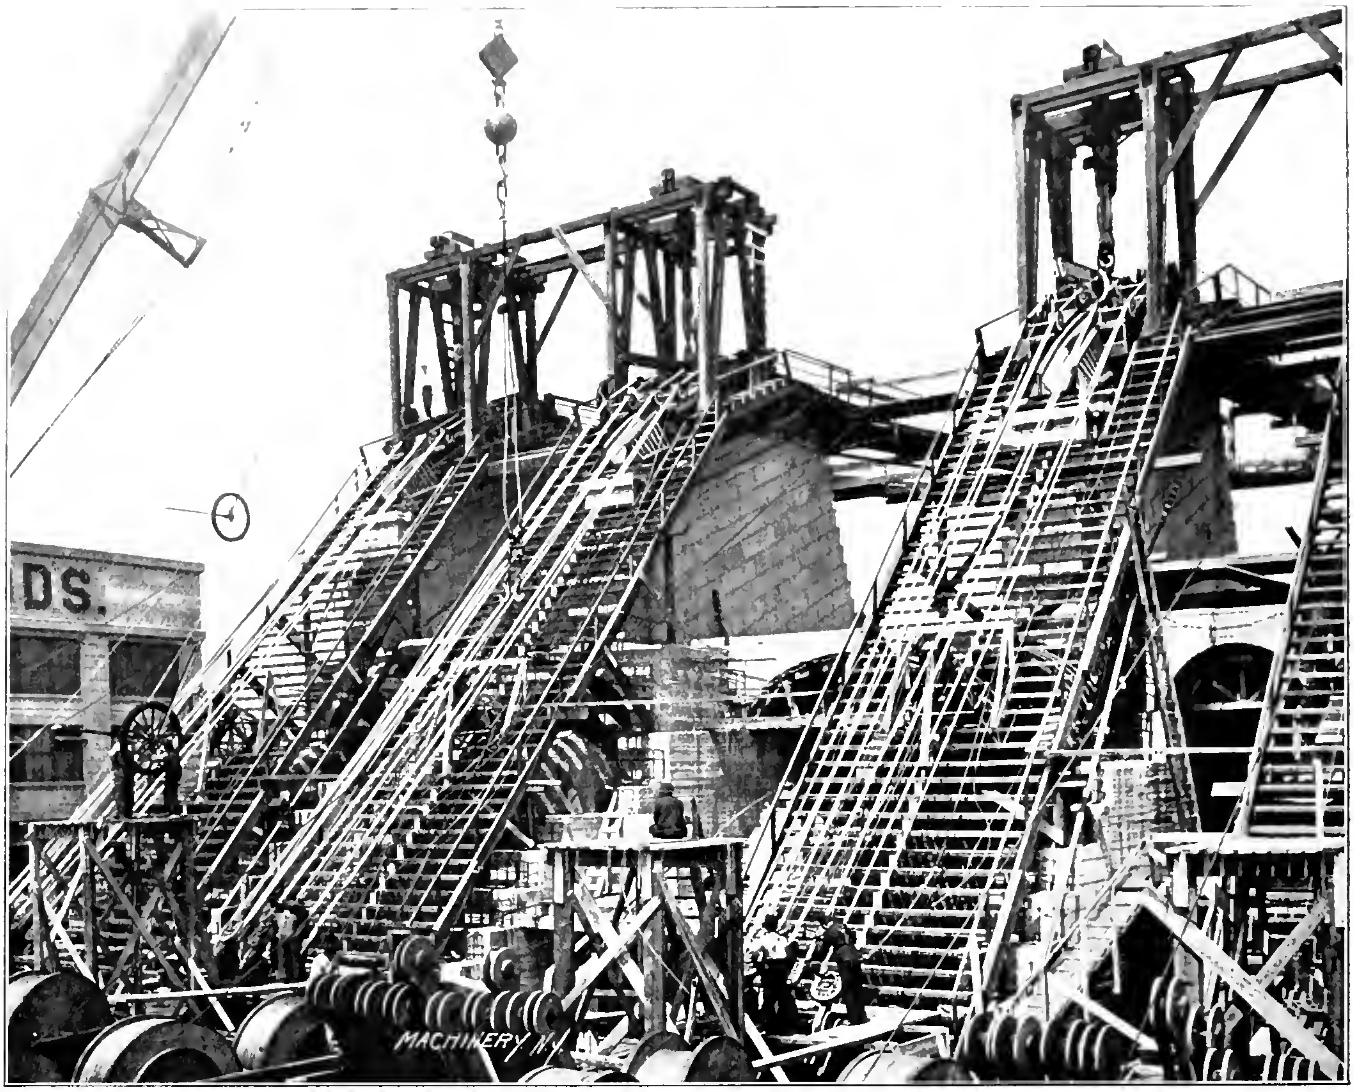

Fig. 1. View of One of the Anchorages of the Manhattan Bridge, showing the Strands which are to form the Main Cables, resting in Temporary Saddles.

Fig. 2. [illegible] Sheave used for Hauling the Small Steel Cable Wires across the River.

Fig. 3. View of the Temporary Foot-bridges which Support the Hauling Cables.

cables. Each cable will contain 37 strands of 256 wires each, a total of 9,472 wires per cable, which must be strung wire by wire. The enormous amount of work involved will be done by machinery driven by electric motors.

The stringing of the wires in each cable is accomplished by means of two traveling sheaves carried on opposite legs of an endless steel rope. Each sheave consists of a three-foot grooved wheel fastened to the hauling rope by means of wrought iron brackets, as shown in Fig. 2. The hauling rope is three-quarters inch diameter, and runs above the position of the bridge cables on heavy rollers supported on uprights on the temporary foot-bridge. See Fig. 3. There are five of these hauling rope supports on the center span, two on each end span and one on each tower. The hauling sheaves move back and forth across the bridge from anchorage to anchorage, a distance of 3,223 feet. They are attached one to each leg of the hauling rope so that they move in opposite directions.

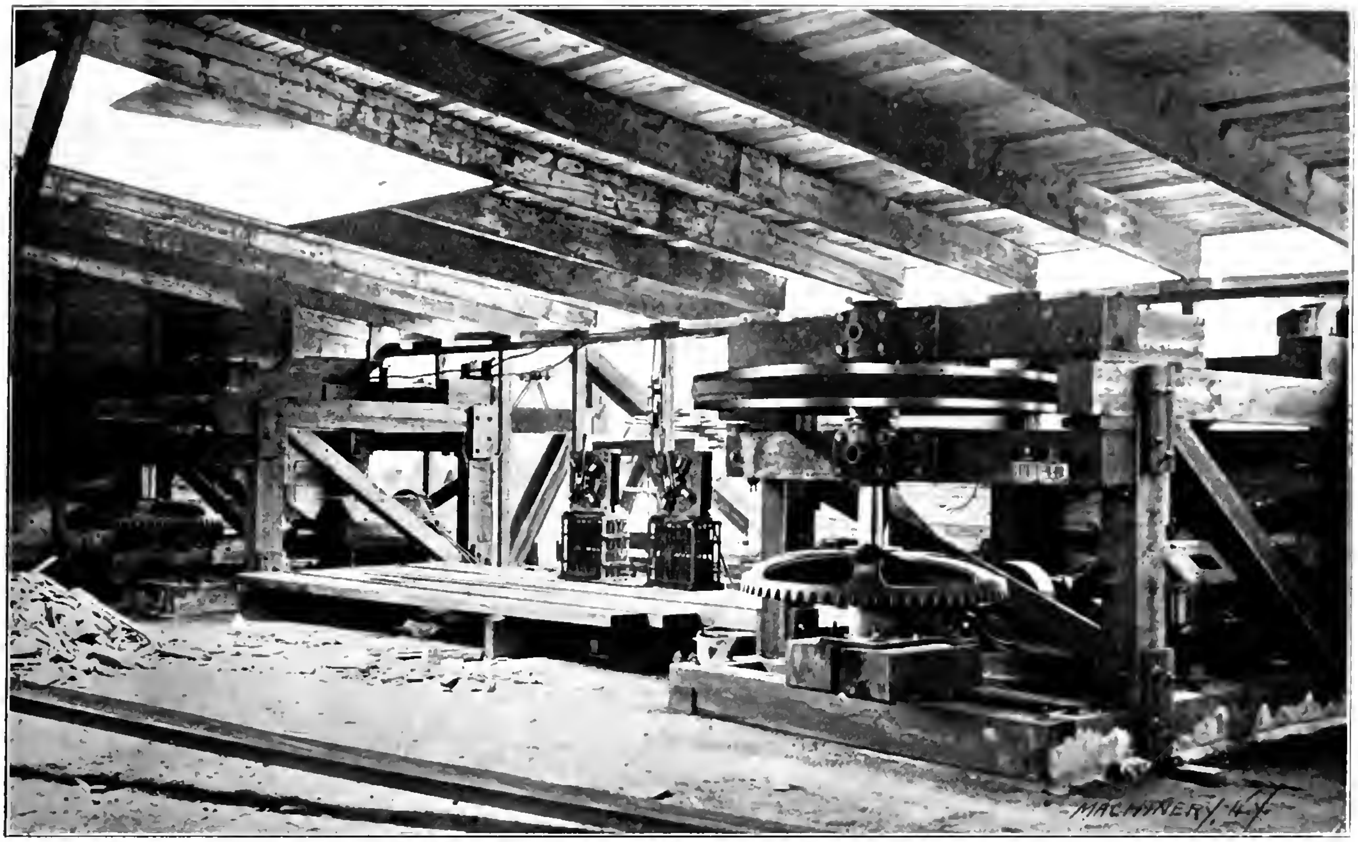

Fig. 4. Cable Hauling Machinery, Brooklyn Anchorage Manhattan Bridge.

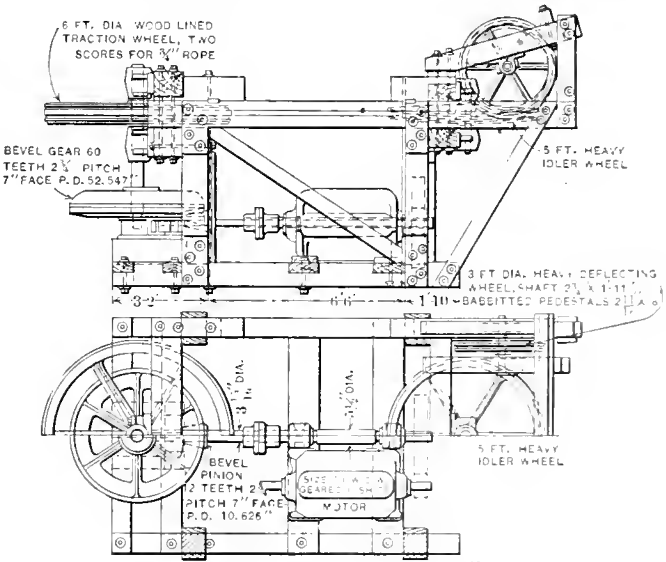
The wire, which is 0.192 inch in diameter (No. 6 Roebling gage), is delivered to the bridge on enormous reels or spools, weighing three tons each. Half of these reels are placed at each end of the bridge. The end of the wire from a reel at each end of the bridge is put over the hauling sheave at that end and fastened to the anchorage. The machinery is then started and the sheaves move across the bridge, unwinding one wire from each reel. Two wires are thus strung by each sheave every time it crosses the bridge. When the sheave reaches the opposite side of the bridge the bight of the wire is taken off and made fast to that anchorage, and a new wire hauled from that side on the return trip.

The wires are laid in temporary saddles of four grooved pulleys at each anchorage. See Fig. 1. As the hauling of each strand of 256 wires is completed, the wires are bound together at intervals, and the strand is lifted from the temporary saddle by means of a chain hoist and laid in its proper place in the permanent saddle. Two strands of each cable are strung simultaneously by the two sheaves of each hauling rope.

There is a separate hauling mechanism for each of the four bridge cables, so that they are strung independently of each other. Delays are, therefore, not cumulative. The delays in one cable affect that cable alone, and the work proceeds on the others. This results in a very considerable saving of time.

Each hauling rope is driven by a 50-H.P. 220-volt Crocker-Wheeler form W motor. This is the type of motor designed by the Crocker-Wheeler Company for rolling mill duty, and is well adapted to work of this kind where sudden overloads and frequent starting and stopping are likely. The motors are fully enclosed and capable of withstanding all kinds of weather and rough handling. The driving mechanism is shown in Figs. 4 and 5. Each motor is geared to a counter-shaft at a ratio of 5 to 1, and the counter-shaft is bevel geared to the driving shaft at a 5 to 1 ratio. On the driving shaft, above the gears, is a wood-lined, grooved, six-foot traction wheel, which drives the hauling rope. A five-foot idler wheel is also provided so that the hauling rope passes the traction wheel twice, to produce the necessary grip. The driving motors are all located on the anchorage at the Brooklyn end of the bridge.



Machinery, N.Y.

Fig. 5. Elevation and Plan of the Cable Hauling Machinery.

The hauling rope moves at a speed of approximately 480 feet per minute. It carries the sheaves across the river in about seven or eight minutes. Allowing for the time used in attaching wires at each end, about three trips are made per hour. It is estimated that at this rate the work of hauling

will occupy four months, some time being consumed in fixing guide wires for each strand and in adjusting the wires after they are hauled.

The reels of wire, as already stated, are stored at both ends of the bridge. The wire was delivered by John A. Roebling's Sons Co., the same firm which delivered the wire for the old Brooklyn Bridge thirty years ago. The work of building the cables is being carried on by the Glyndon Contracting Co., of New York City.

The hauling equipment for this bridge differs from any previously used. It will be remembered that in hauling the cables for the Williamsburg Bridge two steam engines were used, connected to the same driving shaft. It later became necessary to cut this shaft and use the engines independently to avoid cumulation of delays. Even with that arrangement only two cables could be hauled simultaneously. The Glyndon Company's cable hauling plant has doubled the capacity, and besides being electrically- instead of steam-driven, it is easier of manipulation and control.

* * *

FITCHBURG COOPERATIVE INDUSTRIAL SCHOOL COURSE.

The Fitchburg Iron Workers' Association, Fitchburg, Mass., recently tendered a banquet to the members of the Fitchburg city government and school board, and laid before them the plans for an industrial school to be incorporated in the present high school system, which was readily taken up by the city government, and has been put into operation.

The idea is somewhat unique, and bids fair to become an essential factor in industrial education in towns and cities of limited size throughout the country. The plan, as outlined, is in a form of an apprenticeship system whereby boys having passed the first year in high school, take up during three years, a mechanical course studying one week in the school, and the following week working in the shops. A special instructor has been employed, and special text-books provided. The boys are taken in pairs by the manufacturing companies, and the boy who has studied in school a week, on Saturday morning at 11 o'clock goes to the shop and learns on what particular job the other boy has been working, and how it is handled, so that he can come in the following Monday morning and begin work where his mate left off, thus following the shop course without necessitating instruction on the part of the shop foreman.

Mr. Hunter, the man in charge of this work, has had more applications than could be taken care of the first year, and at the present time all the boys are working in the shops and will continue to do so until the school opens. The cooperative industrial high school course is as follows:

FIRST YEAR, ALL SCHOOL WORK.

English	4	periods	per	week.

Shop work consists of instruction in the operation of lathes, planers, drilling machines, in bench and floor work, and in other machine work according to the ability of the apprentice as pertaining to the particular branch of manufacture in the shop where he is employed.

Copy of the rules and conditions of this system is given below:

Rules and Conditions.

Under Which Special Apprentices Taking the Four-Year Coöperative Industrial Course at the High School of Fitchburg Are Received for Instruction at the works of

Blank Machine Co.

1. The Applicant for apprenticeship under this agreement must have satisfactorily met requirements for entrance to this course at the high school.

2. The apprentice is to work for us continually, well and faithfully, under such rules and regulations as may prevail, at the works of the above company, for the term of approximately 4,950 hours, commencing with the acceptance of this agreement, in such capacity and on such work as specified below:

Lathe Work,
Planer Work,
Drilling,
Bench and Floor Work.
And such other machine work, according to the capacity of the apprentice, as pertains to our branch of manufacturing.

This arrangement of work to be binding unless changed by mutual agreement of all parties to this contract.

3. The apprentice shall report to his employer for work every alternate week when the high school is in session, and on all working days when the high school is not in session, except during vacation periods provided below, and he shall be paid only for actual time at such work.

4. The apprentice is to have a vacation, without pay, of two weeks each year, during school vacation.

5. The employer reserves the right to suspend regular work wholly, or in part, at any time it may be deemed necessary, and agrees to provide under ordinary conditions other work at the regular rate of pay, for the apprentice during such period.

6. Should the conduct or work of the apprentice not be satisfactory to employer, he may be dismissed at any time without previous notice. The first two months of the apprentice's shop work are considered a trial time.

7. Lost time shall be made up before the expiration of each year, at the rate of wages paid during said year, and no year of service shall commence till after all lost time by the apprentice in the proceeding year shall have been fully made up.

8. The apprentice must purchase from time to time such tools as may be required for doing rapid and accurate work.

9. The said term of approximately 4,950 hours (three-year shop term) shall be divided into three periods as stated below, and the compensation shall be as follows, payable on regular pay-days to each apprentice:

For the first period of approximately 1,650 hours: 10 cents per hour.

For the second period of approximately 1,650 hours: 11 cents per hour.

For the third period of approximately 1,650 hours: 12½ cents per hour.

10. The above wage scale shall begin the first day of July preceding the apprentice's entrance upon the first year of shop work of the high school industrial course.

The satisfactory fulfilment of the conditions of this contract leads to a diploma, to be conferred upon the apprentice by the school board of Fitchburg upon his graduation, which diploma shall bear the signature of an officer of the company with which he served his apprenticeship.

AN AMERICAN MECHANIC IN EUROPE.

With reference to installment No. 5 of the above series which appeared in your August issue, we find on page 909 (engineering edition) a reference to ourselves in which it is stated: "The company usually builds the machines in lots of three throughout all departments, only occasionally making a larger number at a time."

We believe the above must be a printer's error or due to a misunderstanding on the part of the author, as we informed him we built the machines in lots of *three dozen*. This applies to machines 3 feet 6 inches, and 4 feet radius, and to a number of lighter machines up to 5 feet and 6 feet radius on special classes of work. The heavy type of machines weighing from 7 to 8 tons and upwards cannot, of course, be put through in such large quantities.

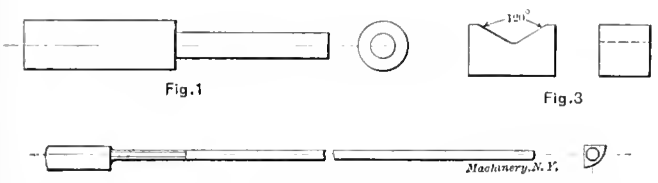
Halifax, England. WILLIAM ASQUITH, LTD.

THE STEAM HAMMER AND ITS USE.

JAMES CRAN [*]

One of the greatest changes in the way of improvement in the art of blacksmithing came with the steam hammer. It made possible the making of heavy forgings from one solid piece of iron or steel, which previously had to be made in sections and welded together. Welding is still necessary on a great many kinds of blacksmith work, but with the steam hammer it can be done in less time and to better advantage than is possible by hand. The majority of people, including blacksmiths, seem to have only one conception of a steam hammer, that of a piece of machinery intended for striking a heavy blow; this is the principal, but by no means the only purpose for which it can be used. With a good equipment of tools and a good operator it is possible to do nearly any kind of machine blacksmithing—all but the finishing touches—at the steam hammer. If necessary it can also be used to do drop forging and as a trimming press, shears, bulldozer, and vise, and for a variety of other purposes.

With all its advantages it is, as a rule, one of the most abused pieces of machinery to be found around a manufacturing plant. For every other kind of machine there is usually a skilled operator. If it happens to be operated by a boy, or any one else who does not thoroughly understand it, he is generally doing so under the directions of a competent man. For the steam hammer, as with every thing else in the blacksmith shop, anything is good enough—an ordinary laborer, a small boy, or any one who comes along, provided he can be hired for a small amount of money, regardless of safety or economy. To get the best results from a steam hammer, however, as with any other kind of machine, it is absolutely essential that the operator thoroughly understands his business. He should be as conversant with the working parts and mechanism as an engineer should be with an engine, and should be able to do all minor repairing, such as packing glands, adjusting guides, valves, etc. As a machine operator, he should be classed with skilled labor, and paid according to his ability. Like all other classes of help, really good steam hammer operators are scarce from the fact that the unskilled laborer usually gets the same rate of wages.



Figs. 1 to 3. Example of Work, and Tools for "Breaking Down" Forgings.

The purpose for which the steam hammer is principally used is to draw iron or steel to smaller dimensions in the making of forgings. This can be done to the best advantage if the dies are slightly crowned in the center, not necessarily over 1/16 inch for each die, and the edges rounded off to about a radius of 3/32 inch. Any one who has done work with a steam hammer will appreciate the advantage of having the dies crowned. In drawing stock with perfectly level dies, the drawing is most in evidence where the edges come in contact with the metal; in the center it is simply spread out, there being nothing in the dies themselves to give it a tendency to draw when a blow is struck by the hammer. With the dies crowned, a blow will be more effective, and the spreading of stock will be reduced to a minimum. It is also an advantage to have the sides of the dies square, so that in making forgings such as are shown in Fig. 1, the shoulder will be as near as possible at right angles with the body of the piece.

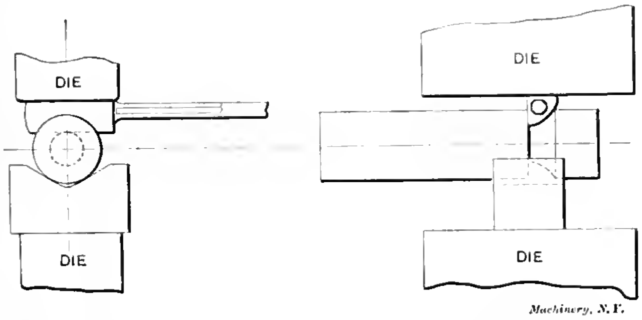


Fig. 4. Use of Breaking Down Tool and V-block in the Steam Hammer.

In "breaking down" stock for a shoulder a tool similar in construction to Fig. 2 should be used, the head or part which does the work being in the shape of one-quarter of a circle, with the edges slightly rounded to prevent cutting. This tool will break down a shoulder square. It can be used either right or left-hand, and its shape gives it a tendency to crowd towards the shoulder which will leave the stock at that point up to, or slightly larger than, the original dimensions. This tool presents decided advantages over the round tool commonly used, as this latter has a tendency to drag down the edges near where it is used, making it necessary to upset and finish the work by hand to get the body of the forging uniform throughout. When round stock is being broken down it is usually placed in a circular tool similar to a swage, which necessitates the using of a different tool for each size of stock. If a tool is used of the style shown in Fig. 3, which is made in the form of a V-block with a circular bottom, it will accommodate several sizes of stock. Four or five such tools of different sizes will cover a large range of work.

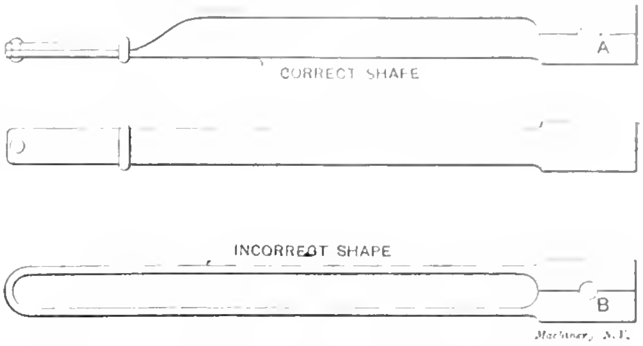

Fig. 5. Correct and Incorrect Types of Swages for Steam Hammer.

Fig. 6

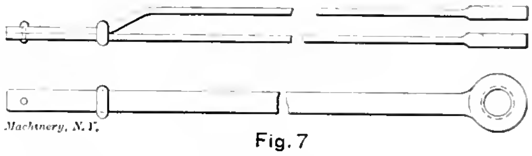

Fig. 7

Fig. 6. Swages for Making Blank-headed Eye-bolts. Fig. 7. Swages for Forging Hubs.

Fig. 4 shows how the breaking down tool and the V-block should be used in the steam hammer. The V-block is placed upon the bottom die, the work is laid in the V-block, and the breaking down tool on top of the work at the point intended for the shoulder. The tool is guided by hand until the piece has been marked all the way around. It can then be driven in, turning the piece continually, until it has reached the required depth. In drawing the shank of a forging, such as is shown in Fig. 1, it should be kept square until it has been reduced to the required size; the corners are then worked in until an octagon shape is obtained; and, finally, the corners are rounded. This procedure prevents the center being "piped."

In finishing round work, it should be done as far as possible at the steam hammer, using spring swages. Of these there are several styles. Fig. 5 shows at the top the style which is simplest and most satisfactory to use. The swages are made in two separate parts and held together by one rivet, and provided with a band to keep them in alignment without having to use a guide pin. The impression in each

---

[*] Address: 916 West Third St., Plainfield, N. J.

part should be half the depth of the diameter of the piece the swages are intended to finish, so that it would be impossible to swage a forging under size. The edges or lips should be well backed off to prevent a fin or flash being formed. If a fin or flash is formed upon a piece of work while it is being finished in swages or dies, it is liable to get worked into the forging when it is turned for the next blow of the hammer, forming what is known as a cold shut. This may not be noticed on the forging, but will show up when the work is machined; it is unsightly on machine steel pieces, and renders tool steel useless for all cutting purposes.

Swages of the style shown at the top in Fig. 5 can be made to form collars, ends for connecting-rods, blank-headed eye bolts, forgings with ball ends, and a variety of other pieces. No machine work is necessary on this kind of swage, as it can be made and finished complete in the blacksmith-shop by using a dummy, or a forging made as near as possible to the dimensions of the pieces for which the swage is intended. This sample forging is used for finishing the impression, after it has been partly worked to shape, by heating the swage, and placing the dummy in it. The swage takes its impression from the dummy in the same manner as forgings take their shape from swages or dies. This method of making tools is known as typing, and can be employed to good advantage on a great many kinds of forgings, when the quantity to be made is such that it will justify the making of tools. All forgings made in tools as here described will be duplicates and finished in less time than would be possible by hand.

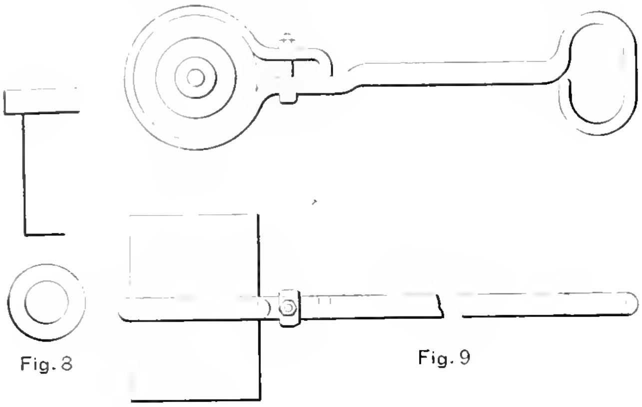

Fig. 8

Fig. 9

Machinery, N.Y.

Figs. 8 and 9. Pin to be Forged, and Tool used for Carrying Out the Operation.

Fig. 6 shows a swage for making blank-headed eye bolts, or any forging with a circular head and a plain round shank. These are different from other swages in that they have the edges of the impression sharp where the head of the forging is formed to insure a perfect circle. A fin or flash may be worked out where the impressions meet, but it will do no harm as it can be trimmed off with a chisel. The edges of the part of the impression where the shank is formed should be rounded off, as a flash formed at that point would cause trouble in finishing with ordinary spring swages.

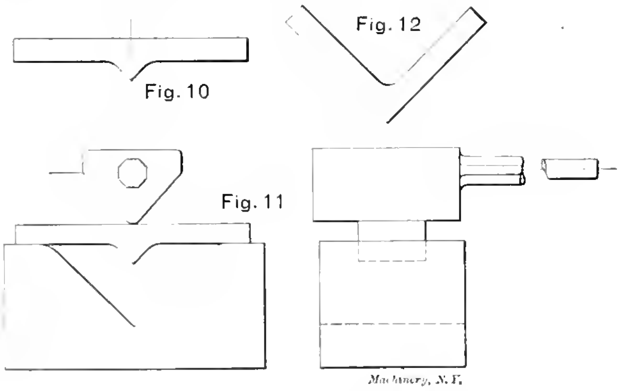

Fig. 10

Fig. 11

Fig. 12

Machinery, N.Y.

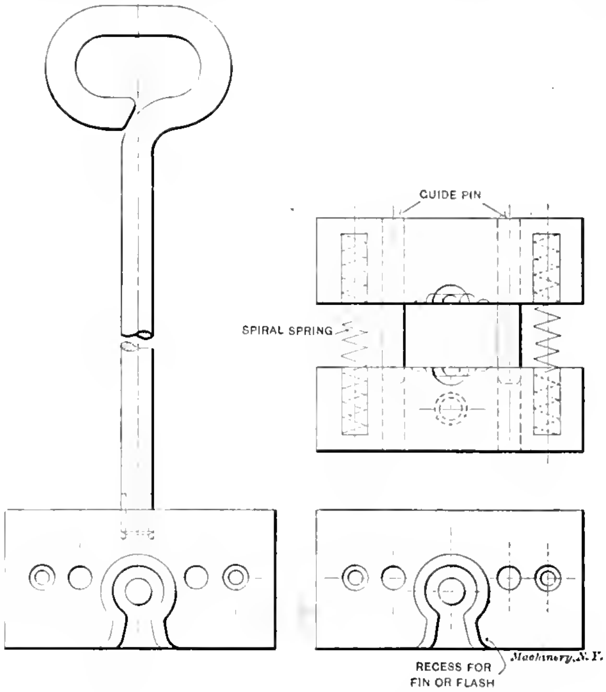
Figs 10, 11 and 12. Forging an Angle Iron.

When forgings with hubs are to be made, ring swages, as shown in Fig. 7, should be used. All that is necessary is to select stock heavy enough to allow the ends of the hubs being finished. The work is heated, placed in the swage, given a few blows by the steam hammer, and the hub is formed, both sides being in perfect alignment. The stock worked out at the sides can be trimmed off with a chisel. This may seem wasteful, but the time saved will more than compensate for the loss of material. For round bosses a tool similar to half the swage, Fig. 7, should be used; or a plain ring made of round stock would answer the purpose, by being placed upon the stock while it is hot, and struck a few blows with the steam hammer. It may be well to explain the difference between hubs and bosses; hubs project on both sides of a forging, while bosses only project on one side.

Machinery, N.Y.

Fig. 13. Tool for Drawing Work too short for Breaking Down under the Steam Hammer.

In making forgings of the style shown in Fig. 8, it is customary to draw them from stock of larger diameter than the shank, and finish them in a heading tool. When a quantity has to be made, it is of advantage to use stock the proper size for the shank, cut in lengths, and to use a tool as shown in Fig. 9. This tool is bored out just deep enough for the length of the shank and counterbored to accommodate the head. The stock should be heated on one end, placed in the tool, a few blows given by the steam hammer, and the forging is completed. A small hole should be drilled through the bottom of the tool, so that it can be turned up side down, and the forging removed with a punch. Six forgings can be made in this way in the same time as it would take to make one, if drawing it from heavier stock.



Machinery, N.Y.

Fig. 14. Dies for Drop Forging under the Steam Hammer.

In making angular forgings, stock of about the right size for the ends of the angles is usually selected, bent, and the corner worked back until it is square. This takes considerable time and careful working, or a cold shut will be formed inside the corner. With a steam hammer, pieces of this shape can be made with very little trouble by using stock heavy enough to allow a solid corner being formed as shown in Fig. 10, which can be done by using a round tool to break down each side of the piece intended for the angle, drawing the ends to the required size. Then the piece is bent in a V-block with a tool made for the purpose, as shown in Fig. 11. The result will be a piece as shown in Fig. 12. The V-block should have an included angle of 90 degrees, and be rounded at the top edges, as shown, to prevent marking the ends. The tool for bending should have the edge or corner rounded so that it will form a fillet inside the forging. Nearly any size of angle can be made with the same tools.

A tool for drawing work which is all broken down to one side, or between shoulders or bosses, when the distance is too short to reach across the dies, is shown in Fig. 13. The head is square, and the corners rounded, each to a different radius, so that fillets of different dimensions may be formed with the same tool.

Small pieces can be drop forged at the steam hammer without changing the ordinary dies, by using dies as shown in Fig. 14. The impressions are sunk the same as in regular drop forging dies. The dies are kept in alignment by two guide pins, and opened by two spiral springs placed on the guide pins. The dies are removed from the hammer dies by means of the handle attached to the back as shown. Forgings made in this style of dies are equal in every respect to regular drop forgings, with the exception that it requires more time making them. The steam hammer can be used to trim the forgings by using a trimming die and punch as shown in Figs 15 and 16. Trimming dies of the style in Fig 15, with open end, should be made heavy enough to prevent spreading, or breaking through the back, as they have no supporting device of the kind provided for dies in the trimming press. They also ought to be deep enough to allow of the forging dropping out of the reach of the punch when it is trimmed. Fig. 16 shows the punch, the face of which should be concaved to fit the forging it is intended to be used for. Fig. 17 shows the forging made in the dies in Fig. 14. The ends of the shanks are left heavy so that they can be finished either for eye-bolts or hooks. When made into hooks the shanks are left longer, finished in spring swages, and bent on a former made specially for that purpose. The style of dies here described can only be used for small work, and only then when the quantity is such that it will justify the expense of making the tools.

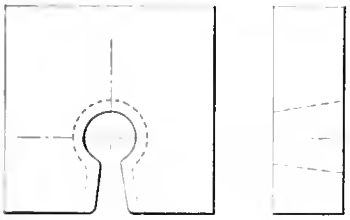


Fig. 15

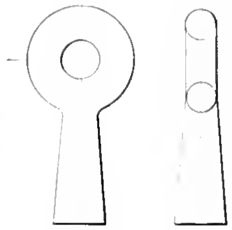

Fig. 17

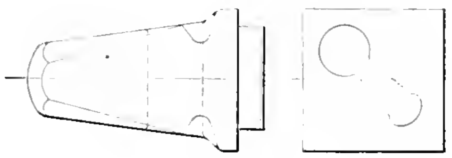

Fig. 16

Figs. 15, 16, and 17. Trimming Die and Punch, and Completed Work.

The steam hammer can be used as a punch press, when that machine is not available, by using a die and punch as shown in Fig. 18. The die is made on the same principle as spring swages, the top part acting as a guide for the punch. The lower part, or die proper, should be thick enough to allow the scrap from the hole and the punch dropping below the level of the guide, otherwise the punch would be liable to be bent or broken. Punches need never be longer than the depth of the die, and should be tapered from the face to give them clearance when being driven through the stock. This style of die and punch can be used on hot work, as for removing the stock between the jaws of wrenches, the centers of eye-bolts when being forged by hand, etc.

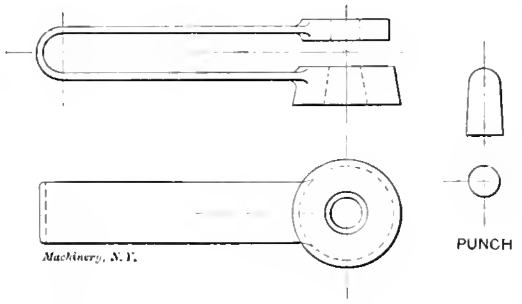

Fig. 18. Punch and Die for Punching Holes under the Steam Hammer.

In shops where there are no shears the steam hammer can be used for cutting off cold stock by using tools as shown in Figs. 19 and 20. Only one tool of each kind is shown, but the tool can, of course, only be used in pairs, one below and one over the stock, so that their edges will just pass by each other, the same as the jaws of shears. Fig. 19 shows the tools used for flat stock, while Fig. 20 shows the shape of tools for round stock. These tools are not as handy as shears, nor quite as safe, but are superior to saw or chisel in cutting up stock for forging.

Fig. 19

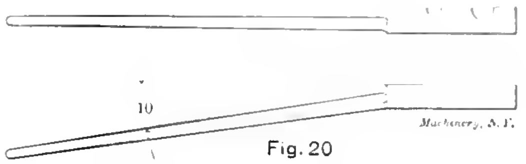

Fig. 20

Figs. 19 and 20. Tools used under Steam Hammer for Shearing Off Stock.

In forging rings of rectangular section it is customary to use stock of about the right dimensions for the section, bend it to shape, and weld it. This is all right for small rings, or large rings with small section; but when the size exceeds 5 inches inside diameter, and the section 1¼ inch square, it is advisable to make the rings from the solid stock for several reasons, principal of which are the saving of time, a more uniform section, and a perfectly solid forging when the ring is finished. This latter is impossible with a welded ring, except at cost and labor out of all proportion with the size of the job. To begin with the ends of the stock must be upset to allow for waste in welding, and bent in the form of a circle, which distorts the shape of the material; the outside is drawn out while the inside is upset or compressed. The only part of the stock which retains its original size is the neutral line at the center of the bar. After the ring has been welded, it has to be flattened and trued up all over to get it anything like uniform. Then, there are always chances of a poor weld, which makes the finished piece useless for all practical purposes.

Fig. 21. Steam Hammer Fixture used when Forging Rings.

When rings are to be made from the solid, the first thing to be done is to find the right amount of stock to use, which can be done by consulting hand-books, or by figuring out the cubic contents of a solid piece having the same diameter and the same thickness as the ring for which it is intended, deducting the number of cubic inches equal to the hole, and allowing enough extra material for waste in forg-

ing, and for finishing in the machine shop. Cut off a piece of round stock the proper length, and upset it under the steam hammer until it is of the same thickness as the face of the ring to be forged. Punch a hole in the center, and "drift" until it is approximately of the diameter required in the finished ring. The lower die should then be removed from the steam hammer, and a fixture of the style shown in the half-tone, Fig. 21, keyed in its place. This fixture is made in the form of a double V-block, the V's being circular in the bottom, and of an angle of about 120 degrees, allowing the use of different sizes of mandrels in drawing the rings to the required size. The ring or piece of stock with the hole punched through it is then placed between the V's, and the mandrel slipped through the hole and turned by means of the handles clamped to the shank. In turning the mandrel, the ring is turned with it, bringing a different point in line with the top die for each stroke of the hammer. This is done until the proper size has been reached, using larger mandrels as the hole increases in size. Rings up to 50 pounds can be made complete in two heats. Larger rings up to the full capacity of the steam hammer can be made by using a larger fixture in the anvil block by removing the chair for the lower die. It is advisable to use hollow mandrels for the larger sizes to facilitate their handling. Rings made from the solid in the manner here outlined can be completed in one-third the time required for welded rings. The section is uniform throughout, and no poor welds or overheated spots show up in the machining.

If the steam or power hammer were used, as it should be, to do the heaviest and most difficult work, the art of blacksmithing would be made more attractive, and the manufacturers' profits would be increased.

* * *

THE GISHOLT SHOP BAND.

The Gisholt band illustrated here is an outgrowth of the Gisholt Club, a social organization of the employes of the Gisholt Machine Co., Madison, Wis. The main object of the club is to promote acquaintanceship and good fellowship among the employes and their families. A room is provided by the company in which various entertainments are given during the year, and lecturers are employed from time to time to speak on topics of general interest. An event of importance is an annual picnic held on ground across Lake Mendota, near Madison. The picnic this year took place on August 8. In all these entertainments the Gisholt band is in evidence, and its members have acquired such proficiency that it plays very good music. A pleasing feature of the club during the summer is the open-air concerts given by the band on a piece of vacant property adjoining the Gisholt works. The club organization and the band auxiliary tend to bind together the employes to work for the common good, and are in line with all sound movements for the promotion of progress in coordinating human interests and manufacturing methods.

Gisholt Machine Co. Band.

JIGS AND FIXTURES—7.

EINAR MORIN.*

EXAMPLES OF DESIGNS OF OPEN DRILL JIGS.

A typical example of an open drill jig, very similar to the one developed and explained in the September issue, is shown in Fig. 73. The work is located against the three locating pins *A*, and held in place against these pins by the three set-screws *B*. The three straps *C* hold the work securely against the finished pad in the bottom of the jig. These clamps are so placed that when the work has been drilled and the clamp screws loosened, the clamps will swing around a quarter of a turn, allowing the work to be lifted directly from the jig and a new piece of work inserted, when the clamps are again turned around into the clamping position, and the screws tightened. These straps are integral parts of the jig; at the same time, they are quickly and easily manipulated, and do not interfere with the rapid removal and insertion of the work. The strength and rigidity of the feet in proportion to the jig should be noted, this strength being obtained by giving proper shape to the feet, without using an unnecessary quantity of metal.

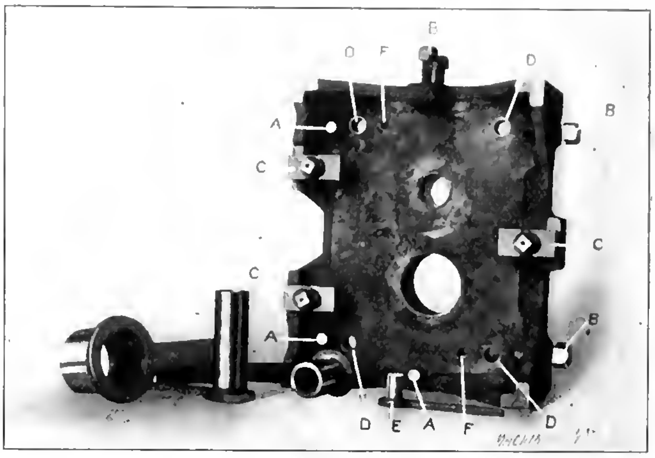

Fig. 73. Example of Open Drill Jig. View showing Front Side.

The jig in Fig. 73 is also designed to accommodate the component part of the work when it is being drilled. When this is done, the work is held on the back side of the jig, shown in Fig. 74. This side is also provided with feet, and has a finished pad against which the work is held. The locating pins extend clear through the central portion of the jig body, and, consequently, will locate the component part of the work in exactly the same position as the piece of work being drilled on the front side of the jig. The same clamping straps are used, the screws being simply put in from the opposite side into the same tapped holes as are used when clamping on the front side of the jig. The four holes *D* are guide holes for drilling the screw holes in the work, these being drilled the body size of the bolt in one part, and the tap drill size in the component part. The lining bushing in the holes *D* serves as a drill bushing for drilling the body size holes. The loose bushing *E*, Fig. 73, is used when drilling the tap holes in the component part, the inside diameter of this bushing being the tap drill size, and the outside diameter a good fit in the lining bushing. The two holes *F*, Fig. 74, are provided with drill bushings and serve as guides when drilling the dowel pin holes, which are drilled below size, leaving about 0.010 inch, and are reamed out after the two component parts of the work are put together. The two holes shown in the middle of the jig in Fig. 73, and which are provided with lining bushings, and also with loose bushings, as shown inserted in Fig. 74, may be used for drilling and reaming the bearing holes for the shaft passing through the work. In this particular case, however, they are only used for rough-drilling the holes, to allow the boring-bars to pass through when finishing the work by boring in a special boring jig, after the two parts of the work have been screwed together.

---

* Address: 833 West Sixth St., Plainfield, N. J.

The large bushings shown beside the jig in Fig. 73 are the loose bushings shown in place in Fig. 74. It will be noted that the bushings are provided with dogs for easy removal, as explained in the installment in the May issue, and illustrated in Fig. 11. As the central portion of the jig body is rather thin, it will be noticed in Fig. 74 that the bosses for the central holes project outside of the jig body in order to give a long enough bearing to the bushings. This, of course, can be done only when such a projection does not interfere with the work. The bosses, in this particular case, also serve another purpose. They make the jig "fool-proof," because the pieces drilled on the side of the jig shown in Fig. 73 cannot be put on the side shown in Fig. 74, the bosses preventing the piece from being placed in position in the jig.

Attention should be called to the simplicity of the design of this jig. It simply consists of a cast iron plate, with finished seats, and feet projecting out far enough to reach below the work when drilling, three dowel pins, set-screws for bringing the work up against the dowel pins, three clamps, and the necessary bushings. The heads of all the set-screws and bolts should, if possible, be made the same size, so that the same wrench may be used for tightening and unscrewing all of them. It can also be plainly seen from the half tones that there are no unnecessarily finished surfaces on the jig, a matter which is highly important in economical production of tools.

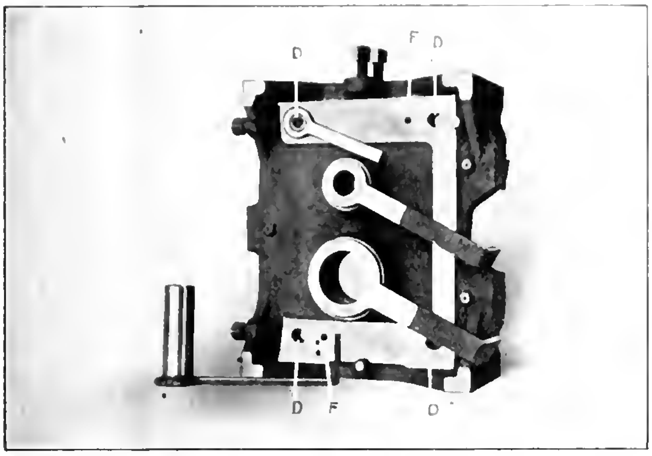

Fig. 74. Rear View of Drill Jig shown in Fig. 73.

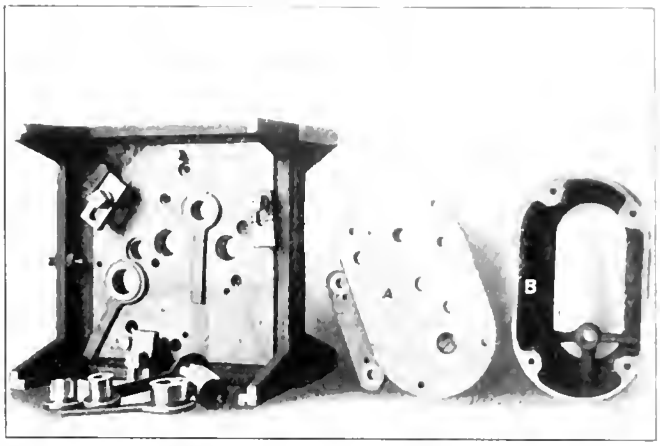

Fig. 75. Drill Jig used for Drilling Work shown to the Right.

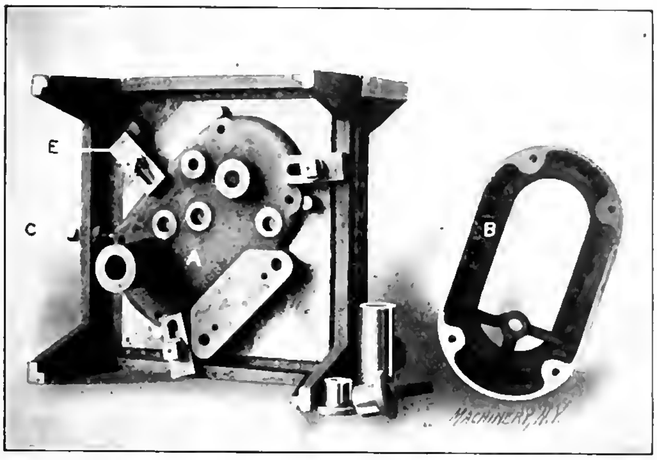

Fig. 76. Drill Jig shown in Fig. 75 with Work in Place.

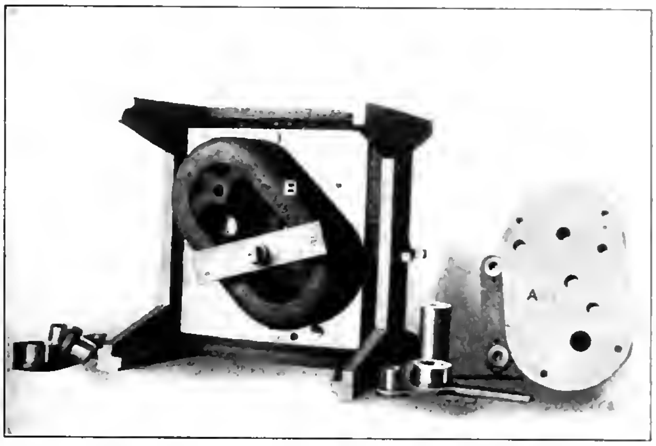

Fig. 77. Rear View of Drill Jig shown in Fig. 75, with Cover to be Drilled in Place.

Fig. 76. Drill Jig for Parts of Friction Clutches which are shown at the Right.

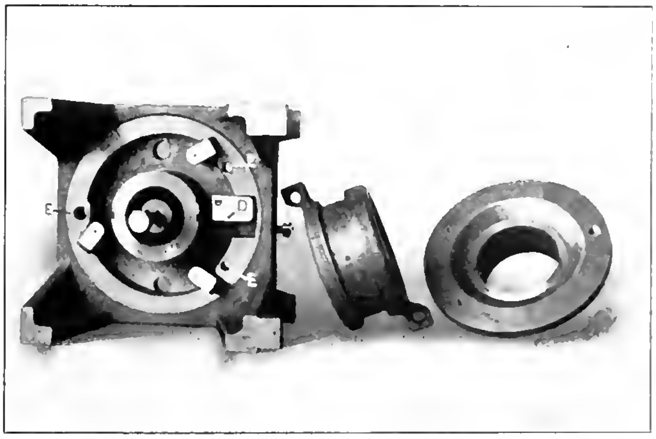

Fig. 79. Drill Jig shown in Fig 78, with one of the Pieces to be Drilled in Place.

Another example of an open drill jig, similar in design to the one just described, is shown in Fig. 75. The work to be drilled in this jig is shown at *A* and *B* at the right hand side of the jig. In this case, the work is located from the circular ends. The two pieces *A* and *B* are component parts, and when finished are screwed together. The piece *A* is located against three dowel pins, and pushed against them by set-screw *C*, and held in position by three clamping straps, as shown in Fig. 76. In this case, the straps are provided with oblong slots as indicated, and when the clamp screws are loosened, the clamps are simply pulled backward, permitting the insertion and removal of the work without interference. It would be an improvement on this clamping arrangement to place a stiff helical spring around the screws under each strap, so that the straps would be prevented from falling down to the bottom of the jig when the work is removed.

At the same time this would prevent the straps from swiveling around the screws when not clamped.

In Fig. 77, the part *B* in Fig. 75 is shown clamped in position for drilling, the opposite side of the jig being used for this purpose. In jig design of this kind it is necessary to provide some means so that the parts *A* and *B* will be placed each on the correct side of the jig, or, as said before, the jig should be made "fool-proof." In the present case, the parts cannot be exchanged and placed on the wrong side, because the cover or guard *B* could not be held by the three straps in Fig. 76, on account of the screws for the straps not being long enough. On the other hand, the piece *A* could not be placed on the side shown in Fig. 77, because the long bolt and strap used for clamping on this side would interfere with the work.

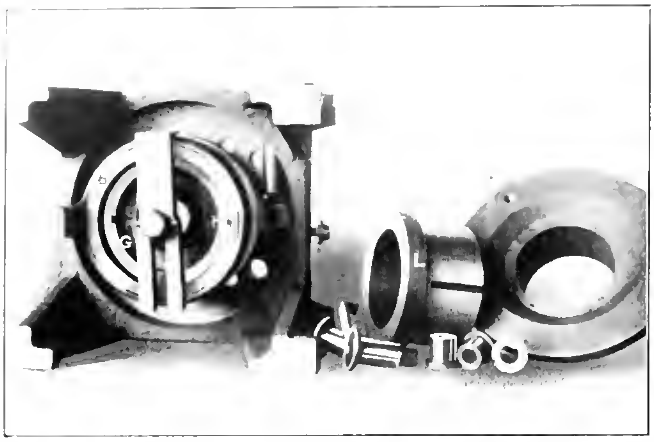

Fig. 80. Drill Jig shown in Fig. 78 used for Drilling Friction Sleeve

It may appear to be faulty design that three straps are used to fasten the piece *A* in place, and only one is employed for holding piece *B*. This difference in clamping arrangement, however, is due to the different number and the different sizes of holes to be drilled in the different pieces. The holes in the piece *A* are larger and the number of holes is greater, and a heavier clamping arrangement is, therefore, required, inasmuch as the thrust on the former is correspondingly greater, the multiple spindle drill being used for drilling the holes. If each hole were drilled and reamed individually, the design of the jig could have been comparatively lighter.

In the design shown, the locating of each piece individually in any but the right way is also taken care of. The piece *A*, which is shown in place in the jig Fig. 76, could not be swung around into another position, because the strap and screw at *E* would interfere. For the same reason the cover or guard *B* could not be located except in the right way. As shown in Fig. 77, the strap and screw would have to be detached from the jig in order to get the cover in place, if it were turned around. The locating pins for the work pass clear through the body of the jig, and are used for locating both pieces. The pieces are located diagonally in the jig, because, by doing so, it is possible to make the outside dimensions of the jig smaller. In this particular case the parts are located on the machine to which they belong, in a diagonal direction, so that the additional advantage is gained of being able to use the same dimensions for locating the jig holes as are used on the drawing for the machine details themselves. This tends to eliminate mistakes in making the jigs as well.

Sometimes, when more or less complicated mechanisms are composed of several parts fitted together and working in relation to each other, as, for instance, friction clutches, one jig may be made to serve for drilling all the individual parts, by the addition of a few extra parts applied to the jig when different details of the work are being drilled. In Figs. 78, 79, and 80, such a case is illustrated. The pieces *A*, *B*, and *C*, in Fig. 78, are component parts of a friction clutch, and the jig in which these parts are being drilled, is shown in the same figure, to the left. Suppose now that we wish to drill the friction expansion ring *A*. The jig is bored out to fit the ring before it is split, and when it is only rough-turned, leaving a certain number of thousandths of an inch for finishing. The piece is located, as shown in Fig. 79, against the steel block *D* entering into the groove in the ring, and is then held by three hook-bolts, which simply are swung around when the ring is inserted or removed. The hook-bolts are tightened by nuts on the back side of the jig. Three holes marked *E* in Fig. 79, are drilled simultaneously in the multiple spindle drill, and the fourth hole *F* (see Fig. 78), is drilled by turning the jig on the side. The steel block *D*, Fig. 79, is hardened, and has a hole to guide the drill when passing through into the other side of the slot in the ring. The block is held in place by two screws and two dowel pins.

When drilling the holes in the lugs in the friction sleeve *B*, Fig. 78, the block *D* and the hook-bolts are removed. It may be mentioned here, although it is a small matter, that these parts should be tied together when removed, and there should be a specified place where all the parts belonging to a particular jig should be kept when not in use. The friction sleeve *B* fits over the collar *G*, Fig. 80. This collar is an extra piece, belonging to the jig, and used only when drilling the friction sleeve; it should be marked with instructions for what purpose it is used. The collar *G* fits over the projecting finished part *H* in the center of the jig, and is located in its right position by the keyways shown. The keyway in the friction sleeve *B*, which must be cut before the piece can be drilled, and placed in the right relation to the projecting lugs, locates the sleeve on the collar *G*, which is provided with a corresponding keyway. A flange on the collar *G*, as shown more plainly at *L* in Fig. 80, locates the friction sleeve at the right distance from the bottom of the jig, so that the holes will have a proper location sideways. Two collars, *G* and *L*, are used for the same piece *B*, this being necessary because the holes *M* and *M* in the projecting lugs shown in Fig. 78 are placed in the same relation to the sides of the friction sleeve. The collars are marked to avoid mistakes, and corresponding marks on the jig provided so as to assure proper location. The friction sleeve is clamped in place by a strap which in this case does not form an integral part of the jig. This arrangement, however, is cheaper than it would have been to carry up two small projections on two sides of the jig, and employ a swinging leaf and an eye-bolt, or some arrangement of this kind. Besides, the strap is rather large, and could not easily get lost. The jig necessarily has a number of loose parts, on account of being designed to accomodate different details of the friction clutch.

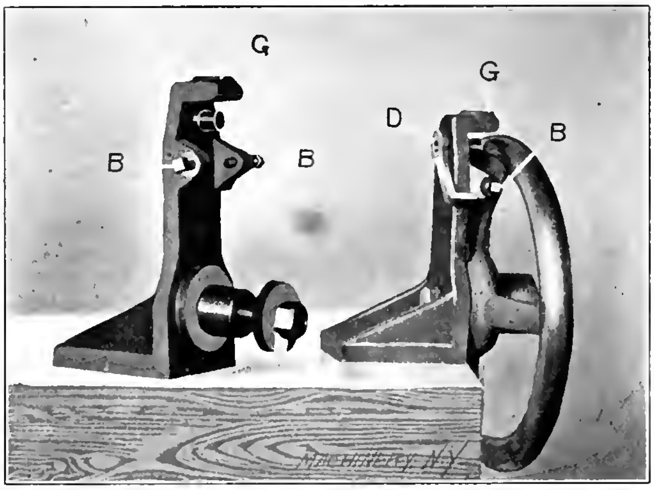

Fig. 81. Drill Jig for Holes in Rim of Hand-wheel.

The friction disks *C*, in Fig. 78, when drilled, fit directly over the projecting finished part *H* of the jig, and are located on this projection by a square key. The work is brought up against the bottom of the jig and held in this position by the same strap as is used in Fig. 80 for holding the friction sleeve. The bushings of different sizes, shown in Fig. 80, are used for drilling the different sized holes in the different parts.

In all the various types of drill jigs described above, the thrust of the cutting tools are taken by the clamping ar-

rangement. In many cases, however, no actual clamping arrangements are used, but the work itself takes the thrust of the cutting tools, and one depends entirely upon the locating means to hold the piece or jig in the right position when performing the drilling operation. It may be well to add that large bushings ought to be marked with the size and kind of cutting tool for which they are intended; and the corresponding place in the jig body where they are to be used should be marked so that the right bushing can easily be placed in the right position.

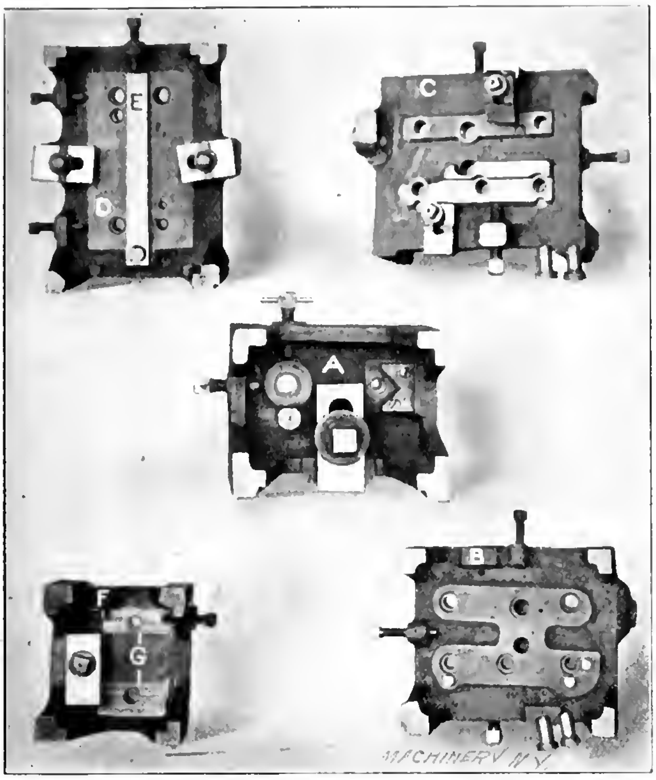

Fig. 82. Miscellaneous Examples of Open Drill Jigs.

A few more examples of open drill jig designs of various types may prove instructive. In Fig 81 are shown two views of a jig for drilling two holes through the rim of a hand-wheel. To the left is shown the jig itself and to the right the jig with the hand-wheel mounted in place, ready for drilling. As shown, the hand-wheel is located on a stud through its bore, and clamped to the jig by passing a bolt through the stud, this bolt being provided with a split washer on the end. The split washer permits the easy removal of the hand-wheel when drilled, and the putting in place of another hand-wheel without loss of time. The hand-wheel is located by two set-screws *B* passing through two lugs projecting on each side of a spoke in the hand-wheel, the set-screws *B* holding the hand-wheel in position while being drilled by clamping against the sides of the spoke. The jig is fastened on the edge of the drill press table, in a manner similar to that indicated in the half-tone, so that the table does not interfere with the wheel. The vertical hole, with the drill guided by bushing *G*, is now drilled in all the hand-wheels, this hole being drilled into a lug in the spoke held by the two set-screws *B*. When this hole is drilled, the jig is moved over to a horizontal drilling machine, and the hole *D* is drilled in all the hand-wheels, clamping the jig to the table of the machine in a similar manner as on the drill press.

In Fig. 82, at *A*, an open drill jig of a type similar to those shown in Figs. 73 and 75, is shown. This jig, however, is provided with a V-block locating arrangement. An objectionable feature of this jig is that the one clamping strap is placed in the center of the piece to be drilled. Should this piece be slender, it may cause it to bend, as there is no bearing surface under the work at the place where the clamp is located, for taking the thrust of the clamping pressure.

At *B* and *C* in the same engraving are shown the front and back view of a drill jig, where the front side *B* is used for drilling a small piece located and held in the jig as usual; and the back side *C*, which is not provided with feet, is located and applied directly on the work itself in the place where the loose piece is to be fastened, the work in this case being so large that it supports the jig, instead of the jig supporting the work.

At *D* in the same engraving is shown a jig for locating work by means of a tongue *E*. This tongue fits into a corresponding slot in the work. This means for locating the work was referred to more completely in connection with locating devices. Finally, at *F*, is shown a jig where the work is located by a slot *G* in the jig body, into which a corresponding tongue in the work fits.

It has not been possible to show actual designs of more than a few types of open drill jigs, the design, of course, varying according to the work to be drilled. The examples shown, however, will indicate the most common constructions, and exhibit plainly the application of the general principles laid down for jig design in the previous installments of this series.

* * *

AUTOMATIC PROFILING MACHINE.

The accompanying half-tones illustrate a profiling machine of the horizontal type, which, while on the one hand being provided with a guiding pin resting on a former, as in ordinary profiling machines, also combines this guiding arrangement with the feature of having a positive rotary as well as linear movement of the work-carrying slide. This permits work of any shape being profiled, either circular or nearly circular, or such having a long, narrow oblong outline. In the latter case, if the machine were not provided with a combination movement of the kind referred to, it would require that the cutter head would rise and fall through a considerable distance. With this combination movement, however, supplementing the movement caused by the guide pin on the former, any shape can be profiled with but a very slight movement of the cutter head.

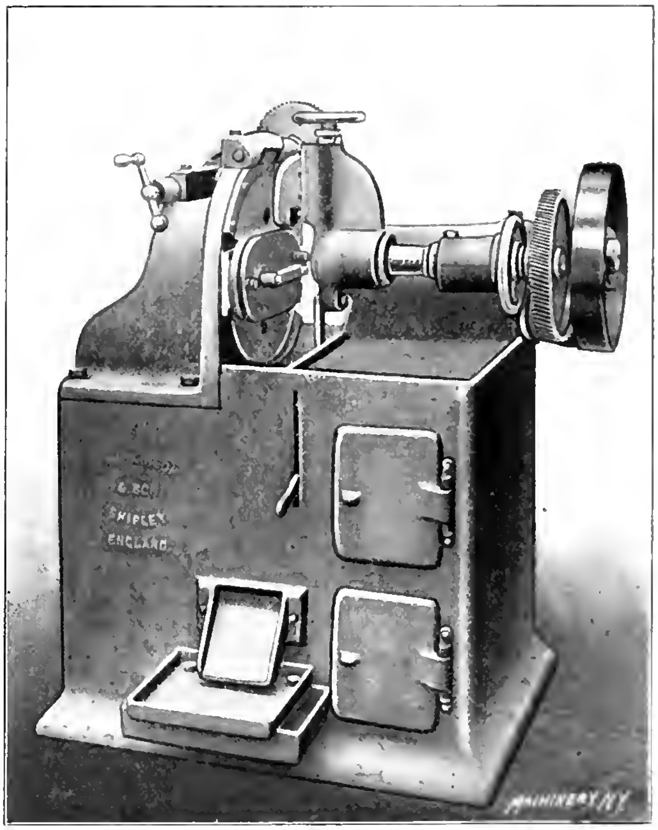

Fig. 1. Automatic Profiling Machine built by Messrs. J. Parkinson & Son, Shipley, England

The machine is built by Messrs. J. Parkinson & Son, Shipley, England, and was originally designed for milling the outline of bicycle cranks and the connecting-rods for small combustion engines. In the accompanying half-tone, Fig. 4, a bicycle crank is shown fastened to the work-carrying slide. The main features of the machine may be stated in a summary manner as follows: The rate of feed is the same on both the rotary and linear movements, so that the rate of output is

governed only by the strength of the cutter and the quality of finish required. It profiles automatically right around the article to be machined either once or as many times as desired; if required, the machine can be set to trip automatically on the conclusion of a portion of a revolution. The alteration for different lengths of linear motion in proportion to rotary motion is made simply by replacing a single pin, while the turning of a tumbler lever converts the action of the machine to a purely rotary one. There is but one trip movement for the double change from rotary to linear motion and back from linear to rotary motion.

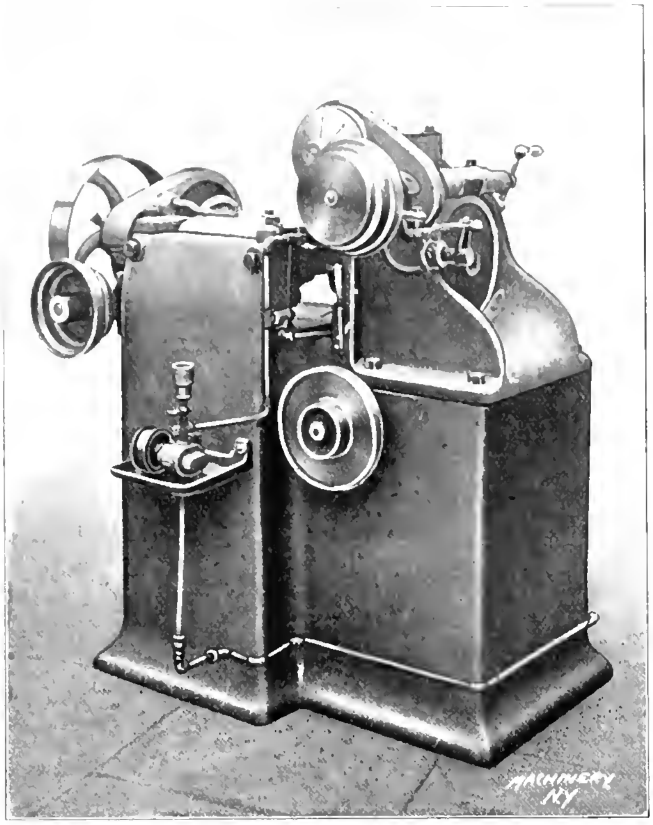

Fig. 2. Rear View of the Automatic Profiling Machine.

The general appearance of the machine is shown in Figs. 1 and 2, the former showing a front view and the latter a back view of the machine. It is driven by a single belt from the counter-shaft, both the cutter spindle and the work-holding head receiving its motion from this pulley. The spindle is carried by a swiveling bracket as shown, and driven by a pair of spiral gears. The cutter can be lifted clear of the work by means of a hand lever indicated at the front of the machine. The former-pin or runner is carried by the same bracket as the cutter spindle, and the latter's path is made to conform to the path of the former-pin by means of a pantograph link thereby transferring the shape of the former geometrically to the work to be machined.

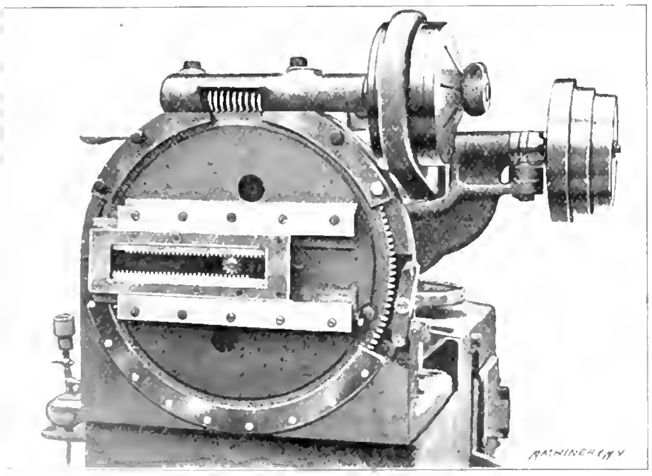

Fig. 3. View of the Work Head showing the Slide for Linear Motion.

The work head is driven from a cone pulley on the back of the machine, which can be connected to or disconnected from the driving mechanism of the head by a clutch. There are two worm-wheels in the head, one at the front and one at the back. These two worm-wheels are driven at exactly the same speed, but the front worm-wheel is only driven intermittently. The front worm-wheel carries the guides in which works the slide for the linear motion, as shown in the half-tones, Figs. 3 and 4. In this slide are fixed two compound racks placed face to face. The racks are made compound in order to be able to compensate for wear and eliminate back-lash. Between the two racks a pinion is placed which is driven directly through a shaft from the back worm-wheel. The pinion is so placed that when in mesh with one rack it just clears the other, as plainly shown in Fig. 3. This arrangement, of course, throws the axis of the two worm-wheels eccentric with each other to an extent equal to the addendum of the rack teeth. In order to understand the action of the machine it should first be kept in mind that the back worm-wheel and therefore the pinion meshing with the rack, are always revolving at a constant speed.

Now, suppose that the front worm-wheel is stationary. The small pinion which rotates with the back worm-wheel will drive the rack with which it is in mesh. When the slide thus driven reaches the desired position in its travel, the screw at the end of the slide comes in contact with a lever by means of which the front worm-wheel is engaged and commences to rotate. This is done either by allowing a friction gear to start driving the worm or by allowing a positive clutch to come into action. Both worm-wheels are now revolving in unison, and therefore the linear movement of the racks and the slide ceases; but inasmuch as the axis of the front worm-wheel is eccentric with that of the pinion, the rack that was in mesh with the pinion is gradually withdrawn, and the other rack is brought in mesh until at the end of half a revolution the pinion is in full mesh with the second rack and the front worm-wheel is brought to a stand-still automatically on account of releasing the pressure on the lever by the screw in the end of the slide.

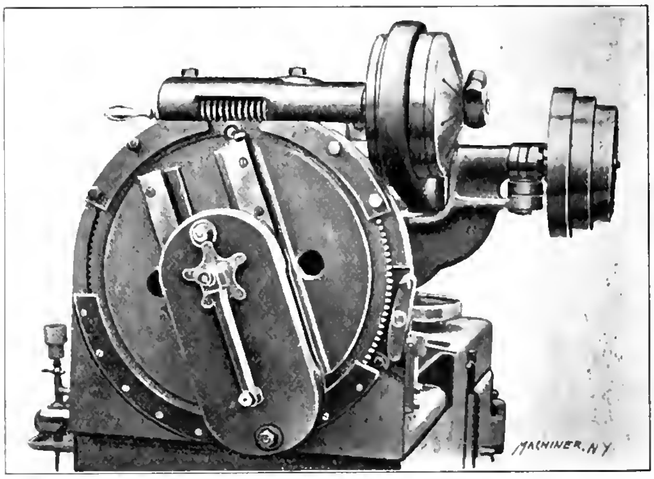

Fig. 4. Bicycle Crank fastened to the Work-carrying Slide.

Immediately when the front worm-wheel ceases to rotate, the slide is once more driven in a linear direction by the pinion, but the motion of the slide is in the opposite direction in relation to its guides on the worm-wheel. This cycle can be repeated any number of times. When a different length of linear motion is required a longer or shorter screw is placed in the end of the slide to act on the stop. When a purely rotary movement is required the stop is permanently removed from the front worm-wheel.

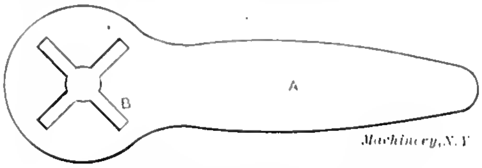
* * *

A creosoted wood conduit was recently removed from Sixth Avenue, New York City, and was found to be in excellent condition after 21 years' use. This conduit, which is the product of the Wyckoff Creosoting Co., was placed in 1887, and had to be removed this year in the excavation for the Hudson River Tunnels. It is in as good shape as when laid, and is being stored for possible future use.

ITEMS OF MECHANICAL INTEREST.

A WRENCH FOR WING NUTS.

Most of us have had to tighten up wing nuts by hand, which, of course, is what they are intended for, but sometimes it is convenient to be able to apply some tool for the tightening up of these nuts. For such a purpose the simple little tool illustrated in the accompanying line engraving, taken from the *Horseless Age*, will be found convenient. The wrench is made of flat stock about 3/16 inch thick. The handle *A* is made in various sizes, according to the size of the wing nut, five times the distance across the wings of the nut being the usual practice. Two slots *B* are cut at right angles to each other in the circular part of the wrench, as shown. At their intersection the central opening is enlarged, so as to permit the screw on which the wing nut turns to enter.



A Wrench for Tightening Wing Nuts.

INTERESTING TYPE OF EMERY WHEEL.

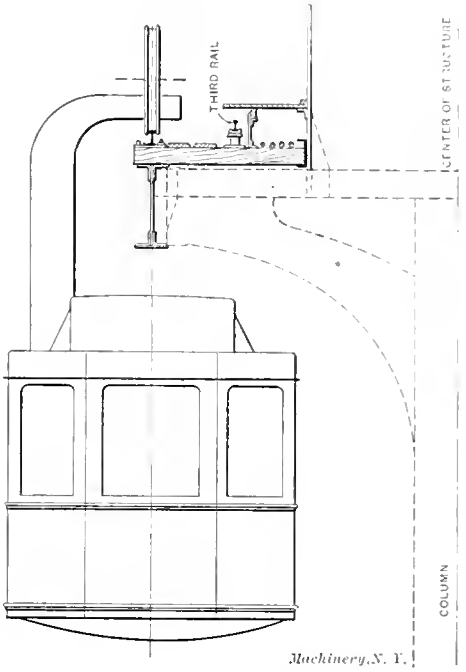
The accompanying illustration, reproduced from *The Mechanical Engineer*, July 17, 1908, shows a type of emery wheel which is claimed to be a decided improvement on the ordinary type of cup wheel made in a continuous ring. The advantages depend, it is claimed, on the fact that the spaces between the teeth, or blocks, of the emery wheel permit the air to freely play around them, thereby keeping them cool, and giving the dust created by the grinding an opportunity to more easily escape. The teeth are, in reality, loose sections or segments, held in a special chuck. Each segment is secured thoroughly by a set-screw which is tapped through the enclosing casing, the screws acting on special clamping plates, forcing the segments down into the opening provided for them, thereby wedging them in place. This type of emery wheel has been patented by Messrs. Luke & Spenser, Ltd., Broadheath, England.

New Type of Emery Wheel which, it is claimed, is Superior to the Ordinary Cup Wheel.

It is difficult to say, off-hand, to what extent a wheel made up in this manner will prove practical. It seems that there are some very strong points in its favor. While it may seem at first sight as if a wheel of this type would be more expensive to make than the ordinary cup wheel, that factor is likely to be offset by the fact that the "teeth" of the wheel shown are very simple parts to make, and the great loss incidental to emery-wheel manufacture due to breakage and cracking during the drying processes are largely eliminated. The same advantages in this respect as are manifest in inserted teeth milling cutters would be gained in this "inserted teeth" emery wheel.

THE BERLIN SUSPENDED RAILWAY

The transportation problem within the city limits has lately commanded a great deal of attention in Berlin, Germany, on account of the rapid extension of the city. The city is already provided with subway and elevated railroads, running from east to west, but has not adequate rapid transit facilities from north to south. It has been concluded that the expenditure incident to a subway would not be warranted by the traffic, and it was necessary to decide upon some kind of an elevated structure. It was considered, however, that the ordinary elevated railroad structure, as found in American cities, shut out too much light from the street below, and the type of suspended railroad, as indicated by the accompanying line-engraving, is projected. The dotted lines indicate one-half of the steel structure, which consists simply of a single column, or pedestal, in the center of the street, being provided at the top with the necessary structure for carrying one rail on each side. As shown in the illustration, but one rail is necessary for the traffic in each direction, the car being suspended below the rail by substantial hangers, and the center of gravity of the car being exactly below the center of the rail. In curves, the car will swing inward or outward, according to the direction of curvature, and the unpleasant sensation to passengers commonly experienced on curves is avoided. The system permits not only much sharper curves than are permissible in ordinary railroad construction to be used, but there is less need of slower speed around the curves, the average speed being twenty miles an hour. In order to make the objection to the elevated structure as slight as possible, an ornamental design has been adopted, and the rails are located 34 feet above the level of the street.



End Elevation of Car resting upon the Single Rail upon which it Travels.

* * *

It is announced in *Figaro* that work has begun on the construction of a central station of wireless telegraphy in Paris to be used in connection with the Eiffel tower. The station itself, which will be provided with receiving and transmitting apparatus of exceptional power, is placed under ground, and is joined by wires with the extreme top of the tower. It is claimed that there are good reasons for believing that with a similar station erected in New York, direct communication between New York and Paris would be possible. Lee DeForest has announced that such a station will be established in the tower of the Metropolitan Life building and that he hopes to establish telephonic as well as telegraphic communication across the Atlantic.

Entered at the Post-Office in New York City as Second-Class Mail Matter.

MACHINERY
REGISTERED IN UNITED STATES PATENT OFFICE
DESIGN—CONSTRUCTION—OPERATION.
PUBLISHED MONTHLY BY
THE INDUSTRIAL PRESS,
49-55 LAFAYETTE STREET, CORNER OF LEONARD,
NEW YORK CITY.
Alexander Luchars, President and Treasurer.
Matthew J. O'Neill, Secretary.
Fred E. Rogers, Editor.
Ralph E. Flanders, Erik Oberg, Franklin D. Jones, Associate Editors.

The receipt of a subscription is acknowledged by sending the current issue. Checks and money orders should be made to THE INDUSTRIAL PRESS. Money enclosed in letters is at the risk of the sender. Changes of address must reach us by the 15th to take effect on the following month; give old address as well as new. Single copies can be obtained through any newsdealer.

We solicit communications from practical men on subjects pertaining to machinery, for which the necessary illustrations will be made at our expense. All copy must reach us by the 5th of the month preceding publication.

OCTOBER, 1908.

PAID CIRCULATION FOR SEPT., 1908, 20,196 COPIES.

MACHINERY is published in four editions. The practical work of the shop is thoroughly covered in the Shop Edition—$1.00 a year, comprising more than 430 reading pages and 36 Shop Operation Sheets, containing step-by-step illustrated directions for performing 36 different shop operations. The Engineering Edition—$2.00 a year, coated paper $2.50—contains all the matter in the Shop Edition, including Shop Operation Sheets, and about 250 pages a year of additional matter, which includes a review of mechanical literature, and forty-eight 6 x 9 data sheets filled with condensed data on machine design, engineering practice and shop work. The Foreign Edition, $3.00 a year, comprises the same matter as the Engineering. RAILWAY MACHINERY, $2.00 a year, is a special adition, including a variety of matter for railway shop work—same size as Engineering and same number of data sheets.

COOPERATIVE INDUSTRIAL EDUCATION.

The cooperative educational plan instituted in Cincinnati by which students in the Cincinnati University are enabled to obtain practical knowledge of machine construction and mechanical work in the Cincinnati shops has attracted much favorable attention. Analogous to this plan is a new movement in industrial education just put into effect in Fitchburg, Mass. This, we believe, is one of the most practical plans of industrial education ever formulated, and an account of it will be found on another page of this issue. Briefly, the plan is to educate young men in the machine-shop art and in the high school, simultaneously. The students taking the cooperative course are arranged in pairs, one student spending one week in the high school while his partner works in the shop. The next week the position is reversed, and so on. The lads taken into this course must have previously spent one year in high school, and they are required to take a three-year apprenticeship course in mechanical work, so that a four-year high school course and the machine shop apprenticeship are finished the same year.

The general result of such an educational system should be highly satisfactory, both as regards the manufacturers and the boys. It is common experience that the most active mental state exists with a moderate degree of physical exercise, so that students attending high school one week and working in the shop the next should be in the fittest condition for acquiring the elements of a trade and appreciating the value of an academic education. The condition of such a boy upon graduation is advantageous. He is not necessarily committed to being a machinist all his life, but is as free to enter any other vocation as are his mates who have only the advantage of an academic education. The fact that he is the master of a trade will be a very valuable help to him, however, even if his ambition lies in the direction of higher education and a profession. A poor boy can earn his way in a more dignified and agreeable manner than the majority of poor students, who generally have to resort to all sorts of menial occupations to get along. If the cooperative student chooses to become a machinist, his general education and special mechanical instruction should fit him to fill, ultimately, the highest positions in the manufacturing world.

UNLAWFUL USES OF PATENTED MACHINES.

An interesting point in patent law was recently passed on by the Circuit Court of the United States in the Eastern District of Pennsylvania, in a suit to enjoin the further use of patented machines that had been sold for scrap. The court enjoined the use by a manufacturing concern of two crankshaft lathes sold by the complainant company to a junk man. The machines, which were nearly complete in all essential details, were bought, repaired, and put in use by a competitor. The judge of the circuit court in granting the injunction restraining the use of the machines by the defendant company, held that while the purchaser of a patented article from one who is authorized to sell, becomes possessor of an absolute property right in it (Keeler *vs.* Standard Folding Bed Co., 157 U. S. 689) which he is capable of also transmitting to others, in this case the right of use did not follow the sale, inasmuch as the complainant company sold the machine as scrap. "A sale as scrap was a sale not to use, but to destroy; and cannot be wrested into a sale of the patented machines because the different parts could be picked up and put together again. (Wortendyke *vs.* White, 2 Ban. & Ard. 25; Cotton Tie Co. *vs.* Simmons, 106 U. S. 89)." It was also alleged by the complainant company that the machines were fraudulently disposed of by a foreman who now is an officer of the defendant company.

The principal enunciated in the judge's decision is important to users of second-hand patented machinery and apparatus of whatever description, especially if the route by which they came into the user's factory is obscure. It seems doubtful that the decision is entirely sound, as such a ruling might easily be made to impose unwarranted hardship on innocent purchasers. If there were no other remedy for the unlawful use of discarded patented machines, there would be good reason for the injunction, but any concern about to dispose of machinery for scrap can separate the parts and break them up so that reconstruction is impossible. The sale of a machine in workable or nearly workable condition, and without destroying the possibility of use, appears to us to carry with it an implied right to make further use thereof for its original purpose. The decision referred to, if sustained, might have unexpected results. For example, it might cause serious interference with the sale of second-hand patented steam boilers, if the manufacturers were disposed to place an embargo on their further use. Steam boilers are commonly disposed of by power companies and others to junk dealers, when they have outlived their usefulness for high-pressure work. The junk men sometimes sell them to persons who want low-pressure boilers for steam heating and other work not so severe as power generation, and it seems unreasonable that such a boiler, sold without breaking up, should not be used by the purchaser for the designed purpose. The fact that it was sold to the junk dealer ostensibly as scrap should not entail the destruction of the boiler unless a specific agreement was made to that effect. The second-hand value of a boiler having a possible further use is greater, of course, than if it were sold to be converted into scrap; but if the fact that the construction happens to include some patented feature can be used to prevent further use beyond the original buyer, an injustice would undoubtedly be worked on unsuspecting purchasers.

The case in point is considerably complicated by the allegation that an employe of the complainant company disposed of the machines fraudulently, having sold them among other scrap when the officials of the company had no intention of disposing of the machines, which it is alleged had simply been removed from the machine-shop while awaiting repairs and further use. It is not clear from the text of the decision whether the judge took particular cognizance of this fact in granting the injunction, or whether he based his opinion entirely on the fact that the machines were sold for scrap and that such sale did not carry with it the right of use for their original purpose. A fraudulent sale, of course, would not carry with it the right of use of a patented article, or any other right or title; but as the complainant company was unable to establish a fraudulent sale, it appears that the court's decision was based simply on the assumption that a sale for scrap is not a sale for use, and that the user may be enjoined from such use.

PRESERVING RECORDS.

Some time ago we published an editorial on "Keeping Things Seven Years," in which was questioned the advisability of storing away for future use odds and ends left around the shop. There are two departments in the shop, however, where almost everything pertaining to the work should be kept, even when it apparently has passed its time of usefulness. These departments are the general office and the drafting-room. Little need be said about preserving the records in the office. Those pertaining to the mercantile end of the business are, of course, carefully preserved; but in the drafting-room, the practice is not always well defined. Regular drawings, it is true, are filed away, but a considerable part of the work in the average drafting-room consists in making small sketches, often in a hurry, for some special work in the shop. Often these are made simply in pencil and are not traced or blue-printed, the sketch itself being sent out in the shop, so that no record is left in the drafting-room. Sometimes the sketch is lost in the shop, the work perhaps being half completed, and under such circumstances it is much more difficult to make another drawing that will conform to the work partly done, than it was to make the original lay-out. The saving of time incident to this method of sending sketches and drawings into the shop is usually so small that it does not seem worth while to invite all the trouble that often comes from it; and for this reason a record of everything in the shape of a drawing, sketch, order or specification which goes into the shop from the drafting-room, should always be kept in some form so as to preserve a permanent record. While it may require a few more hours' work, at times, to systematically adhere to this policy, in the long run it will save a great deal of trouble and expense. Of course, we know that in hundreds of drafting-rooms such a system is already in force, but we also know that in a great many the haphazard methods referred to are practiced.

The faculty of memory, while one of the most wonderful qualities of the human mind, is at the same time one of the most uncertain, and it often fails at the very time when its accurate working is of the greatest importance. For this reason *anything worth remembering is worth placing on record.* The drafting-room may seem to be overcrowded with the card indexes, files or cabinets necessary to a scrupulous adherence to this principle; but there will be less time wasted searching for things mislaid or destroyed. Time is money.

* * *

GUESSWORK IN MACHINE TOOL DESIGN.

Machine tool designers and men engaged primarily in the construction of small machinery of that type, who have not had experience along other lines of mechanical achievement, are often prone to look upon calculations and formulas for the strength of materials and similar means for exact analyses as rather unnecessary, and of interest, not to practical men, but merely to the student. Engaged, as they are, in work where no great damage is done if a part proves too weak and breaks, as it can easily be repaired and replaced, the new part being sometimes made a little stronger or of the same dimensions and liable to break again under too heavy stresses, they do not seem to fully realize that in some kinds of engineering work such failures cannot be risked, for they may result in loss of life and property of appalling magnitude.

If a belt from the counter-shaft to the driving pulley should happen to be too narrow and should break under the stress of a heavy cut, the mishap may be inconvenient and cause a little trouble, but as a rule no great damage is done; while if the mast on a crane intended to lift 10,000 pounds buckles and fails when a large casting of this weight is suspended from the hook, with several men on the foundry floor near by, the danger and the loss is too serious to be lightly considered. A lever on an automatic machine subject to constant vibrations may finally break; the breakage may cause temporary difficulty, but no great harm is done, and the damage is merely a small pecuniary one; but if one of the trusses on a railway bridge is improperly calculated and designed and gives way under the weight of an express train, the damage cannot be expressed in dollars and cents.

Thus there is some reason why men engaged in the design of small machinery should leave so much to guesswork, depending largely on "snap" judgment, a condition which is not permissible in the design of machinery subjected to stresses where failure means considerable damage. This element of chance and guesswork plays an important part in the design of machine tools, too important, in fact, for the continued prestige of designers. There are many things that could be calculated to a certainty, even on machine tools, which are proportioned merely on the designer's judgment, and the outcome is left to chance in many cases where it is unnecessary. The judgment of a machine tool designer, of course, is one of his greatest assets, but he should not despise the manner in which the designer of other classes of machinery works, where it is necessary to determine exactly the dimensions and the conditions of the design. He should learn rather to adapt himself to methods of exact analysis when and where the conditions demand it. The combination of the qualities of instinctive machine design and design by mathematical analysis is most invaluable.

* * *

MACHINE TOOL BUILDING AND ECONOMICS.

The mechanical progress of the last twenty-five years has been marvelous. The new inventions which have been brought forth, and which are constantly being perfected, have placed the machine industry, and particularly the machine tool manufacture, on an extremely high plane mechanically. Our highly developed and firmly established shop systems, proper management, and general all-around intelligence, have made economical production in the shops possible in a degree which was not expected even a few years ago. But, in spite of all this, we have temporary depressions in the machinery trade, for which there seems to be no reasonable cause. The fact is, however, that our business men, as well as our mechanics, while they have developed the science of individual economics of the shop to a high perfection, invented and improved labor-saving machinery, and, in general, placed the business, industrially, on the firmest ground, have not given due attention to the outside influences, those influences which do not depend upon the individual economics of each shop, but upon the economical principles applied to the nation as a whole.

It is not the office of MACHINERY to teach political economy, but inasmuch as the machine tool industry, and all other industries in the country, for that matter, can only secure for themselves a small portion of the prosperity to which they are actually entitled, if they are hampered by adverse conditions of economics applied to the nation, we consider it proper to ask our readers to give more attention to a subject that is fully as important to the development of the trade to which they have devoted themselves, as the economical and commercial development of the individual shops.

There is but one legitimate cause for hard times and that is the failure of crops. When depressions and hard times occur without being provoked by this cause, the reason is an artificial one, which can be removed if we only give due attention to the economic problems that cause it. Wonderful as our industrial progress during the past century has been, it will prove of little value in the end, if the manufacturer as well as the mechanic do not find it easier to secure, on the one hand, a fair profit, or, on the other, continuous employment at fair wages. It is time that the men employed in industries which depend so largely on the solution of some of our economic problems, should no longer ignore giving attention to so important a subject.

Inventions alone are not the only thing necessary to the prosperity of the machine industry. It is equally important that each man, whether he be a manufacturer or an employe, receives a fair equivalent for his exertions, and that he should not need to fear depressions caused simply by artificial economic conditions. If the business men and the mechanics of this country would give more attention to economic conditions and problems of this character, they could better safeguard themselves against such difficulties.

ENGINEERING REVIEW.

CURRENT MECHANICAL EVENTS—LEADING ARTICLES OF THE TECHNICAL PRESS.

As the result of the agitation which has been in progress for many years, the technical schools and universities of Prussia have, by a recent decree, been opened to women. Such privileges had already been granted in some of the smaller states.

The experiments on the elevated railway lines in Chicago to eliminate noise by the use of a gravel roadbed on the structure, has recently been abandoned, as the gravel not only failed to reduce the noise, but held water, with injurious effects to the structure.

The best preventative for spontaneous ignition of coal, says *Compressed Air*, is a small cylinder containing compressed carbon dioxide, fitted with a fuse plug melting at 200 degrees F. A cylinder one foot long and 3 inches in diameter is sufficient to take care of 8 tons of coal.

Two motor shows are to be held in France the latter part of this year, one being for private and the other for commercial vehicles. Both exhibits will take place in the Grand Palais. The show for pleasure cars will be open from November 28 to December 13, and that for commercial motors from December 22 to 29.

The importance of cement in engineering work is indicated by a contract recently made by the United States Government with the Atlas Portland Cement Co. for the Panama Canal. The contract is for 4,500,000 barrels of Portland cement at a cost of $5,500,000. This, it is said, is the largest single contract ever given out in the Portland cement business. The contract calls for a minimum shipment of 2,000 barrels a day and a maximum of 10,000. The present productive capacity of the company is 40,000 barrels per day.

The Pennsylvania Railroad forestry department has just completed its forestry planting for this year. It is stated by *Railroad Men* that 625,000 trees were planted. This makes a total of 2,425,000 trees set out by the Pennsylvania Railroad up to the present time. The object is to create an adequate supply of timber for ties required in years to come. The Pennsylvania Railroad evidently is taking active steps in regard to the preservation of natural resources. The true way of preserving our forests is not necessarily not to use them, but to replant them.

Cotton gins, printing, spinning, weaving machines, and scientific instruments are being exported from Japan to China, India and the United States. The exports of machinery for 1907 is reported by Consul General H. B. Miller, of Yokohama, to have increased 61 per cent, and there is an increase over the average for five years of 250 per cent. Thus far the exported machines have been mostly copies of foreign models, but the makers of violins at Nagoya have invented labor-saving appliances, and the tea-firing machinery used in Japan is chiefly of native invention.

The twelve new torpedo boats under construction for the German Navy are to be driven by steam turbines. According to *Engineering*, it is planned to try four different types of turbines. The three boats which the Vulcan yards near Stettin are constructing are to be equipped with turbines of the Curtis type. The four boats which the Schichau yards of Elbing and Danzig have undertaken to build, will have Melms and Pfenninger turbines. Of the five torpedo boats under construction at the Germania yards at Kiel, four are equipped with Parsons, and one with Zoelly turbines.

A union railway station is now in the course of construction at Leipzig, Germany, which will be one of the largest in the world. The five terminal stations which are in Leipzig at the present time, will all be removed upon the completion of the new terminal. This latter is to have 26 parallel tracks which will accommodate the trains of 13 different lines, and between each pair of tracks is to be a walk 40 feet wide, so that the total width of the train shed will be nearly 1,000 feet. The main facade of the building will be 1,115 feet wide, or over 350 feet greater than the facade of the new Union Terminal at Washington, D. C., which is at present the largest in this country.

The Cunard steamer *Lusitania* broke all records on her western trip ending August 21. She crossed the Atlantic in 4 days and 15 hours, the total distance traversed being 2,780 knots. The best day's run was 650 knots. The best hourly speed was 25.66 knots and the average for the trip was 25.05 knots. This trip demonstrates the ability of the vessel to make the average speed required by the terms of the subvention allowed by the British Government, it being required by the terms that the vessel make one trip at the rate of 25 knots.

While the discussion of the recent disaster of the collapse of the Quebec bridge is still occupying the engineering profession, reports of a similar accident come from Germany. On July 9 a bridge under construction over the Rhine, at Cologne, fell, and at least fourteen of the men engaged on the bridge work lost their lives, and nine men were taken from the water severely injured. The traveler used in erecting the central span collapsed, and carried with it all of the steel work. While not as disastrous an occurrence in regard to the loss of life as the Quebec bridge collapse, it was perhaps, merely by chance that no more men were, at the time, engaged on the work on the bridge, and the occurrence of two accidents of so similar a character, one in America and one in Europe, indicates that the engineer has still a great deal to learn and that, particularly in structural work, too great pains can never be taken by those in charge of design or erection.

In an editorial in *Engineering News* attention is called to the practice of sending catalogues to prospective customers without price lists, even though a price list may have been specifically requested. The idea is that the customer should state in detail the particular machines he is interested in, and prices will be furnished him for these only. Sometimes, however, the lack of definite information given to the customer is the cause of loss of big contracts. In the present case, a firm in Chile had requested manufacturers of mining and smelting machinery to furnish catalogues and prices. Many American manufacturers furnished catalogues, but did not attach price lists, whereas all the European manufacturers gave definite prices and terms. As correspondence between Chile and the United States requires some six weeks or two months in each direction, and delay was not permissible in this case, the result was that an order for $75,000 worth of machinery was cabled to Europe and lost by the American trade.

The original supply of coal in the state of Pennsylvania is estimated by Mr. M. R. Campbell, of the United States Geological Survey, to amount to 21,000,000,000 short tons in the anthracite fields, and 112,574,000,000 short tons in the bituminous fields. It is interesting to note the statement that by the methods of mining anthracite coal in former years, for every ton of coal mined and marketed one and one-half ton were either wasted or left in the ground as pillars for the protection of the workers, so that the actual yield was only about 40 per cent. This percentage of waste has been greatly reduced in later years. Of the original available supply, as mentioned above, it is estimated that there is 17,000,000,000 tons of anthracite coal left, of which one ton can be mined for each ton lost. This would indicate that the Pennsylvania fields can still yield 100 times the quantity

of anthracite produced in 1907. The supply of bituminous coal at the rate of production in 1907 would not be exhausted for nearly 500 years.

Economy in the use of material is the first law in manufacturing, but there are certain economies that may be obvious when once known, but which have developed slowly and have to be seen to be appreciated. In the manufacture of twist drills it formerly was the practice to cut bar stock for drills into short lengths about six feet long. It finally was realized that "every bar has two ends," and that the proportion of waste with the six-foot bars was more than with the 12- to 14-foot bars. The Standard Tool Co., Cleveland, O., no longer cuts its stock into lengths as short as 12 or 14 feet even, but stores them in mill lengths of 24 to 28 feet, thus reducing the waste due to croppage to a minimum. The stock is stored on end in a concrete storage warehouse specially constructed for convenience in unloading from cars and supplying the needs of the factory. The stock is leaned against the side walls and a central rack. Each stock has its own stall, the sizes running from ¼ inch up. Of course, the small sizes come in shorter mill lengths, it not being feasible to handle or store these in lengths of 24 feet or more. The central rack in this storehouse has three arc lights overhead for illuminating the stock at night or during the dark days in winter. The storehouse is warmed by five hot-air discharge flues distributed in the warehouse so as to keep the steel at a comfortable temperature to handle, no matter what the outside weather may be.

AERONAUTIC RECORDS.

Leon Delagrange, president of the Aviation Club of France, established a new world's record with his aeroplane at Issy, near Paris, September 6. His machine remained in the air 29 minutes, 54 4/5 seconds, and circled the field 15 1/2 times, covering a distance of about 15 1/4 miles. On the following day Delagrange remained in the air 31 minutes, but was penalized three minutes because his machine touched the earth while making the first round of the field. On September 5 Wilbur Wright made a flight with his aeroplane at Le Mans, France, of 19 minutes 48 2/5 seconds and traveled between 14 1/3 and 15 miles. Following is a partial record of the progress of the heavier-than-air flying machines during the past year, taken from the *New York Times*:

Oct. 15, 1907—Henry Farman traveled 285 meters near Paris.

Jan. 13, 1908—Farman won the Deutsche Archdeacon Prize by sailing a kilometer in a circle near Paris.

March 20—Farman flew his aeroplane 1½ miles near Paris.

May 13—The Wrights flew 3 miles in 3 minutes near Paris.

May 18—Baldwin's aeroplane *White Wings* made a short flight near Hammondsport, and five days later traveled 183 yards and then upset.

May 27—Delagrange's aeroplane flew 6 miles before the King of Italy at Milan, and next day made a record flight of 10 miles.

June 29—Bieriot's monoplane won the Aero Club's medal by flying 100 yards.

July 4—Curtiss's aeroplane the *June Bug* flew one mile, and won the *Scientific American* Cup.

July 7—Farman won Armongaud's $2,000 prize by remaining twenty minutes and twenty seconds in the air.

Aug. 2.—Farman, at the Brighton Beach track, went 700 yards in forty seconds.

Sept. 2—Two Cornell instructors covered three miles in five minutes in an aeroplane of their own making.

Sept. 3—While Orville Wright at Washington covered two-thirds of a mile in one minute, his brother Wilbur, at Le Mans, France, covered six miles in ten minutes.

Sept. 5—At Le Mans, Wilbur Wright covered 15 miles in twenty minutes in his aeroplane.

Sept. 9—Orville Wright made two record-breaking flights near Washington with the machine under perfect control. The distance covered in the longest flight was about 40 miles, the time being 62 minutes and 15 seconds.

Sept. 11—Orville Wright again breaks his record by remaining in the air 70 minutes and 24 seconds.

SMOKELESS FUEL.

Mechanical Engineer, August 14, 1908

Mr. Sherard Cowper-Coles of Grosvenor Mansions, 82 Victoria Street, Westminster, London, has recently patented the following process for the manufacture of smokeless fuel About one-third part by weight of wet peat and two thirds part by weight of bituminous coal in a finely divided state, are placed in a retort and heated to a temperature sufficiently high (about 850 deg. F.) to drive off those hydrocarbons that produce smoke, the generation of the steam from the peat assisting in this operation. It will be understood that the temperature is not raised materially higher than is necessary to drive off the hydrocarbons, as above stated. The heat is applied for about five hours. The bituminous coal binds the peat together to a coherent mass and forms a fuel of high calorific value, which is readily ignited in a grate in the ordinary way and burns economically and without smoke. In practice the retort may be provided with relief valves and arranged so as to maintain a pressure of 10 pounds per square inch. The retort may also be fitted with a plunger which is forced to one end when the contents are in a plastic state, and it may be heated in any convenient way, such as by heat externally applied or by burning some of the gases generated after partial purification. The watery extract, containing tar of complex constitution, pyroligneous acid, and other products derived from the carbonization of peat, in addition to the gases above referred to, is advantageously condensed and utilized for the production of a pitch of superior quality, and the usual condensible products obtained from the bituminous coal in the retort may be collected and used for any desired purpose. In some cases the contents, after the above described process has been completed, may, either while still hot or after they have cooled, be discharged into a solution of calcium chloride. By this means the smokeless fuel is rendered slightly deliquescent and always retains a certain quantity of moisture. The coal or the peat, or both, may also be moistened with a solution of calcium chloride before being placed in the retort.

THE MANUFACTURE OF SLAG-CONCRETE BRICKS.

Engineering, August 14, 1908.

The amount of slag produced per ton of iron from the blast-furnace, varies in amount from ½ ton to about 1½ ton, according to the ores used; and, with the enormous output of pig iron at the present time, it is not surprising that attempts are continually made to find some satisfactory means of turning this material to account. The manufacture of concrete bricks from blast-furnace slag has become a commercial process of some value. The material, containing as it does a large amount of lime and silica, is eminently suitable for such a purpose. The granulation of the slag is first effected by running it, while still in a molten condition, into water. After granulation, the slag is passed between squeezing-rollers for the purpose of removing the excess of water and crushing any large particles. For mixing with the slag, white unslaked lime has proved most satisfactory, ground to an 8,000 mesh. The lime should not contain more than ½ per cent magnesia. The slag and unslaked lime in proportions of 95 to 93 per cent slag to 5 to 7 per cent lime, are tipped into a large hopper and passed thence to a steam jacket mixing machine; the heat, together with the moisture in the slag, starting the reaction of the lime. It is then taken to the presses, in which the pressure is exerted on the 9 x 3-inch side, thus insuring uniform thickness of all bricks, and from these presses the bricks are taken to steaming chambers. The slag must be of uniform grey quality, or variations in the color of the bricks will result. The success of the bricks depends on the care and uniformity with which the various operations are carried out. Uniformity of mixture and of pressing are most important. The moisture carried by the slag, when mixed with the unslaked lime in the mixing hopper, should not be more than 8 to 10 per cent. The resulting bricks compare very favorably with red bricks, and are of a more uniform quality than cement bricks made of zinc slag and lime, or refuse clinker. They have a crushing strength of between 2,500 pounds and 3,000 pounds per square inch, and have withstood very severe

boiling and freezing tests. The bricks are satisfactory for building purposes, and masonry built with them has fire-resisting qualities as good as, if not superior to, that built of red brick. Coloring matter can be added, if necessary, when mixing the lime and slag. The cost-sheet suggests that there may be a considerable future before this process, for the prices compare favorably with other bricks of equal quality.

BRAZING CAST IRON AND OTHER METALS.

Frank N. Blake in the *Horseless Age*, August 26, 1908.

Brazing consists in uniting metal parts by flowing melted brass, technically termed spleter, between them. It is practically identical with soldering, except that spelter is substituted for solder, and that a much greater degree of heat is necessary. In the greater degree of heat required to melt spelter lies one of the advantages which brazed work possesses over that which is soldered, the finished work enduring more heat without breaking or weakening; but the chief advantage lies in its superior strength at all temperatures and its applicability to a large variety of uses. Cast iron is a common material which is prone to break, and which can now be brazed. The production of the necessary heat is an important part of the process of brazing, and constitutes the chief difficulty and almost the only source of expense. For small work, a plumber's hand gasoline torch can be used in what may be termed an amateur sort of way, but for common use a forge, gasoline brazer, or a jet of gas supplemented by a blast of air can be satisfactorily used. The latter constitutes the cleanest, most convenient, and effectual brazing fire.

A bed of coke or charcoal on a forge hearth is an excellent resting place for the work during the process of brazing. A backing of firebrick or of asbestos is of considerable assistance in confining and reflecting the heat, though, of course, these do not contribute to the heating process in the way that inflammable backings do. There is considerable opportunity for the display of judgment and discretion in the arrangement of the backing; aside from the saving of time and fuel there is, on large and difficult work, all the difference between success and failure in the way the heat is applied and utilized.

Before work is assembled for brazing it should be well cleaned by file, scraper, scratch brush or other means; rust and scale do not favor the ready flowing of the fused spelter, though it will sometimes take hold of even such unfavorable surfaces. Cast iron may be cleaned by first heating to a bright red, and, after cooling, brushing the fracture and adjacent parts with a scratch brush. After thoroughly cleaning the work and securing good bright surfaces, the parts must be fastened together in the exact position they are to occupy when the job is completed. Usually the pieces are secured by pinning, but sometimes screws, bolts, wire, clamps of various sorts, and even fire-clay can be used to hold the parts in place. Whenever practicable, the parts should be secured in such a manner that the job can be turned over during the process of brazing, without disturbing the relation of the parts to each other, thus affording a better chance to apply the flux and spelter.

Alcohol used in a common gasoline torch has been said to give a greater heat than gasoline, the reason given being that it requires less air, and consequently the flame is cooled less by it. As alcohol contains fewer heat units than gasoline, it would seem a less suitable fuel to use for this purpose, but perhaps the need of less air may explain the difference claimed for it.

A simple and good formula for cast iron brazing is as follows:

	Ounces.
Boric acid	16
Chlorate of potash, pulverized	4
Carbonate of iron	3

Mix and keep dry, as moisture or long exposure to air renders it less efficient. When used, mix with grain spelter. Heat the work to a nice brazing heat and apply flux and spelter with an iron rod, flattened and spoon shaped at the end.

Borax is much used for flux in brazing wrought iron and steel; it is not expensive, and one can be sure of getting a good article by buying of a reputable dealer. In any brazing, the work is first brought to a bright red heat, flux is applied, and then mixed flux and spelter. Sometimes considerable "coaxing" is required in order to make the melted metal flow into the joints; but with the flux applied first and allowed to find its way into the cracks and openings, the spelter will follow if carefully led and rubbed with the hot iron rod. After one side of the work has been brazed, it is turned over and the other side is treated in the same manner.

In preparing work for brazing, too close a fit may be made, for the melted brass will not find its way into the most minute recesses. One one-thousandth of an inch is about as small a space as spelter will readily flow into.

After brazing cast iron, it is a good plan to let it cool slowly, sudden chilling being regarded as injurious in some cases. Whatever process is employed it is a good rule to have the work bright and clean, and to use plenty of heat; these, together with good flux and spelter, constitute the essentials. Experience is always valuable, but that comes only with practice.

TESTING STEEL TAPES AT THE NATIONAL BUREAU OF STANDARDS.

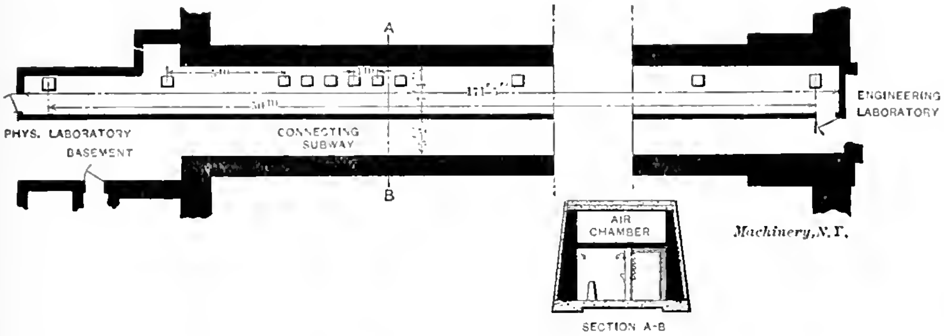
Herbert T. Wade in the *Engineering News*, August 13, 1908.

One of the most important functions of the National Bureau of Standards at Washington, D. C., is the testing and standardization of steel tapes of various lengths and forms, used in engineering work. These tests range from the minute and critical examination and study of the steel and invar tapes of the U. S. Coast and Geodetic Survey, employed in the accurate measurement of base-lines, to the inspection of the ordinary steel tapes of the surveyor and engineer. All of these tests are carried on in a specially designed laboratory, which is, without doubt, the best equipped for this kind of work of any testing bureau or physical laboratory in the world. In fact, it can be only compared with a somewhat similar room of less than half the length at the International Bureau of Weights and Measures at Sevrès, near Paris. Both of these laboratories are located underground, in order to secure a constancy of temperature, but the Washington testing room not only is better designed and equipped, but already its constants are known with a high degree of precision. The room is about 8 feet below the surface of the ground, 171 feet in length, and is about 8.2 feet in width and height. It is lined with white enamel brick, lighted by electricity, and contains steam and brine coils in addition to ventilation inlets and outlets, so that by the aid of thermostats the temperature can be controlled within narrow limits.

On one side against the wall is the United States Bench Standard of length, which consists of a steel bar mounted on rollers and supported horizontally on brackets. Opposite this standard is the comparator proper, used for the determination and standardization of steel and invar tapes for base-line measurement, and also for standardization of base bars of 5 meters in length from the national prototype meter standard. The floor of the room is of concrete, on which is laid a track for the carriage containing the ice trough in which the bar, used as a standard, is carried when measurements and comparisons are being made. There are eleven stone piers spaced 16.4 feet apart, and on these are mounted the micrometer-microscopes. Each pier is 14 × 14 inches in cross section and is set on a concrete base 16 inches square and 18 inches deep, the bases of the piers being separated from the floor by a space of 2 inches. This makes the piers and their foundations entirely independent of the floors or the structural walls of the building. At the north end of the tunnel the base of the terminal pier was built through a small vault to solid ground beneath, and is about 8 feet in height and 6 feet square. The piers at the ends carry not only the micrometers but also the marking bolts identifying the beginning and end of the standard distance. The tunnel thus arranged affords a comparator 50 meters (164 feet) in length, which is sufficient for the long tapes used in geodetic surveying. It might be said, in passing, that the development of the accurate use of tapes in the measurement of base-lines has been a striking feature of the work of the U. S. Coast and Geodetic Survey in recent years, and such precision has been attained in the use

of these tapes for measurements of base lines that they seem destined to supplant the more cumbersome base-bars.

Within a few years, invar tapes, made from an alloy of steel and nickel, discovered by M. Ch. Ed. Guillaume, of the International Bureau of Weights and Measures, have been thoroughly tested in the field after standardization in the laboratory, and the accuracy and convenience of their use has been clearly demonstrated. In using the comparator, the first step is to standardize a 5-meter steel or other bar in terms of the U. S. National Prototype Standard, which is a meter bar of platinum-iridium made at the International Bureau of Weights and Measures at Sevrès, and like the other similar national standards of length of the nations of the world, known most accurately in terms of the International Prototype Meter preserved at the Bureau. To transfer the meter to the five-meter bar, there are in the third interval of five meters between the piers, measuring from the south end of the tunnel, four similar and intermediate piers spaced a meter apart. These piers are of similar size and construction to the others, and on them the micrometer-microscopes can be placed so that the meter bar passed successively over the intervening five meter distances will give a standard distance of five meters with which the five-meter standard may be compared. The micrometer-microscopes are placed on iron brackets or arms which are attached firmly but in an adjustable manner to the tops of the stone piers, each of the latter having a hole cut through its top below the microscope arm so that light from an incandescent lamp hung back of the pier can be used for the illumination of the microscope and bar.



Horizontal and Vertical Sections of the Tape Testing Chamber.

The micrometer-microscopes used in the standardization work of the Bureau, have been tested for many years by the Division of Weights and Measures of the Bureau of Standards and, previous to its establishment, by the Office of Standard Weights and Measures of the Coast Survey, so that the constants and operation of these instruments are known thoroughly, though the usual adjustment is for one division on the head of the micrometer to correspond to one micron on the bar. The standard meter is placed in shaved ice in a trough mounted on two trucks. This trough can be raised or lowered by simple and exact adjustments, and, in fact, the bar in the trough may be adjusted under the microscopes to a micron, or one-thousandth of a millimeter. The standard meter is placed under one of the microscopes at the beginning or end of the five-meter interval, and the cross hairs are set with great precision on the fiducial line marking the limit of the standard distance. Then the second microscope and its cross hairs are set on the line at the opposite end of the bar with similar accuracy. The bar on the supporting carriage is then moved along between the second and third piers and similar adjustments are made. In this way the standard length of five meters is established, and the value of the five-meter bar which then can take the place of the standard meter in the ice trough, is obtained. The value of the meter at the temperature of melting ice, 0 degree Centigrade, is accurately known, and this temperature figures as a standard in all metric determinations. With a five-meter standard accurately determined, it is possible to measure successively the ten intervals of the 50-meter base of the tunnel, the process being precisely similar to that followed in getting the value of the five-meter bar.

Not only must the temperature of the bars in the ice trough be known and regulated, but the temperature of the tunnel itself and of the tapes under test. For this purpose there are carried on the walls of the room 14 lines of pipe, the upper twelve of which are used for circulating brine cooled to a temperature of —10 degrees Centigrade and enabling the temperature of the room to be reduced to 0 degree Centigrade with facility. The two lower lines of pipe contain steam when desired, so that not only can the coefficients of expansion of the tapes be measured, but the temperatures of ordinary field work duplicated. This, of course, does not obviate the necessity of taking exact thermometer readings at each observation and determination, and these are made as usual with carefully calibrated thermometers.

The microscopes at the ends of the 50-meter comparator, to which reference has been made, are referred to the bronze bolts in the pier foundation to insure their greater stability. Having the distance between the two terminal microscopes accurately determined with the ice bar apparatus, it is only necessary to substitute the steel or invar tapes and to apply the standard tension with spring balances which previously have been calibrated with correct weights in another laboratory of the Bureau. The tapes can be supported at such intervals as would be employed in field work, and, by the temperature regulating apparatus already described, the temperature of the vault can be varied and the coefficients of expansion can be determined with great precision.

In making the standard tests, measurements are made with the ice bar apparatus in the morning and then again at night, and the mean of the two measurements is the standard distance for the day. The tapes ordinarily are measured after they have remained all night in the laboratory comparator room and have assumed its temperature. In recent tests of invar tapes the coefficient of expansion of tapes of 50 meters in length was determined with precision to a micron, and was found to range from 0.000000374 to 0.00000044 for 1 degree Centigrade. Thus invar has a coefficient of expansion of about 1/28 that of steel, so that working under ordinary conditions where the refinements of the most precise geodetic work are not necessary, a temperature correction can be neglected. The determination of the expansion of the invar and steel tapes involved a study of the constants of the comparator room itself, and it was found that the entire tunnel shrinks about six-hundredths of an inch in passing from a temperature of 100 degrees F. to 32 degrees F.

The work in the laboratory is so arranged that there can be measurements made each day, and there is a direct comparison of the tapes with the five-meter bar on each occasion. This bar, which has been used for many years, so that its constants are known with high precision, is of steel, with the terminals of the standard distance indicated by lines on platinum-iridium plugs. In testing invar tapes the tension used is 10 kilogrammes, while ordinary steel tapes of 100 feet are stretched at a tension of 10 pounds. The chief practical advantage of the invar tape is that its small coefficient of expansion not only simplifies measurements generally, but in particular, permits of accurate measurements being made in the daytime instead of at night, as is essential in using steel tapes in base-line measurement.

On the wall opposite the comparator is the 50-meter U. S. Bench Standard for testing ordinary steel tapes. This has been formed of five cold-rolled steel bars, about 33 feet in length, welded end to end with thermite. As previous to the welding the bars were well fitted and cleaned, the result is a continuous bar 165 feet in length. Not only are the terminal distances marked by platinum-iridium plugs with fine transverse lines, but at various regular intervals similar plugs are inserted, so that the intermediate distances on a tape can be verified with accuracy. These plugs are inserted every 10 feet for the tapes with the customary divisions, and every 5 meters for the metric tapes, the distances being correct at 62 degrees F. for the customary measures, and at 0 degree Centigrade for the metric scale. Ordinarily, the tapes are laid flat on the steel bar, but if desired they can be suspended

on small pins on the outside of the bar and the conditions of support arranged to simulate those in the field. The bar itself is free to move on rollers carried on brackets fastened to the masonry wall and spaced at intervals of 40 inches, so that not only is it kept hornzontal, but it is free to expand and contract with changes in temperature.

The Bureau of Standards not only tests metal tapes for the various government departments, but also for manufacturers and engineers upon payment of nominal fees, depending on the length of the tapes and the number of divisions examined. The charges range from 75 cents for tapes not longer than 100 feet, and supported throughout the entire length, to $2.25 for tapes 400 feet in length with comparisons at the 100, 200, and 300-foot divisions. If the tape is supported at intervals, the Bureau doubles the charge, while determining the coefficient of expansion, testing under different tensions, determining the modulus of elasticity, or other tests are made for suitable and reasonable fees.

The tests can be made as elaborate as desired, but in most cases it is sufficient to compare the tapes with the U. S. Bench Standard for the total distance and some of the more important subdivisions, as the coefficient of expansion of the majority of steel tapes is practically that of the standard steel bar—0.0000063 per degree Fahrenheit or 0.0000114 Centigrade—so that a direct comparison with the latter suffices and will afford an adequate determination of its accuracy for most purposes. If the tape in construction and tests complies with the requirements of the Bureau, it will be certified, and the Bureau of Standards test number corresponding to the number of the certificate issued will be stamped or etched on the tape.

Since the Bureau has undertaken the testing of tapes there has been an increase in the accuracy of those available for engineers, and there is no reason to-day for any one to have any uncertainty about the accuracy of his measures with the Bureau of Standards ready to make final and conclusive tests on payment of a small fee. In the year ending June 30, 1907, 135 tapes were submitted for test by engineers and surveyors in all parts of the country.

THE DIRECT PRODUCTION OF COPPER TUBES, SHEETS, AND WIRE.

Paper by Mr. Sherard O. Cowper-Coles read before the British Institution of Mechanical Engineers, July, 1908.

The numerous processes involved in the production of suitable copper and its subsequent conversion into copper sheets, tubes, and wire by a series of operations, such as rolling, drawing, and annealing, would occupy too much time to be referred to even briefly; therefore the author has limited the paper to the direct production of copper tubes, sheets, and wire by electrolysis from impure copper. The methods described are all based on the work of Davy and the law of electrolysis established by Faraday in 1833, namely, that when a current of electricity is passed through a solution containing metallic salts and two or more electrodes, one of which is soluble in the solution, a known quantity of metal is transferred from one electrode to the other for a given quantity of electric current; that is to say, if the soluble electrode (the anode) is connected to the positive pole, and assuming the metal and the electrolyte employed to be pure, a weight of metal will be deposited upon the cathode connected to the negative pole, corresponding to the amount dissolved from the anode. If the anode is of impure metal many difficulties are introduced, and if the current is increased, to a sufficient density to enable the metal to be deposited at such a rate as will give commercial results, other serious difficulties arise. Electro-metallurgists have been working for thirty years or more devising methods to overcome the difficulties experienced in applying Faraday's law to the commercial production of copper tubes, sheet, and wire from comparatively impure copper having the physical properties of wrought copper, when deposited at a sufficiently rapid rate.

The refining of copper by electrolysis has now assumed vast proportions, and the annual output of electrolytic copper in the year 1907 has been estimated at 400,000 tons, equal to 56 per cent of the world's production, and the capital sunk in the industry at about £15,000,000. The whole of the copper thus produced is in the form of rough slabs or cathode plates which have to be smelted and worked to the desired forms. Electro-metallurgists have been striving for many years to devise a process which does away with the smelting of copper after it has been electrolytically refined, and to electro-deposit copper after the refining operation in such a form that it can be placed direct on the market as finished sheets, tubes, and wire.

The author, when carrying out some experiments on the production of copper tubes and sheets by electro-deposition on rotating cathodes, observed that when the speed was greatly increased, entirely new results were obtained, and that a current density of 200 amperes or more per square foot could be employed, the copper remaining smooth and having a tensile strength equal to the best rolled or drawn copper, and in some cases a tensile strength some 50 per cent higher than that obtained by the ordinary process of casting and rolling, the tensile strength increasing with the rate of rotation of the mandrel. The result of revolving a mandrel at a comparatively high speed is that every molecule, as it is deposited, is burnished or rubbed down so as to produce a tough fibrous copper, the usual order of things being reversed, the present practice being to put the mechanical work into a mass of copper by rolling or drawing instead of treating each molecule separately. This observation led to further experiments, which resulted in evolving the process now known as the centrifugal copper process for the manufacture of sheets, tubes, and wire, which will now be described in detail, together with the results obtained.

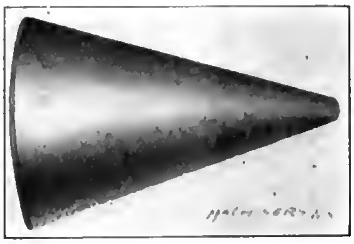


Fig. 1. Copper Cathode in the Form of a Cone to determine Critical Speed.

After a long series of experiments had been made to determine the best composition for the electrolyte and the most economical current density to employ, the critical speed was accurately determined by means of revolving cathodes in the form of cones, Fig. 1. By observing the point at which the copper remains smooth, and by measuring the circumference of the cone at that point and multiplying it by the number of rotations per minute, the critical speed is readily determined; 200 amperes per square foot is found to be the most economical current density, although a current density up to 500 amperes per square foot can be employed by increasing the rate of rotation, but the increased cost due to increased voltage renders such a current impracticable for ordinary commercial work.

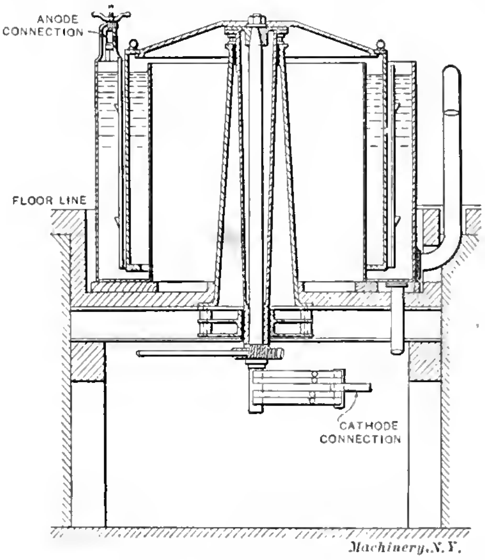

Fig. 2. Vat used for producing Copper Sheets by the Centrifugal Process.

One of the chief difficulties inherent in any electrolytic or wet process for the production of copper tubes and sheets, is having any working parts, such as bearings, in an acid copper sulphate solution, and this was one of the first troubles en-

countered when working the centrifugal process on a commercial scale. This difficulty was eventually overcome by constructing vats in the form of an annular ring, as shown in Fig. 2. It will be observed that by such an arrangement all working parts are outside the vat and do not come into contact with the electrolyte, so that the bearings can be lubricated in the ordinary way; only the actual face of the mandrel on which the copper is to be deposited is immersed in the electrolyte. The cathode consists of a steel or cast-iron cylinder closed at one end, to which is attached on the inside a steel rod projecting below the edge of the mandrel to guide it into position; the cylinder can be 5 or 6 feet in diameter or even larger, so as to produce a copper sheet of say 20 feet long by 4 or 5 feet broad. Anodes, composed of crude copper, are placed around the mandrel with intervening spaces, and are fed forward by suitable mechanical means, as the copper dissolves away, so as to keep the voltage constant.

One great advantage of the centrifugal process is that a very low voltage is required even when employing a very high current density; for instance, only 0.8 of a volt is required at the terminals of the vat when working at a current density of 200 amperes per square foot of cathode surface. The effect of revolving the cathode is five-fold; it keeps the electrolyte agitated, so that there is always a fresh supply of copper ions in proximity to the cathode; each molecule of copper as it is deposited on the cathode is burnished or rubbed down by means of the skin friction between the revolving cathode and the electrolyte; the rotation prevents any foreign matter that may be in suspension in the electrolyte settling on the cathode and becoming entangled by further copper being deposited around or over it; it brushes away any air-bubbles on the cathode, which are the cause of nodules forming; and the rotation of the cathode ensures the thickness of copper being uniform, even when a mandrel of say 8 feet in length is employed.

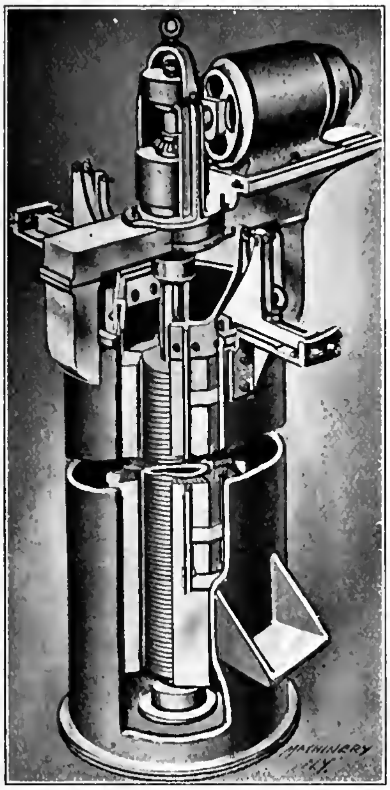

Fig. 3. Vat used when making Tubes by the Centrifugal Process.

The method of making tubes by the centrifugal process is as follows: A mandrel somewhat smaller than the finished internal diameter of the tube is prepared by coating it with an adhesive coating of copper by first depositing copper upon the surface from an alkaline solution and then thickening it up in an acid solution, the surface being highly burnished and treated chemically to ensure the easy removal of the deposited tube. The mandrel thus prepared is then placed in a vat as shown in Fig. 3. When the desired thickness has been obtained, the mandrel is removed and placed in a horizontal or vertical lathe, and a round-faced roller run over the surface so as slightly to expand the deposited copper, which can then be readily drawn off.

Copper sheets are prepared in a similar manner, the only difference being that the mandrels are of much larger diameter, and a narrow insulating strip is fitted down one side so that the sheet can be easily removed by inserting a tool under one of the edges of the deposited copper. It is no more costly by the centrifugal process to make thin sheets than thick ones; copper foil can be made in five minutes, direct from crude copper. Copper tubes produced by this process without any drawing, have given a maximum stress of 17 tons, and tubes after drawing have withstood a pressure of 3,000 pounds per square inch without showing any signs of distress. Sheets made without any rolling have given a maximum stress of 28 to 30 tons per square inch, according to the peripheral speed at which the mandrels were revolved.

The production of copper wire by electrolytic means is a more difficult problem than the production of copper tubes and sheets. Various processes have been suggested and tried from time to time, such as the electro-deposition of copper on thin wire, until it has obtained a considerable thickness, and then drawing the thickened wire down to a comparatively fine wire. Experiments have been made with such processes, but so far they have not been worked commercially.

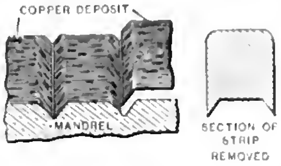

Fig. 4. Diagram showing Method of forming Weak Line of Cleavage due to Crystalline Structure

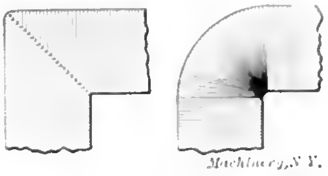

Fig 5 Diagram showing the Effect of Sharp and Rounded Corners on the Crystalline Structure of Metal deposited on Mandrel

Copper wire is made by the centrifugal process in the following manner: A mandrel similar to that used for making copper sheets is employed, around which a spiral scratch is made, the pitch being determined by the size of wire required. The effect of the spiral scratch (which need only be very light, but must be angular), is to cause the crystalline structure of the copper to form a cleavage plane, as shown in Fig. 4. It will be observed that the copper divides exactly at the apex of the scratch, that is, the copper deposited in the scratch is equally divided and forms a small V-shaped fin on two sides of the copper strip. If the scratch is not angular, but rounded at the base, the copper will not divide, as the crystals are radial, as shown in Fig. 5. After the desired thickness has been obtained, approximating the pitch of the spiral scratch, the mandrel is removed from the depositing cell and placed in a vertical position on a special lathe, and the copper strip is unwound, as illustrated in Fig. 6, at an angle of about 45 degrees to the face of the mandrel. During the process of unwinding, the small fin or burr is removed by passing the wire through a suitable die and then through a wire-drawing machine provided with three or more draw-plates to reduce the strip to the desired diameter. By employing a mandrel of 6 or 7 feet in diameter, lengths of wire 4 or 5 miles long can be made in one operation. Reference was previously made to this method of making copper wire in the November, 1905, issue of MACHINERY.

The advantages of an electrolytic process as compared to a smelting process are many, and the day is not far distant when copper will no doubt be leached direct from the ore and electrolyzed with insoluble anodes, to produce finished copper sheets and tubes in one operation direct from the ore without the intermediate process of smelting and refining. The centrifugal process is a step in this direction, as it is capable of depositing copper from its solutions by using insoluble anodes in the form of finished tubes or sheets in one operation. The centrifugal process is at least ten times faster than any existing electrolytic process, and a high current density can be employed without deteriorating the quality of the copper. The plant is simple and free from mechanical complications, and the amount of copper locked up for a given output is small compared to other processes. The process is of interest to mechanical engineers, as it conclusively proves that to get a high tensile strength in metals combined with ductility, it is not essential to put a large amount of work into the metals as hitherto has been considered necessary, by the processes of swaging, rolling or drawing, but that a very small amount of energy will suffice when applied in the manner described.

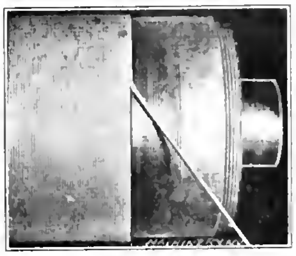

Fig. 6. Unwinding the Copper Strip from the Mandrel.

CUTTING AND KEYSEATING CHANGE GEARS ECONOMICALLY.

RAQUET

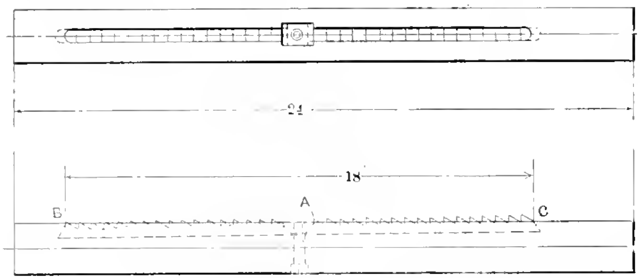
This article is a kind of appendix to the one on machining change gears which appeared in the April issue. Through information obtained later, I was rather surprised to learn that the method of broaching keyseats therein described was comparatively unknown in America. So I thought a bit more information might be acceptable.

Of course the "pull" broaching machine as made by the Lapointe Machine Tool Co. in America and Smith & Coventry in England, are well known examples of broaching machines, but I do not fancy either of them (from a casual knowledge of the machines) for keyseating change gears, because every time a gear or stack of gears has been operated on, the machine must be stopped to place another in position.

With the "push" method the machine runs continuously, it being comparatively easy to keyseat a gear at every stroke, the machine running at from 120 to 140 strokes (forward and return) per hour.

Another objection to the "pull" type when applied to this work is the difficulty of making the long slim cutters which must of necessity be made in one piece, whereas with the cutter bar, illustrated herewith, the cutters may be made in two or more parts. My previous article stated that the cutters were fixed to the bar by screws from the under side, but since that was written we have found a better way.

The objection to the first method is that the cutters must be exceptionally wide to admit of using reasonable size of screws. We have had a lot of trouble with the cutters breaking at the tapped holes, so after some study I evolved the one shown in sketch.



Bar with Inserted Cutters for Keyseating Change Gears.

It will be seen that there are no holes in the cutters, so that they, therefore, may be made the same width as the keyseat to be cut. The beveled ends and the clamping arrangement at the center ensure a solid job and also make it possible to insert new cutters with very little trouble. Of course, it will be understood that the taper of the cutting edges from *B* to *C* is not a straight line from end to end. The presence of the clamping plate at the center necessarily does away with two or three of the cutting edges so that if *BAC* were all in the same straight line the tooth *A* would have two or three times too much stock to remove.

The largest bar we have at present is 1½ inch diameter for keyseats 3/8 inch wide, 3/16 inch deep, and 18 inches of cutting edges seems to be about right. Of course, the overall length of the bar is unimportant, but I should not reduce the length of the cutting edges for 1 inch bars for keyways 1/4 inch by 1/8 inch and over.

While in my previous article I showed how we did the work on a planer, it would be far more convenient, where there is much small keyseating, to make a special machine. This machine would always be ready and it would then pay to keyseat even odd gears in this manner. A machine for this work is very simple and could be made very cheaply. All that is required is a gap lathe bed, a central screw driven by two belts (open and crossed), a reciprocating carriage driven by the screw, and a suitable bracket for the work to press against.

The cutter bars could be kept in close proximity to the machine; then if even a single gear required to be keyseated it would only be necessary to insert the correct size of bush, start the machine, mount the gear on the cutter bar, insert bar in end bracket, and the job is finished in less time than it takes to tell about it.

I think it would pay almost anyone to make a special machine in preference to rigging up a planer; but at the same time it must not be supposed that the machine would be kept constantly at work. It would take rather a big shop and a large number of gears to keep one of these machines in full employment, but an hour or two's run a day will be quite sufficient to pay a good percentage on the investment.

It should also be mentioned that the keyseats are kept up to size (depth) by putting tissue paper under the cutters.

Another point I should like to particularly emphasize is the importance of the method of indexing, christened block indexing for want of a better name, [Also known as multiple indexing—EDITOR] which was referred to in my previous article. I am firmly convinced that where the ordinary consecutive indexing method is in use on gears, say up to 6 diametral pitch, it is possible, by introducing block indexing, to increase the speed and feed so that the output is raised by fifty per cent. Not only this, but with the latter method and the increased speed and feed, the cutter and finished gear will be actually cooler than it would have been under the former conditions after doing an equal amount of work. The Brown & Sharpe Mfg. Co., in the book of instructions sent out with their gear-cutting machines, does not in my opinion attach sufficient importance to this method of indexing; they dismiss the question as follows: "The advantage claimed for omitting one or more teeth before cutting is the more even distribution of heat throughout the blank. On the other hand, however, good results can be obtained by arranging the speed and feed slow enough to avoid heating."

This was written a few years ago, before high-speed steel wakened up machine tool-makers. It was, no doubt, permissible then to "run slow enough to avoid heating," but now modern conditions demand that we should run as near the top speed and feed as we can get, finding ways and means of dissipating the heat generated.

Those mechanics who have never tried this method will be surprised to learn how the heat is dissipated by simply skipping a few teeth. At our works we would never think now of cutting change gears by the ordinary consecutive indexing method. The table (see Data Sheet Supplement) is exactly like the one we use with our B. & S. machine, but it is quite a simple matter to calculate one for any other make of machine. Suppose, for example, that the change gear table supplied with any particular machine gave the following change gears to index a certain number of teeth $\frac{20}{60}$ and $\frac{30}{50}$ (20 and 30 being drivers in both cases): then if we wish to cut say every fifth tooth (this depends on the number of teeth in the gear, it must not be a multiple) multiply the fraction $\frac{20}{60} \times \frac{30}{50}$ by 5. Then we have $\frac{20}{60} \times \frac{30}{50} \times \frac{5}{1} = \frac{1}{1}$ In this particular case equal gears would divide the blank so that every fifth space was cut.

I notice in the series of articles "Gear-Cutting Machinery," which have recently appeared in these columns, that one machine (February, 1908, engineering edition), by J. Parkinson & Son, Shipley, England, is specially arranged for block or multiple indexing, but as shown above, nearly any machine can be set up with very little trouble, though, no doubt, there would be some difficulty with the smaller pinions; but block indexing does not make as much difference when the gears to be cut have only a small number of teeth, so that it is not really a very serious difficulty after all.

* * *

The largest apartment building in the world will be built in New York City, on Broadway and Amsterdam Avenue, between 86th and 87th Streets. It will cover the entire block and will be 350 feet long, 200 feet wide and 150 feet high. It will be twelve stories in height, and will have 175 apartments, containing from nine to fourteen rooms each. The building will be constructed in the form of a hollow rectangle, the courtyard in the center being 250 x 100 feet wide. The structure will cost $3,000,000.

THE STRENGTH OF HELICAL GEARING.*

It has long been possible to produce a double helical form of cut gearing by bolting together a pair of spiral wheels of opposite hand, but this method of construction is far from satisfactory on account of the extreme difficulty of bringing, at anything like a reasonable cost, the two sides into accurate register. About five years ago Herr Wüst, of Zurich, conceived the idea of generating both sets of spiral teeth in a single-wheel blank by using two hobs of opposite hand to cut the teeth simultaneously. The difficulty was to find means whereby the teeth on each side could be cut through to the center. This difficulty was, however, solved when the teeth were staggered, so that the centers of the teeth on one side of the wheel coincided with the centers of the spaces between the teeth on the other side. Wheels and pinions of this form are now manufactured by the Power Plant Company, Limited, West Drayton, Middlesex. The result of the method adopted by this firm will be better understood on reference to Fig. 1, which is a reproduction of an actual pinion of seven teeth which was cut in this way. Not only have wheels so made proved quite satisfactory, but they have been found to possess the advantages incidental to the old stepped type of gearing, *viz.*, greater freedom from backlash and shock; and machine-cut double helical gears of this type are far stronger than straight-cut gears of equal pitch and width. The capacity of a gear-tooth to transmit power depends on the metal section available at the base to resist the maximum bending stress. In the case of ordinary straight-spur gears, the teeth are subjected to greatly varying bending stresses while in engagement, and the maximum stress on a driven tooth occurs when a driving tooth first engages it at the extreme tip. The bending stress is then proportional to the product of the driving force into the height of the tooth.

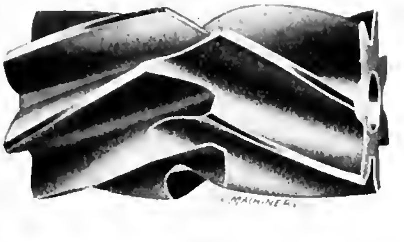


Fig. 1. A 7-tooth Herringbone Gear formed by the Wüst Process.

With double helical wheels the conditions are much less severe. What is meant will be understood on reference to Fig. 2 below, which shows in development a portion of the rim of a wheel of 50 teeth, having staggered double helical teeth cut at 23 degrees, and a width equal to five times the circular pitch. The three teeth, A, B, and C, are all in engagement at the same time, and the normal elevations of these teeth are shown. The wheel of 50 teeth is considered to be driven by a pinion of 25 teeth, and the representation is made at the moment when the center of tooth B is engaged at the pitch line. In order to make a comparison with straight spurs it is necessary to average the contact across the three teeth A, B, and C. This is shown by the horizontal lines in Fig. 3, which are obtained by averaging the ordinates of the contact lines in the upper view of Fig. 2. On comparison of Figs. 2 and 3, it will be noticed that the average contact for A is at its lowest and C at its highest, while the average for B is about the pitch-line. As the wheels roll on, these average contact lines change in position, but on any one tooth they never rise above the level shown for A in Fig. 3, nor fall below that for C in the same figure. Thus for every tooth there is a zone within which the limits of average contact must lie, as illustrated by Fig. 4. Here the shaded portion Y shows the variation of average contact for the case under consideration, while X is the working height of the tooth. For teeth cut at 23 degrees to the axis, on a wheel whose width is five times the circular pitch, Y equals about $0.44X$ for a wheel of 50 teeth driven by a pinion of 25 teeth.

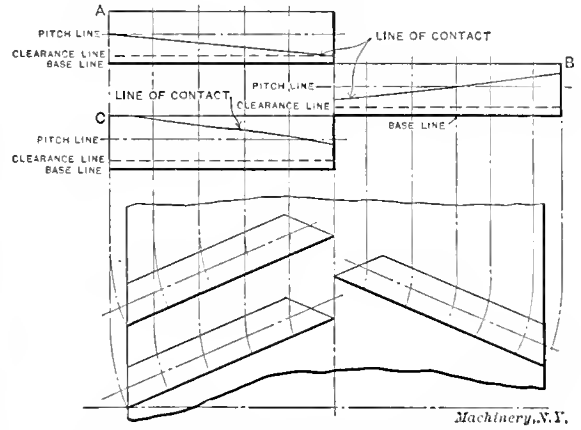

Fig. 2. The Instantaneous Lines of Contact made by Three Contiguous Teeth with their Mating Teeth.

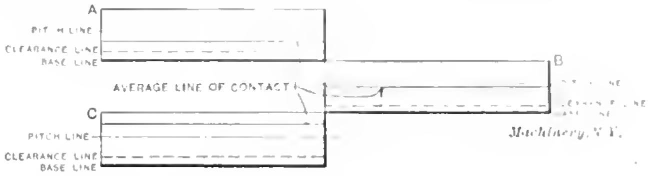

Fig. 3. The Average Lines of Contact on the Three Teeth.

Fig. 5 shows the corresponding variation of contact, and of bending stress, in a straight-cut spur-wheel under similar conditions. It will therefore be seen that the reduced variation of stress allows the employment of much finer pitches, for equal powers and speeds, than are permissible for straight-cut gears.

The particular case considered is merely given for illustration, but the same method of comparison holds good for any combination. In general, the variation of bending stress on double helical staggered teeth is less than in the case considered, because the comparatively fine pitch employed usually leads to wheels of many teeth, the number being rarely less than 100, and rising sometimes to 500. Another advantage claimed for these helical teeth is that their gradual engagement tends to eliminate shocks, and this effect is increased by the stepped form of teeth adopted. The smoothness of running, which is the direct outcome of these special features, consequently makes it possible to produce noiseless gears without having recourse to intrinsically weak pinion materials, such as raw hide, or fiber.

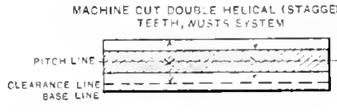

Fig. 4. Shaded Area shows Range of Average Line of Contact on Herringbone Tooth.

Fig. 5. Shaded Area shows Range of Line of Contact on Spur Gear Tooth.

[The form of gearing here shown is that produced by the Wüst machine, described in the April, 1908, installment of the series of articles on gear-cutting machinery which we have just finished. The great advantage of this form of herringbone gearing would seem to be the possibility of producing it at a reasonable cost. We do not understand the difficulty mentioned in the above article of bringing the two sides of a split gear of this style into accurate register. If the two sides are not in accurate register, the pinion will float sideways on the gear slightly until it is in engagement equally on each side. The shaft should be left free for end-wise movement for this purpose, and no collars are necessary. We are not, furthermore, inclined to believe that the staggered form of tooth is of any advantage whatsoever, except as it facilitates manufacture. The herringbone gear itself has the effect of a stepped gear of an infinite number of steps, so it is perfect in this respect, and staggering the teeth cannot make it any more perfect.

The main subject matter of this article, however, relating to the strength of helical gearing, is new so far as we know. It is evidently a fact that helical gearing is stronger than spur gearing of the corresponding size, owing to the fact that at no time is the whole breadth of any one tooth subjected to the maximum pressure, that pressure occurring only at one point. —EDITOR.]

OXY-ACETYLENE PROCESS OF METAL CUTTING AND AUTOGENOUS WELDING.*

Within the past seven years a valuable tool, unique in its characteristics, has been developed for cutting, shaping, and welding metals, in the oxy-acetylene "torch," which now is so well advanced that it bids fair to displace other emergency cutting and welding means to a large extent. The oxy-acetylene process had its inception in France, the first experimenter being Mr. Edmund Fouche, of Paris, who began his work on it in 1901. The principle of the oxy-acetylene torch or burner is essentially the same as that of the oxy-hydrogen blow-pipe, which has been used for many years for generating intense heat. But though the oxy-hydrogen flame is intensely hot, the flame produced by the oxy-acetylene torch is so much hotter that the two are not in the same class. The temperature produced by the oxy-hydrogen flame is rated by authorities at about 4,000 degrees F., while that of the oxy-acetylene flame is estimated at about 6,300 degrees F. Not only is the flame of acetylene much hotter than hydrogen, but the number of B. T. U. per cubic foot is about five times as great, being as 330 to 1,600. Hence both the intensity and amount of heat is greatly increased in the flame of the oxy-acetylene torch. A comparison between the two instruments has been aptly put as like that of "a finely pointed-tool and a blunt instrument."

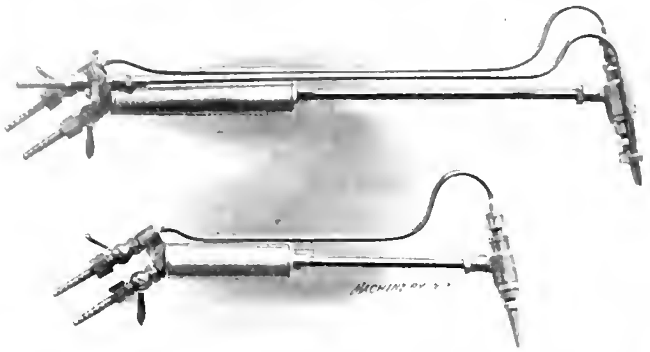

Fig. 1. Davis-Bournonville Oxy-acetylene Cutting and Welding Torches.

While the temperature of the flame of the oxy-hydrogen torch is high enough to melt and even vaporize most commercial metals, when the heat is confined, it is not high enough to fuse the edges of metals and make autogenous welding commercially profitable. At least this appears to be the case in the present development of the art. The rapid radiation and conduction of heat away from the joint prevents perfect fusion and joining, but with the vastly hotter oxy-acetylene flame, autogenous welding becomes easy and rapid. Even aluminum, which conducts heat away with great rapidity and can be locally fused with difficulty, yields to the oxy-acetylene flame and joins perfectly, the joint being entirely homogeneous. In fact, the autogenous weld thus produced is the only known method of joining aluminum that will not separate with use.

Fig 2. Samples of Steel and Cast Iron Welding, and Cutting done with Oxy-acetylene Flame.

The commercial development of metal-cutting and autogenous welding has been taken up by several concerns in the United States and Europe. The processes are essentially the same, the difference being in the construction of the torches and the manner in which the gases are generated. Great difficulties have been met in cheaply producing pure oxygen gas. The cheap production of acetylene had, to a great extent, been satisfactorily solved in the extensive development of acetylene lighting, but even this art had to be further developed to meet all the requirements of metal welding and cutting work. There are four or five commercial means of making oxygen, these being principally the oxone or barium process, the liquid air process, the epurite process, and the chlorate of potash process. The latter process is used by the Davis-Bournonville Co., New York, and the following notes relate to the development of the art of metal cutting and autogenous welding, as reached by this concern.

The chlorate of potash process of generating oxygen is well known, being perhaps the simplest method. It will be found described in elementary works on chemistry. The oxygen of chlorate of potash can be driven off by gentle heat, and, in practice, the potash is placed in a closed retort and subjected to a comparatively low temperature. The reduction is facilitated by the addition of black dioxide of manganese in the proportion of 14 pounds of manganese to 100 pounds potash. The oxygen gas is passed through scrubbers and is pumped into receivers. The pressure in the receivers is varied according to the use, it being desirable to compress from 125 to 150 pounds per square inch for metal cutting, while 15 pounds pressure suffices for autogenous welding. The acetylene gas is produced in the Davis generator which is adapted to all pressures up to 15 pounds per square inch. The machine is automatic and feeds lump carbide perfectly up to sizes that pass through 1-inch screen. The theoretical quantity of water to carbide is about ½ pound to 1 pound carbide, but to absorb the heat of the chemical transformation the generator is required to have a water capacity of 1 gallon water to 1 pound carbide. For repair shops and work outside of the shop, a portable apparatus is required, and for such purposes the oxygen and acetylene gases are stored in small cylinders. The storage of oxygen is a simple matter of pumping the gas into the cylinders until the required pressure has been reached. The storage of undiluted acetylene under pressure in tanks is impracticable, but fortunately, it was discovered in 1896 by Claude and Hesse, two French engineers, that acetone, a fluid derived from the dry distillation of wood, is a remarkable solvent for acetylene, being capable of absorbing 25 times its volume at 60 degrees F. for each atmosphere. At ten atmospheres, or 150 pounds pressure per square inch, a gallon of acetone absorbs 250 gallons of acetylene gas. When absorbed by acetone, acetylene is non-explosive under heavy pressure.

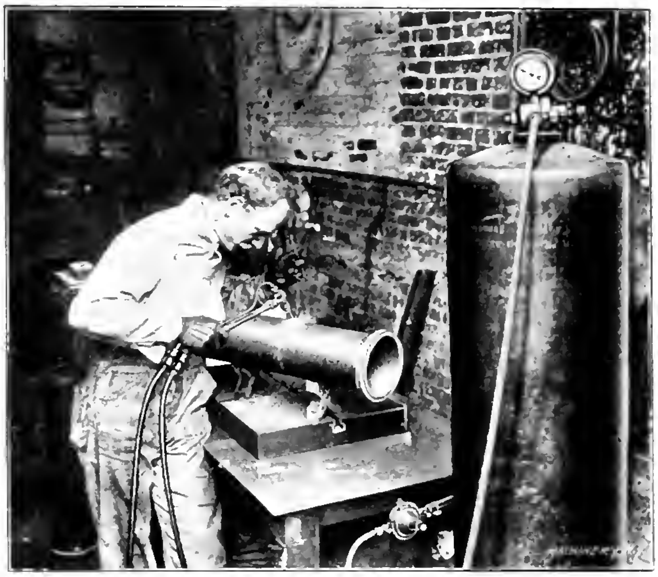

Fig. 3. Welding together the Parts of a Drawn Steel Retort. The Operator feeds the Joint with a Special Grade of Iron Wire.

---

*For other articles on autogenous welding, see "Blow-pipe Metal Welding with Acetylene," March, 1904; "Acetylene Gas for Welding," September, [illegible], and "Autogenous Welding," July, 1907. For articles on storage of acetylene gas in acetone, see "Acetone as an Absorber of Acetylene Gas Under Pressure," December, 1903, and "The Acetylene Safety Storage System," August, 1904. For article on oxygen cutting, see "The Use of Oxygen for Removing Blast Furnace Obstructions," July, [illegible].

A red-hot wire might be thrust into the receiver with absolutely no effect, provided there is no free space occupied by acetylene gas. To prevent the possibility of there being free spaces for the accumulation of gas, acetylene storage tanks were designed by Mr. Edmund Fouche, which are packed with porous brick, asbestos or other neutral porous material, thus filling the entire free spaces and affording storage for the acetone and acetylene gas only in the cells of the filling.

Fig. 1 shows the Davis-Bournonville Co.'s cutting and welding torches. The upper illustration is the cutting torch and differs from the welding torch shown in the lower illustration simply in that it has an auxiliary detachable oxygen tube secured to the side. The welding torch has an acetylene gas tube and an oxygen tube which combine in a tip or nozzle from which the united gases flow and burn. The upper tube in each illustration is for oxygen, while the lower tube is for acetylene, the two gases uniting at the end of the removable tip within the body of the torch. The enlarged portion of the torch in the acetylene pipe is packed with porous material to prevent flash-backs extending beyond the torch itself.

Samples of welding and cutting are shown in Fig. 2. The pieces at the left are parts of two steel strips which were welded edge to edge. The welded piece was cut in two and the lower specimen shown was bent over on the weld through an angle of about 120 degrees. The ground parts on the left end of each piece indicate a perfectly homogeneous union. The piece in the lower right-hand space is made up of cast iron and steel welded together. The cast iron is welded to itself as indicated in the illustration, and to the steel, the union in each case being perfect. However, because of the difference in expansion and contraction, there is danger of a crack appearing in cast iron welded to steel unless it is carefully cooled off. Right here it might be said that expansion and contraction are the greatest foes of autogenous welding, and to effect satisfactory work on some pieces, it is necessary to raise the temperature by pre-heating before welding is commenced. Then the difference in temperature of the welded and unwelded parts is not so great. Moreover, this practice has the advantage of saving gas that otherwise would be required to heat adjacent parts before fusion is reached.

Fig 4. Welding the Broken Flange of a Cast Iron Base. The Operator feeds the Joint with a Cast Iron Rod.

Fig. 5. Cutting Off Steel Sheet Piling with Oxygen Cutting Torch showing Portable Apparatus.

The upper right-hand piece shown in Fig. 2 is a sample of ½-inch steel plate cut out with the cutting torch. The piece illustrated is shown reduced to about one-half the actual size, and it gives an idea of the width of kerf, the kerf being about ⅛ inch wide. Cutting steel with a torch is much more spectacular and impressive than welding, the metal being cut away rapidly and passing off in scintillating sparks. The work is done with comparative rapidity. A No. 1 tip will cut up to ½-inch steel at the rate of 60 feet per hour, with a consumption of 12 cubic feet of acetylene and 15½ cubic feet of oxygen in the heating jet and 60 cubic feet of oxygen in the cutting jet. The cost of operation with labor at 30 cents per hour is estimated at $2.68, or about 4½ cents per lineal foot. The oxygen for the heating jet is carried at 11 to 18 pounds pressure, while the pressure of the oxygen cutting jet supply is much higher, being about 125 pounds pressure. Only one oxygen cylinder is required, however, the low pressure welding flame supply being taken from the high pressure supply and regulated by a reducing valve.

Fig. 3 illustrates the welding of thin steel retorts used for generating oxygen gas. The material for the retorts is brought in drawn shape, one part being made with a collar and the other having a rounded bottom. The length of the retort is too great to permit it being drawn in one piece, hence the necessity of welding the two parts together near the center. The following is an approximate cost of welding 1/16-inch metal. The consumption of acetylene is 2.8 cubic feet per hour; of oxygen 3.6 cubic feet at a pressure of 8 to 10 pounds. The rate of welding is about 50 feet per hour, and with labor at 30 cents per hour, the total cost per hour is 43.6 cents, or less than 9/10 per cent per lineal foot. The cost of welding increases with the thickness of material, of course, reaching an estimated cost of 37 1/2 cents per lineal foot for 7/16- to ½-inch thick metal.

In Fig. 4 is illustrated the welding of a broken flange on a casting. This job, which would have been difficult and expensive by brazing, was easily accomplished. In this illustration, as in Fig. 3, the operator is shown feeding material into the weld, the same as a tinner feeds solder when soldering. For welding steel and wrought iron a special iron wire is used, and for welding cast iron, rods of cast iron.

Fig. 5 illustrates the use of the cutting torch cutting off steel sheet piling. This work, as before stated, is done with rapidity, and is a very spectacular performance. In the case of cutting, the combustion of the steel materially raises the temperature and assists in the work. This was pointed out by Chevalier C. de Schwarz in a paper read before the May, 1906, meeting of the Iron and Steel Institute, and it gives one a startling idea of the power of the oxygen cutting flame when the concentration of the heat units produced is known. Burning 1 pound of acetylene with oxygen produces from 18,250 to 21,500 B.T.U. The mean value may be taken as about 19,750 B.T.U. per pound, and the number of cubic feet at atmospheric pressure at about 14½. Now, the burning of 1 pound of steel with oxygen produces approximately 2,970 B.T.U., but at atmospheric pressure 1 pound of acetylene gas fills 6,750 times the space of 1 pound of steel. Hence, the intensity of the heat with perfect combustion of the steel in oxygen will be, theoretically, $\frac{6,750 \times 2,970}{19,750} = 1,015$ times the intensity of heat of the oxy-acetylene flame. As a matter of fact, of course, this enormous temperature is not even remotely approached, because the metal dissolves at a far lower temperature and passes off in sparks, which are speedily cooled by the atmosphere.

F. E. R.

DEVICES FOR GRINDING FLUTING CUTTERS.

ERIK OBERG *

In the January issue of MACHINERY a contributor described a simple device for grinding angular cutters. The principle embodied in this device is used in almost all devices for grinding angular cutters, or formed cutters having regular milling cutter teeth. In the case of formed cutters with regular milling cutter teeth, it is, of course, necessary that the teeth be ground around the edges instead of the teeth being only ground on the faces as is the case with eccentrically relieved teeth. In Fig. 1 are shown two types of milling cutters which may be ground with devices working on the principles indicated and described below. The cutter *A* is a regular fluting cutter for taps, and the cutter *B* is a formed fluting cutter.

In Fig. 3 is shown the device used for grinding a tap fluting cutter. The angle included between the two faces on the fluting cutter is 85 degrees, and the angle between the two faces *C* and *D* in the device for grinding the teeth of these cutters is also 85 degrees, one side making 30 and the other 55 degrees with a line at right angles to the axis of stud *A* on which the cutter is mounted while grinding.

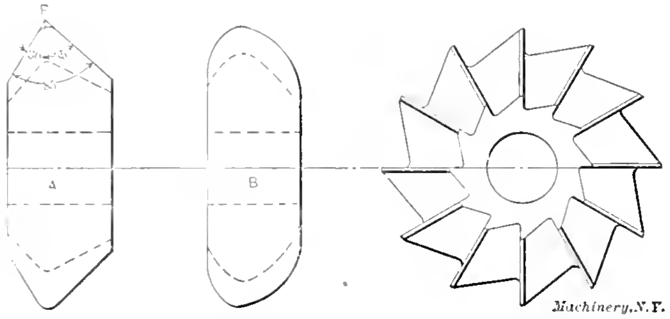

Fig. 1. Shape of Regular Tap and Formed Fluting Cutters.

The device consists of a base-plate *G*, having three feet which rest on a special table on the grinding machine, shown in Fig. 5, which will be more fully described later. On this base-plate *G* slides a cutter holding slide *H*, which has a groove in the bottom, fitting a tongue projecting from the base-plate. An oblong slot is provided in the base-plate as shown at *P*, so that the slide *H* can be clamped to the base-plate by the screw *L*, at any place within the length of the slot. The screw *K* passing through the lug *R* driven into the base-plate *G*, and acting upon the slide *H*, permits the necessary adjustment. The slide *H* holds a stud or spindle *A*, passing through a projecting standard *F* of the slide. The cutter to be ground is mounted on this stud.

It will be evident upon explanation of the action of this device in grinding the cutters, that these must be so mounted upon the stud *A* that the apex of the included angle between the two angular faces (that is, the point *P*, Fig. 1, where the angular sides would meet if extended) shall be on the same center line as the point *N* of the grinding fixture, where the two sides *C* and *D* meet (see Fig. 3). In order to obtain the fine adjustment necessary to bring these two points on the same center line, that end of stud *A* which enters in the bearing in the standard *F* is provided with threaded portions on which adjusting nuts are mounted. Collars are placed on the smaller diameter of *A*, against the shoulder *M*, so that the adjustment necessary to be made by the nuts will be comparatively small, the collars taking up the main difference in width of the various cutters to be ground. On the outside end of the stud *A* is a collar *B*, and a set-screw, having a large round slotted head, which is used for binding the collar against the cutter. It will be noted that this collar is cut off on one side to an angle. This is done in order to permit the collar to clear the emery wheel of the grinder when the side of the cutter tooth next to the collar is being ground.

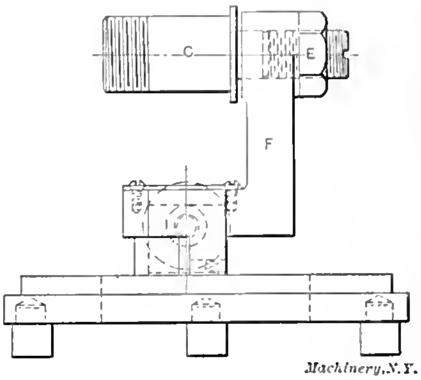

Fig. 2. End View of Formed Fluting Cutter Grinding Device.

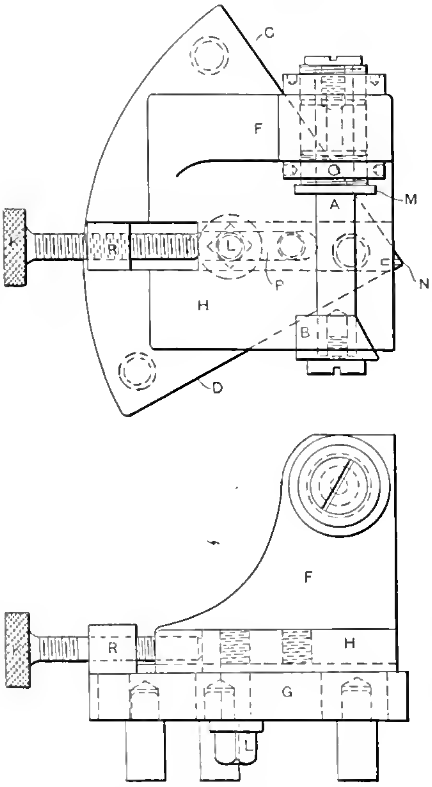

Fig. 3. Device for Grinding Tap Fluting Cutter shown et A, Fig. 1.

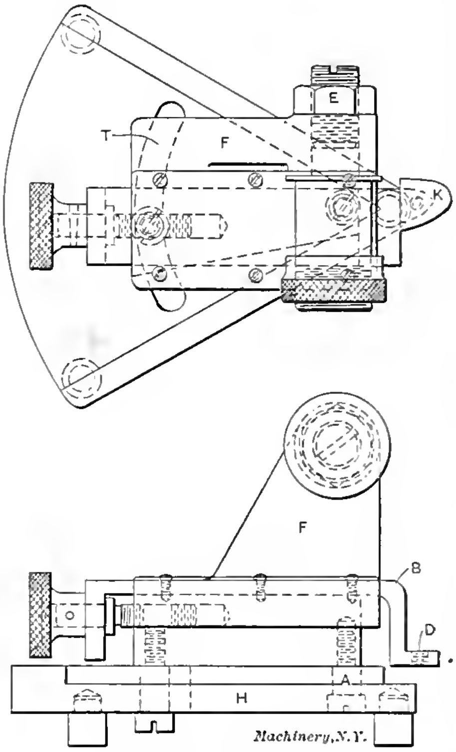

Fig. 4. Device for Grinding Formed Fluting Cutter shown at B, Fig. 1.

As shown at *A*, in Fig. 1, the cutters to be ground have their two faces connected with the small radius, different for different kinds and sizes of fluting cutters. This radius is obtained by permitting the faces of the cutter teeth to project slightly outside of the faces *C* and *D* of the base-plate *G*, Fig. 3, when the cutter is in position on the shaft *A*, the point *P* of the cutter, however, still being in line with the point *N* of the device, as mentioned above. When in use, the grinding device is placed on the table of the grinding machine, as shown in Fig. 5. This table is mounted directly on the grinding machine knee, and is provided with a guide strip *E*. The hardened shoe *N*, in Fig. 3, slides against this guide strip *E* in Fig. 5, and by swinging the device around so that first the face *C* comes along the guide strip *E*, and then turning it around the point *N* until the face *D* rests against the guide strip, the cutter is ground to the same angle as that of the base-plate *G* in Fig. 3, and a radius will be formed at the point of the cutter, its length depending upon the distance the faces of the cutter teeth project outside of the faces *C* and *D*. Different angles may be obtained by putting tapered strips along the sides *C* and *D*, the angle included between the faces of the strips being the same as the angle between the faces of the teeth of the cutter. The base-plate for this device should be made of machine steel, and the faces *C* and *D* should be case-hardened. If tapered strips are screwed onto the faces *C* and *D* to accommodate other angles than the ones referred to,

---

* Associate Editor of MACHINERY.

these strips should also be made of machine steel and case-hardened. Slide *H* is made of cast iron.

The engraving, Fig. 5, shows the special table, previously mentioned, on the cutter grinding machine. This table consists of a cast iron body, provided with two tool steel plates *S* on the top, forming the table surface. These plates are hardened and ground to prevent too rapid wear as the feet of the grinding device constantly slide on their top surface. The guide strip *E* is also made of tool steel and hardened.

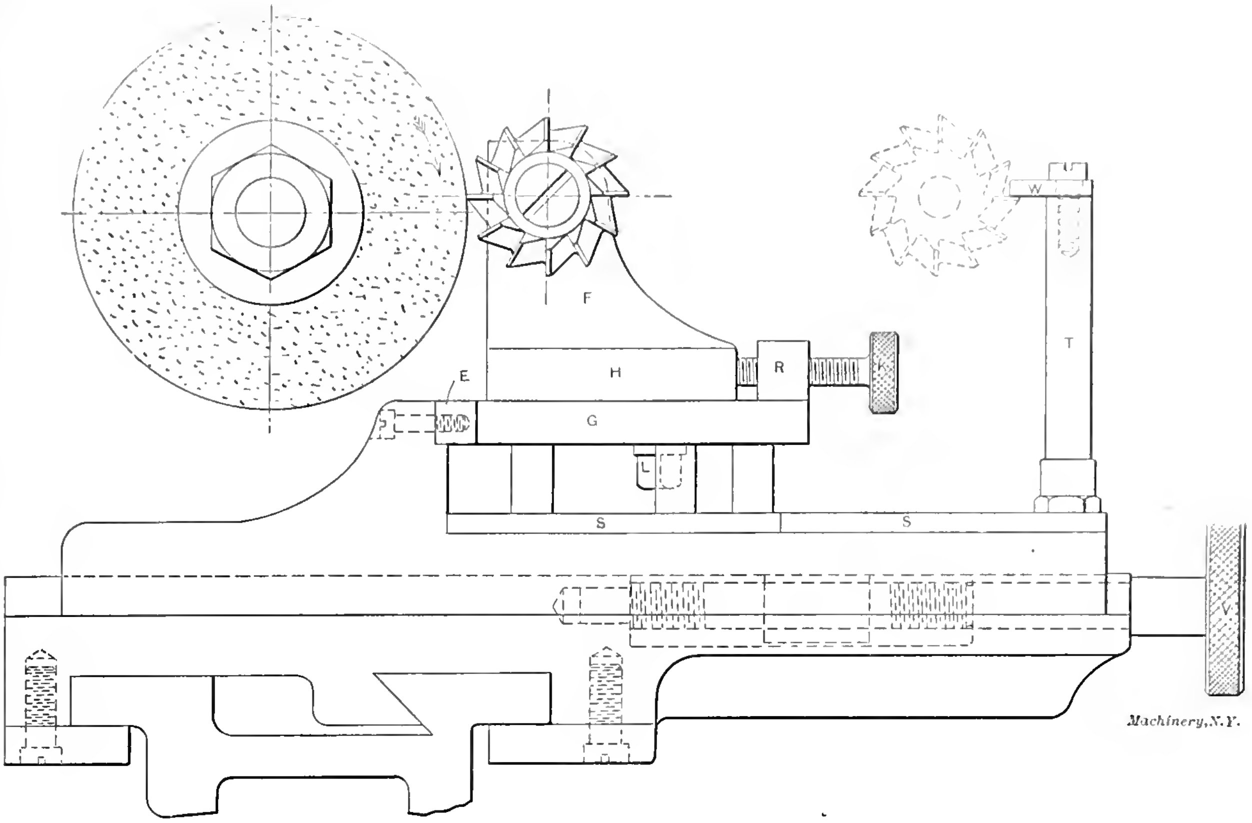

Fig. 5. Grinding Device for Cutters, on Table of Grinder.

At *T* in Fig 5 a stud is shown projecting up from the top of the table. From this stud extends an arm *W*, which is used for setting the cutter tooth, as shown, the cutter being indicated by dotted lines. It is, of course, necesssary that each tooth be exactly at the same height as the others, when ground, so that the diameter of the cutter measured over any two teeth will be exactly the same. The cutter is held simply by frictional resistance, and the indexing around is done by hand by the operator. The table can be fed out and in, by means of a feed-screw with a knurled head *V*, thereby permitting a greater or less amount to be ground off from the teeth of different cutters.

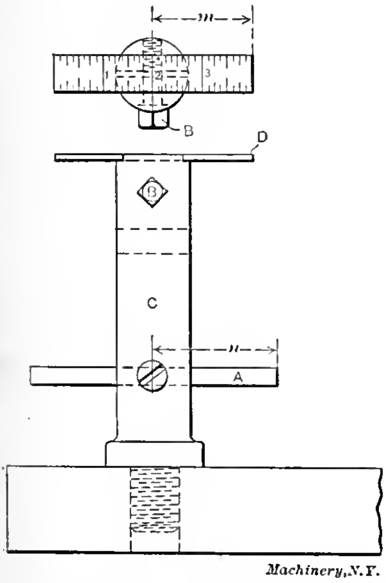

Fig. 6. Device for Setting Grinding Fixtures to grind a Certain Radius at Point of Cutter.

In Fig. 6 is shown a device which is used for setting the slide *H* in Fig. 3 to such a position that the correct radius will be ground at the apex of the angle of the cutter teeth. The stud *C* is screwed into the top of any kind of a base or surface-plate. This stud has a slot or groove cut in its top surface, and a regular 4-inch machinist's scale, preferably graduated in 100ths or 64ths of an inch, is laid in this slot at the top and held by means of the set-screw *B*, the upper part of the round stud *C* being split so that the scale can be gripped in the slot cut for it, as if placed in a split chuck.

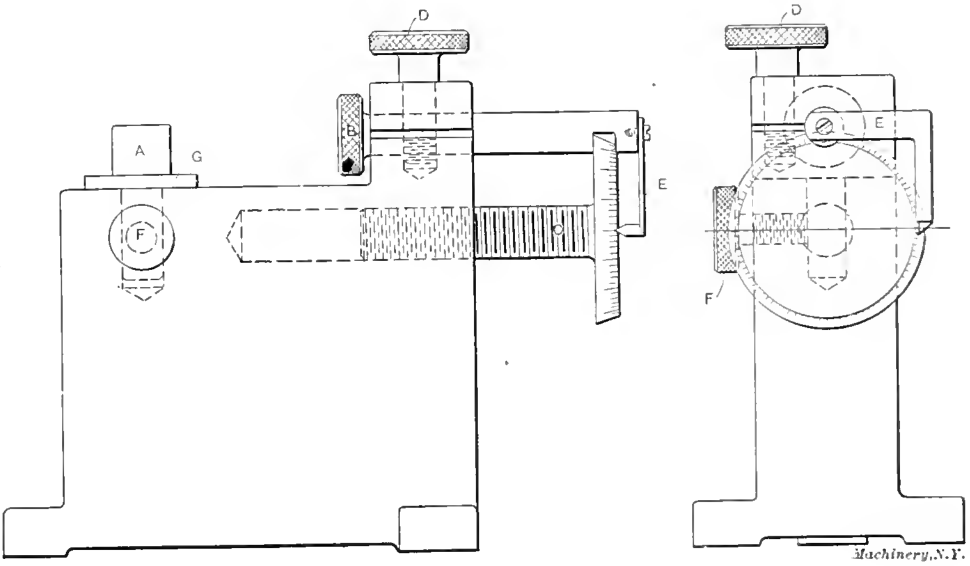

Fig. 7. Gage for Fluting Cutters.

When the device in Fig. 3 is to be set so as to grind a certain radius, the pin *A*, Fig. 6, is placed against the edge of the point *X* in the base-plate *G*, Fig. 2, and the slide *H* is adjusted so that the cutter touches the end *D* of the scale in Fig. 6. When the scale is so set that *m* equals *n*, the cutter to be ground will have no radius, but will have a sharp edge at the point. When *m* is shorter than *n*, the difference between

n and m will give a relative measure of the radius that will result between the faces of the cutter teeth; but it must be understood that this difference does not give the exact radius. This would be measured from the side D of the plate G to the side of the cutter. Of course, the arrangement in Fig. 6 may be used for measuring this length also, by placing the face D against pin A, and the angular side of the cutter tooth against the end of the scale.

The device in Fig. 7, finally, is used for inspecting the cutters when ground. The cutter is placed on the stud A, the stud entering the hole in the cutter, and the gage pin B, having a large head ground flat, is pushed up against the ends of the teeth in the cutter. This permits not only the length of the different teeth in the same cutter to be gaged, but in cases where several cutters are used in a set for fluting taps, all the cutters in the set can be gaged to find out if they are of exactly the same diameter. The gage stud B is fed in and out by means of the micrometer screw C, having a graduated head as shown. When the stud B has been set to the size of one cutter in the set of cutters, it is clamped in place by the clamp screw D. If, however, the other cutters in the set should prove to be smaller or larger than the first cutter, the clamp screw D can be loosened and the micrometer screw adjusted so as to move B in the desired direction, and the amount that the cutters are smaller or larger than the size of the other cutters in the set can be determined by reading off the number of thousandths directly on the graduated head of the micrometer screw C. This head should be graduated so that each graduation reads 0.001 inch. A pointer E is screwed to the end of the gage stud B, for enabling correct reading of the graduations. Collars may be put on stud A to accommodate smaller or larger thicknesses of cutters, or the binding screw F may be loosened and the stud A moved up enough to accommodate thinner cutters, the cutters resting on the shoulder G.

In Fig. 4 is shown a device used in conjunction with the grinding table Fig. 5 for grinding the shape of formed fluting cutters, such as shown at B in Fig. 1. The principle of this device is practically the same as that in Fig. 3. It will be noticed, however, that in order to permit the device to be swung around so as to grind the complete form of the fluting cutter, a slot T, cut on a circular arc, has been provided in the base of the device, and the top portion is swiveled around the stud A. At the front end of the slide B, a threaded hole D is provided for the screw which holds the former for the various drill fluting cutters to this slide, the slide being adjustable to take care of the different diameters of the cutters. In Fig. 2 is shown a side view of this device, which plainly shows the design of the cutter holding slide, the arbor, and its adjustment. It will be noticed that in this case, instead of adjusting the cutter arbor by means of two nuts, on each side of standard F, the stud C has the smaller end threaded directly into the upright F and the nut E simply acts as a binding or check nut. A slot is provided for a screw-driver in the end of the stud C to facilitate adjustment. It will be noticed that in the device in Fig. 4 the former is not attached directly to the base of the device, but is placed on an independent slide. On account of this, there is no need of having any sliding adjustment between the base H of the device and the standard F, all adjustment being taken care of by the slide B, having the formers attached at D, as mentioned. The general shape of the formers used is shown at K.

The experiments undertaken by various inventors for obtaining a satisfactory solution to the problem of wireless telephony seem to be crowned with success. In a previous issue we referred to the achievements of Valdemar Poulsen, the Danish inventor. Three French naval officers have now succeeded in constructing an apparatus by means of which they have, according to the *Petit Parisien*, been able to distinctly hear talking and singing over a distance of 90 miles.

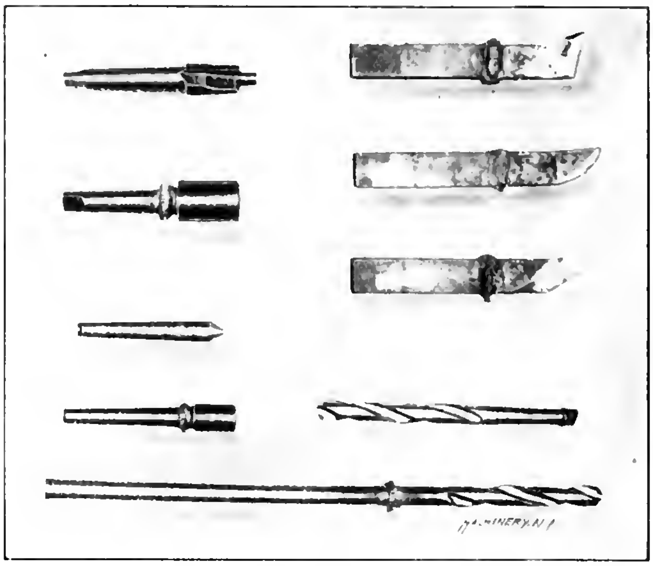
Once in a while a concern hustles so everlastingly to beat a competitor that it works itself out of business. Success is not necessarily in beating the other fellow but in serving your own trade so well that it finds you indispensable.

ELECTRIC WELDING OF TOOLS.

The accompanying illustration received from the Thomson Electric Welding Co., Lynn, Mass., shows samples of electric welding which are of special interest to machine shop managers, foremen, and others interested in economical shop practice. They illustrate the economy in the use of high-speed steel, made possible by the electric welding process. The upper left-hand figures show a counterbore made with a carbon steel shank and high-speed cutting part electrically welded thereto. Below these views are views of a lathe center with carbon steel shank and high-speed steel tip, before and after finishing. In the same illustration are shown diamond point, side and turning lathe tools of high-speed steel welded onto carbon steel or machine steel shanks.



Samples of Tools Electrically Welded for Economy of High Speed Steel and to effect Repairs.

A twist drill broken in the shank can be repaired by welding on a new piece, and with high-speed twist drills, the saving in expense is considerable. The process is also advantageous in making extension drills. The ordinary practice is to weld on a wrought iron shank or to insert a wrought iron filling piece, because of the difficulty of making welds in steel. The electric welding process makes it possible to weld on carbon steel shanks which, of course, are stiffer and stronger than wrought iron. The figure directly below the lathe tools shows a twist drill with a repaired tang, the tang having been twisted off and replaced by another tang electrically welded.

* * *

Mr. G. Scott Ram, electrical inspector of factories in Great Britain, has called attention to the danger of electric hand lamps of certain construction. In some lamps a brass tube is introduced inside of the handle as a chamber for the wire, and the flexible wire is nipped between the porcelain and the end of the brass tube at the lower end. The insulation of the wires is often scraped off far enough to bring it in contact with the brass tube, and as this latter is not always completely covered by a non-conducting handle the danger in handling the lamp is obvious. If a person holding such a lamp happens to be standing on a metal floor or on damp ground, or is otherwise in connection with the earth, he may get a severe shock, and in all probability he will be unable to release his hold of the lamp, and serious results will ensue. The two most important points to be borne in mind in the design of a lamp which can be used without danger is that there should be no metallic connection between the lamp holder and any other metal part of the fitting, and that the flexible wires in passing from the lamp holder shall not be taken through a metal tube, or otherwise in any way come in contact with any metal part of the fitting. In buying electric hand lamps, customers should carefully examine the construction and see that it agrees with the rules laid down above. Here is a case where simple common sense and no extra expense will add greatly to the safety in the industries where hand lamps are required to be used.

MACHINE SHOP PRACTICE.*

MACHINING THE HOLE FOR THE PUNCH AND FINISHING A BLANKING DIE.

In the September issue of MACHINERY, the way in which a common blanking die is planed and laid out was described. After the die has been laid out accurately the next step is to machine the hole for the blanking punch. The way in which this is done will depend somewhat upon the shape of the blank which is to be produced. As the hole through the die which we have selected as an example and which is shown on Shop Operation Sheet No. 76, has circular ends, the lathe can be used to advantage for machining these ends. A plan of the die blank after being laid out, is shown, and also a view of the blank strapped to the lathe face-plate.

First, one hole is drilled and bored to the required radius for the ends, then the blank is shifted on the face-plate and the operation repeated. In order to facilitate setting the work accurately, an indicator *M* is used. This is attached to the tool-post, and its end inserted in the center punch mark located in the center of the hole to be drilled and bored. As the work is revolved, any circular movement of the center punch mark will cause the end *G* of the indicator to move in a much larger circle. By keeping the tail-stock center close to the end *G*, the result of each attempt to shift the work on the face-plate and locate it in its correct position, will be plainly visible. When the center punch mark coincides with the axis of the lathe spindle, the end of the indicater will remain stationary.

The next step is to remove the core. This can usually be done most conveniently by drilling a row of holes just inside the line representing the outline of the master templet. If each alternate hole is first drilled and then the remaining ones, the holes can be spaced closer and drilled with less difficulty, and there will be no bridges between adjacent holes to hold the core in place. It is necessary that a die have clearance, as shown in the sectional views, Figs. 1 and 2, in order that the blanks, when sheared from the stock, may fall through the die; therefore, when drilling, if a thin strip is inserted beneath the blank and on the side farthest from the hole being drilled, so that the hole is inclined to the vertical equal to the clearance angle, considerable labor will be rendered unnecessary when finishing the die. The holes can also be drilled at right angles to the face of the die and then reamed out with a taper reamer, but the former method is more practicable.

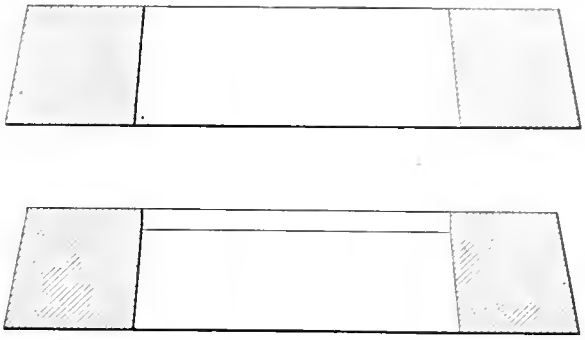
Most of the surplus metal can now be removed with a sharp chisel, but if the die is large it can be conveniently machined on the planer or shaper by strapping it to an angle plate which is inclined to the vertical sufficiently to give the die the proper amount of clearance. Of course, this work may be done more easily on a regular die-slottting machine, if one is available. If chipping is resorted to, the chisel should always be driven away from the top of the die as there is danger, when chipping from the other direction, of the metal breaking away outside of the lines. At times it may be advantageous to drill a single hole large enough to insert a milling cutter, and then work out the core on a vertical milling machine or a horizontal machine with a vertical attachment. A taper cutter can then be used for giving the die clearance.

The next step is to finish the hole to conform to the shape of the master templet. This is usually done by filing. A short piece of heavy wire should be fastened to the center of the blank, and perpendicular with it, as this will be convenient for handling the templet when fitting the die to it.

The die is fastened in a vise with its top or face toward the back of the vise. The hole is then filed to the line previously scribed on the die face. The templet should be frequently tried in the hole, the bearing points being marked with a pencil, and then removed with the file; this operation is repeated until the hole fits the templet perfectly and is large enough to allow it to just pass through. When testing the hole, the surface of the templet should be kept parallel with the top of the die. As the work is nearing completion it may be necessary to remove it from the vise each time the templet is inserted, to enable one to see the minute openings. A piece of white paper held on the opposite side of the blank will, however, suffice for the earlier stages of the work.

The amount of clearance ordinarily given a die is from 1 to 2 degrees. When the hole is being filed to size the clearance angle is made correct and uniform by testing the work with a die-makers' square, which differs from other squares in that the blade is set at an angle with the stock, of 90 degrees plus the clearance angle. In the sectional views shown in the engraving, two methods of giving clearance to dies are illustrated. In the one the clearance extends to the top of the die, while in the other there is a space of about 1/8 inch, which is practically straight, a very small amount of clearance being given. For very soft metals, such as soft, thin brass, the first method is preferable, but for harder materials such as hard brass, sheet steel, etc., it is better to have the clearance end a little below the cutting edge. With a die made in this way thousands of blanks can be cut without any great variation in their size, as grinding the face of the die will not enlarge the hole to any appreciable extent.

The clearance should be filed as straight as possible, so that the blanks, when cut, can fall through the opening easily. To file a narrow surface straight is difficult and requires considerable practice, and while one only becomes proficient in work of this character through practice, still a hint as to the proper method of procedure may be useful. When the file begins its stroke, the downward pressure exerted by the left hand holding the outer end should be maximum, while a minimum pressure is given by the right hand; as the file advances, the pressure from one hand decreases while that from the other increases. After considerable practice, one is enabled, unconsciously, to regulate the pressures on each end of the file so that rocking is prevented. If the surface being filed becomes rounded this can usually be removed by using a sharp scraper which will cut the metal quite rapidly.



Machinery,N.Y.

Sectional Views of Blanking Die Illustrating Two Methods of Giving Clearance.

After the die is finished, the punch is laid out from it. If a die-makers' clamp, such as was illustrated in the Shop Operation Sheet accompanying the September issue, is available, it will be convenient for holding the punch against the die when laying it out. The amount of clearance between the punch and die is varied with the thickness of the stock; for thin material, as for example, tin, the punch should be a close sliding fit, but for heavy plate iron there should be a clearance equal to, at least, 1/16 the thickness of the stock. The pressure required to force the punch through the stock is less when there is clearance between the punch and die, but if this clearance be too great, a tapering hole will be the result. A slight taper is not, however, objectionable on some classes of work.

* * *

It is well known that brass becomes brittle at a temperature of about 550 to 900 degrees F. This is caused by the presence of lead or oxides of lead, or both. This brittleness, it is stated in the *Mining Journal* (London) can be prevented by mixing a certain amount of phosphorus with ordinary brass when heated above 550 degrees F. The proportion of phosphorus varies from 0.03 to 0.10 per cent. In some cases, when brass objects are subjected to high temperatures, and the metal generally does not give satisfactory service, phosphor brass gives excellent results, as for example, in the case of brass tubes for superheated steam.

LETTERS UPON PRACTICAL SUBJECTS.

Articles contributed to MACHINERY with the expectation of payment must be submitted exclusively.

WRITING CAM.

One of the manifold uses to which cam motion may be applied, is illustrated in the accompanying engraving of an arrangement called a writing cam. It consists of two cams of such outlines that a complete turn will make the pencil at the end of the upper follower *A* trace the letters U, W, make the short dashes in place of periods behind each letter, and return to the starting point. A closer inspection shows, that while the upper follower carrying the pencil, makes up and down movements, the lower one *B*, by means of a spring which keeps it in contact with the lower cam face, advances the paper at the proper rate in accordance with the movements of the pencil.

In designing the cams, the first step is to construct the chart shown in the lower right corner. For this purpose the letters or words are carefully drawn out and framed up as shown in the smaller rectangle, which is then divided into a sufficiently large number of equal parts, which are denoted by the letters of the alphabet, reading from right to left. To get the chart proper, a larger rectangle is drawn of any convenient length. The lower part of this figure is of the same height as the letters, and contains the curves of the upper cam *C*, while the height from the base to the top line is equal to the length of the smaller rectangle, as can be seen by the letters on the vertical line, and contains the curves for the lower cam.

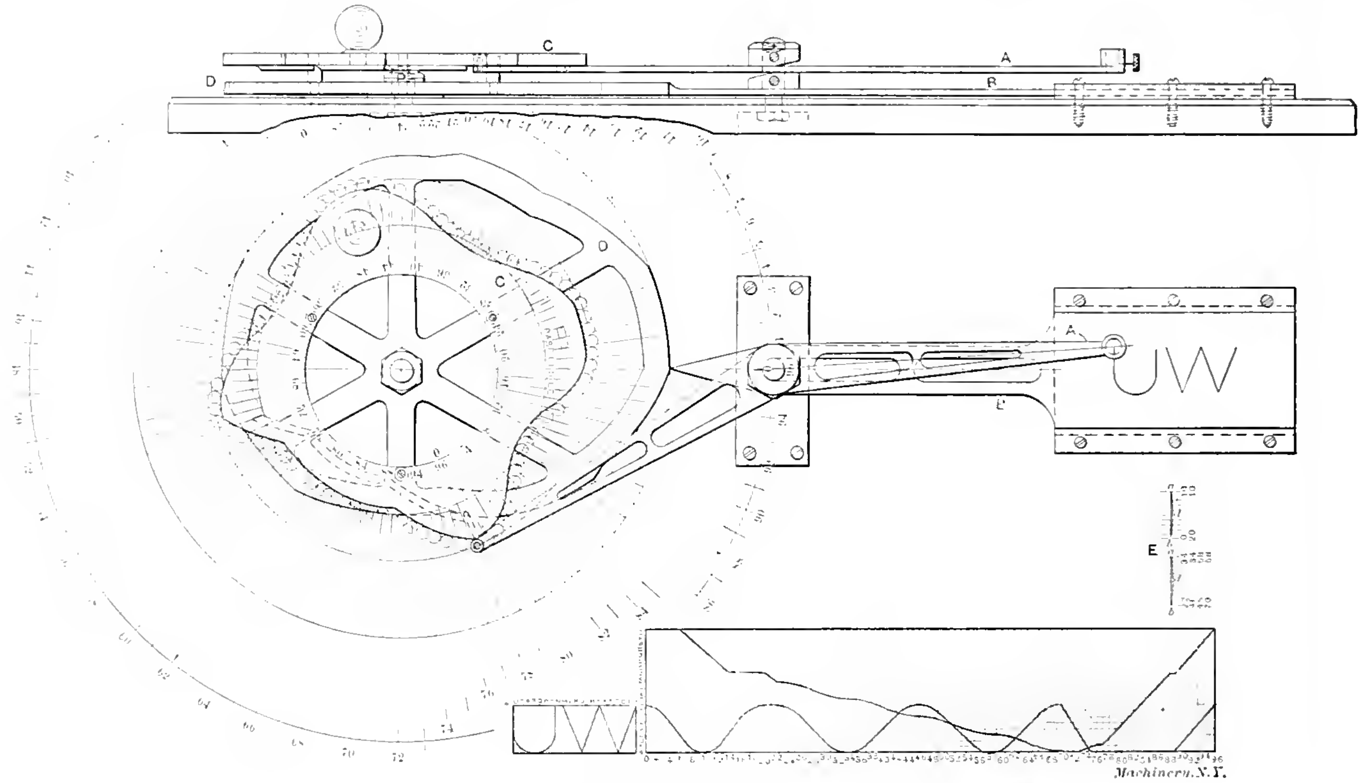

Fig. 1. Method of Laying Out the Curves for the Two Cams which Control the Movements of the Pencil and Paper.

The base line is next divided into an even number of equal parts, a multiple of four being preferable, because these lines represent as many radii, and the base circle has to be divided into the same number of parts. In the present case, 96 divisions were chosen as this permits of convenient subdivision. Having completed this step, the next is to evenly distribute or virtually stretch the letters over the lower part of the figure, leaving enough room for the home stroke, and then referring to the letters at the end of the rectangle, find the curve for the lower cam *D*. For instance, referring to the chart, while the pencil forms the straight line of the U which extends over radius 1-6, the paper does not move, therefore, that part of the curve for the lower cam is a horizontal straight line. The curved part of the same letter covers radius 6-14, and as the motion is uniform, the other curve drops uniformly to the intersection of radius 14 and a line drawn from between *ON*. The curve then stays at this height for the other straight part of the U to radius 20, then drops from *N* to *M* and radius 22, for the break between the two letters. In forming the W, the curve drops successively from *M* 22, to *J* 34, to *G* 46, to *D* 58, to *A* 70, each of these drops corresponding to one straight part of the letter W.

If the uniform law of motion had been followed, the curves would have been straight lines for the straight parts of the letters. In the present case this would, however, result in sharp corners at the joints of the W, which again would result into abrupt changes in the cam outline. To avoid this, the harmonic law of motion has been used, which insures continuous and smooth curves and cam outlines. The lines from 70 to 96 are for the return stroke, and being of minor importance no special law of motion has been employed.

To lay out the cams, the base circle and the large circle which passes through the fulcrum of the upper lever follower, are drawn and divided into the same number of equal parts as the chart. In numbering these radii, care must be taken in locating the zero point for each cam, which lies at the respective point of contact of cam and follower. Going out from the base circle, the distances of the chart are stepped off on the corresponding radii. As, however, the upper follower moves in circular arcs, it is evident that the distances must be laid off on arcs drawn from the various division points of the fulcrum circle with a radius equal to the lengths of the follower from fulcrum to point of contact. Connecting then the various points so found by a continuous line, the theoretical cam curve is obtained.

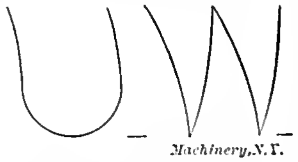

Fig. 2. The Letters as they would appear, owing to the Circular Movement of the Pencil, if the Cam controlling the Movement of the Paper were not corrected to prevent it.

If roller followers are used, the working curve is found by the usual process of reducing the contour an amount equal to the radius of the roller. In this case this applies to the upper cam only.

The working curve of the lower cam is identical with the theoretical, except for a correction due to the circular movement of the pencil, which would give the letters a distorted appearance, as shown in Fig. 2. It is therefore evident that,

if a straight line is to be drawn, the paper must be moved back and forth just enough to take up the arc formed by the pencil. The way to find the proper distance to be added is shown at *E*, where *a-b* is the height of the letters and arc *a-d-b* the path of the pencil. The divisions are the numbers of the radii over which the part of the letter extends. The chart shows that each stroke of the U, covers 10 radii, from 0 to 10 and 10 to 20, while the W requires 12 for each stroke, from 22 to 34, from 34 to 46, from 46 to 58 and from 58 to 70. Two constructions are therefore necessary. Adding now the distance between line *a-b* and arc *a-d-b* to the corresponding radius to the previously found curve, the rectified working outline of the cam is obtained.

To produce the break between the letters, a little metal strip at the bottom of the upper cam, presses the upper follower down at the proper moment and thus lifts the pencil off the paper. The same principle is applied for the return stroke. As soon as the last part of the W is formed, at radius 70, as the chart shows, the pencil is lifted and goes to the bottom line from radius 70 to 75. At radius 75 the metal strip is interrupted and the pencil drops down and forms the dash behind the W from radius 75 to 76, where the lower cam dwells from 76 to 77 to give the pencil time to rise and thus insure a sharp line to the finish. The same process is repeated for the dash behind the U, where the dwell extends from 88 to 89.

As a suggestion, it might be said that it is advantageous to use a fairly large construction and also to avoid letters where straight lines appear, as far as possible, as this would facilitate the work considerably by permitting the use of uniform motion curves throughout and thus doing away with the correction mentioned before. This correction might also be avoided by the introduction of some mechanical device for converting the arc formed by the pencil into a straight line, as for instance Watts straight line motion, or other contrivances.
A. E. SCHULZ.

Chicago, Ill.

TO HARDEN HACK-SAW BLADES IN QUANTITIES.

In the How and Why page of the August issue, H. G. asks for information concerning the way in which hack-saw blades are hardened in large quantities. Blades may be hardened in quantities by using cast iron boxes of the style shown in Fig. 1, in which to heat them. The boxes should be large enough to accommodate about three dozen blades placed on edge with the back down. A little charcoal should be used at the sides to keep the teeth of the outside blades from coming in contact with the sides of the box. The blades are then placed in the muffle of a furnace and allowed to remain until they have reached the proper temperature for hardening. They can then be removed with a pair of tongs made to fit the shanks on the ends of the boxes. The blades should then be carefully dumped on the inclined chute of a linseed oil bath which is shown in Fig. 2. The tank containing the oil is placed inside a wooden tank which is filled with water which keeps the oil from getting overheated. Water is supplied through pipe *A*, and strikes directly on the lower side of the chute down which the blades slide on their way to the bottom where they collect in a wire or perforated sheet metal basket *B*. An overflow pipe *C* is placed at one end of the water tank to carry off the warm water which rises to the top. The oil tank should rest upon legs several inches long, so as to raise it above the bottom of water tank to allow a free circulation of the water. When the blades are fairly cooled off, the basket containing them can be removed from the oil and allowed to drip over the tank until most of the oil has left the blades; they can then be thoroughly cleaned by being immersed in a soda kettle or by placing them in clean sawdust. Flexible blades are treated differently, they being hardened on the teeth only. A fixture of the style shown in Fig. 3 is used for this method of hardening. The blades are placed, back down, between two power-driven rolls *A* which rotate in different directions, and which feed the blades, by friction, between two guides *B* and past the flame from a gas torch which heats the teeth sufficiently for hardening. A compressed air jet strikes the hot teeth immediately after they pass the torch. The temper does not have to be drawn on blades hardened by either process, except at the ends, which is usually done with a torch.

Plainfield, N. J. JAMES CRAN.

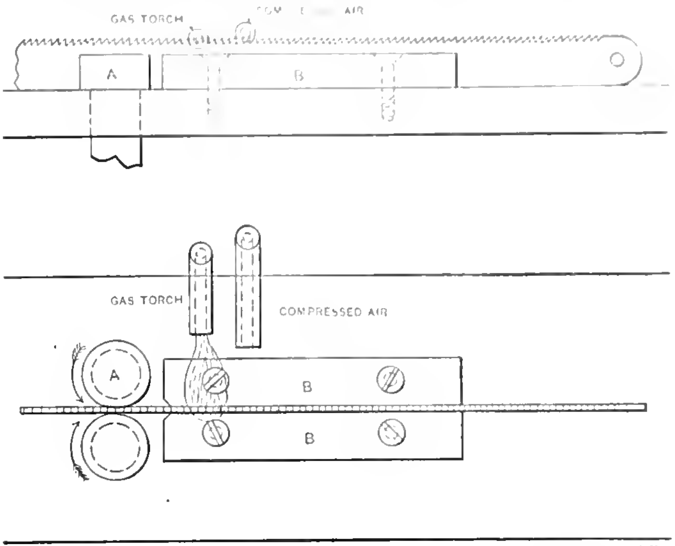

Fig. 3. Method of Hardening Flexible Hack-saw Blades

RACK CUTTING ON THE SHAPER.

We recently had occasion to cut a rack for a mandrel press which was in process of construction in our shops for our own use. As we desired to complete the machine with the facilities at hand, it was somewhat of a question as to what method would be used for spacing the teeth of the rack, which was to be cut in the shaper, a Lodge & Davis machine about twenty years old but still in good repair. The first suggestion was to clamp a finished rack, of the same pitch, in the vise with the rack to be cut, and set the tool for each cut by see-sawing the table back and forth until the tool dropped easily into the finished rack, which would give the proper spacing. The plan was abandoned for several reasons, among which was the fact that we did not have an 8-pitch finished rack to use in this way. Furthermore, the rack was to be cut in a round piece, about three inches in diameter, which had been shaped down flat for a part of its length, as shown in Fig. 1. In addition to this, its shape rendered clamping a finished rack with it somewhat difficult, and as the piece was in position to cut the teeth after shaping, it would have to be reset. The following plan was then adopted:

The diametral pitch of the rack being 8, its circular pitch is $\frac{\pi}{8} = 0.3927$ inch, and this is the amount the table has to be moved for each cut. The number of threads per inch of feed-screw was found to be 4, therefore its pitch is 1/4 inch = 0.25

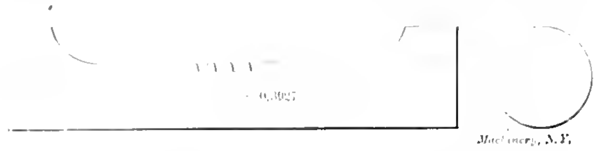

Fig. 1. Mandrel Press Rack to be Cut in the Shaper.

inch, or for one turn of the feed-screw the table is moved 0.25 inch. To move the table a distance equal to the pitch will require $\frac{0.3927}{0.25} = 1.5708$ turns of the feed-screw. The decimal part of this number, or 0.5708 is almost equal to 4/7, so that 1 4/7 turns of the feed-screw moves the table a distance equal to 1 4/7 × 0.25 inch = 0.3927 inch, approximately, which is the proper spacing.

In the practical operation of this scheme, in order to get the fractional part of a turn desired, the index plate and worm-crank from the milling machine were brought into use and placed as shown in Fig. 2. The pawl and ratchet feed of the shaper were removed, and the index plate *A*, with a 49-hole circle, was clamped in its place, a shouldered bushing being used to make the fit and keep the index plate concentric with the feed-screw. The worm-crank *B* was then fastened to the rod *C* with a screw, and this rod clamped to the saddle by a thumb-screw, not shown. The fraction 4/7 = 28/49, and for spacing the 28 holes, a piece of wire *D*, of a proper diameter to fit loosely in the holes of the index plate, was bent at the ends to such a length as to span 26 spaces on the 49-hole circle, leaving the other two holes of the 28 open to receive the pin of the worm-crank, one hole at each end of the wire. The work was then spaced just as the teeth are spaced in the milling machine, and was found accurate. When the feed-screw shaft is too large for the hole in the index plate, the latter may be mounted on the back end of the screw where the nut is placed to take up lost motion.

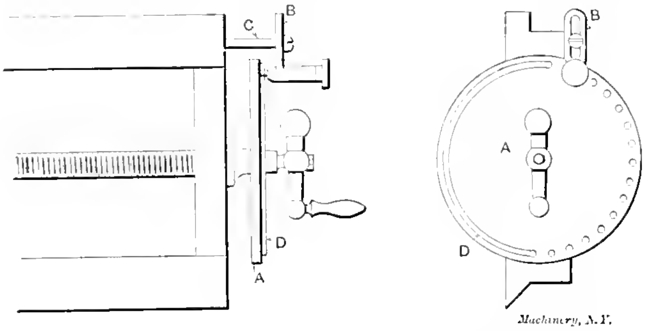

Fig. 2. The Index Plate attached to the Shaper.

TABLE GIVING NUMBER OF TURNS OF FEED-SCREW FOR INDEXING A GIVEN PITCH.

Pitch of Rack.		Pitch of Thread on Feed-screw.									
		1/3"		1/4"		1/5"		1/6"		1/8"	
Diametral.	Circular.	Turns.	Error.	Turns.	Error.	Turns.	Error.	Turns.	Error.	Turns.	Error
3	1.0472	$3\frac{7}{49}$	+4	$4\frac{7}{37}$	+1	$5\frac{4}{17}$	−2	$6\frac{11}{39}$	−2	$8\frac{14}{37}$	+1
4	0.7854	$2\frac{11}{31}$	−4	$3\frac{7}{49}$	+3	$3\frac{38}{41}$	0	$4\frac{35}{49}$	+3	$6\frac{11}{39}$	−1
5	0.6283	$1\frac{38}{43}$	−4	$2\frac{20}{39}$	−1	$3\frac{7}{49}$	+3	$3\frac{30}{39}$	−1	$5\frac{1}{37}$	+1
6	0.5236	$1\frac{28}{49}$	+2	$2\frac{2}{21}$	+2	$2\frac{29}{47}$	−2	$3\frac{7}{49}$	+2	$4\frac{7}{37}$	0

8	0.3927	$1\frac{7}{39}$	+5	$1\frac{28}{49}$	+2	$1\frac{26}{27}$	−1	$2\frac{11}{31}$	−2	$3\frac{7}{49}$	+1
9	0.3491	$1\frac{1}{21}$	+1	$1\frac{17}{43}$	−3	$1\frac{35}{47}$	−2	$2\frac{2}{21}$	+1	$2\frac{23}{29}$	0
10	0.3142	$\frac{16}{17}$	−5	$1\frac{10}{39}$	−1	$1\frac{28}{49}$	+1	$1\frac{38}{43}$	−2	$2\frac{19}{37}$	0
11	0.2856	$\frac{42}{49}$	+1	$1\frac{7}{49}$	+1	$1\frac{21}{49}$	+1	$1\frac{35}{49}$	+1	$2\frac{14}{49}$	+1
12	0.2618	$\frac{29}{37}$	−5	$1\frac{1}{21}$	+1	$1\frac{12}{39}$	−3	$1\frac{28}{49}$	+1	$2\frac{2}{21}$	+1
14	0.2244	$\frac{33}{49}$	+1	$\frac{44}{49}$	+1	$1\frac{5}{41}$	0	$1\frac{17}{49}$	+1	$1\frac{31}{39}$	0
16	0.1964	$\frac{23}{39}$	+2	$\frac{37}{47}$	+4	$\frac{48}{49}$	−5	$1\frac{7}{39}$	+2	$1\frac{28}{49}$	0
18	0.1745	$\frac{11}{21}$	+1	$\frac{30}{43}$	−1	$\frac{41}{47}$	0	$1\frac{1}{21}$	+1	$1\frac{17}{43}$	−1
20	0.1571	$\frac{8}{17}$	−2	$\frac{27}{43}$	−1	$\frac{37}{47}$	+3	$\frac{16}{17}$	−2	$1\frac{10}{39}$	0

As the method has a wide application for spacing equal divisions, the accompanying table was prepared to apply to racks up to 20 diametral pitch, and for a number of different pitches of feed-screw.

Thus, to space a 9-pitch rack on a shaper having a feed-screw with 6 threads per inch, we find from the table that it requires 2 2/21 turns, which will be accomplished with the index plate having a 21-hole circle, taking two full turns + 2 holes on the 21-hole circle. The errors tabulated in the table are in ten-thousandths of an inch for each space, the sign showing whether the space thus given is too great or too small. Thus, an error −1 shows each space to be 0.0001 inch too short. The total error in a rack of 100 teeth would then be but 1/100 inch, which is negligible for most work. However, the errors are all tabulated, that none may fall into error by using the approximations here given. If it is desired to use this method to cut a rack to work with a gear, the pitch of which is given in *circular* measure, the spacing may be done as follows. Suppose the pitch of pinion to be 13/16 inch, and the feed-screw has 5 threads per inch: 13/16 inch = 0.8125 inch, and one turn of the screw moves the table 1/5 inch = 0.2 inch. The turns required are therefore $\frac{0.8125}{0.2} = 4.0625$ = 4 1/16 turns, which will be made by using the circle with 16 holes.

Notre Dame, Ind.

GRAPHICAL DETERMINATION OF THE CROSS-ROLL CURVE.

In the December, 1907, issue of MACHINERY was given a mathematical derivation of the cross-roll curve. In the July, 1908, issue was given a graphical method which, however, seems rather awkward and cumbersome. The following graphical methods will be found far more convenient. Lay out in two views the axis of the cross roll and the center line of the pipe, as shown in Fig. 1. Intersect both projections by several parallel planes, all perpendicular to the axis of the roll. The sections of the pipe will all be ellipses; the corresponding sections of the roll must be circles tangent to these ellipses. The radii of these circles may be set off from the axis of the cross-roll in their respective planes, and the form of the cross-roll curve thereby determined.

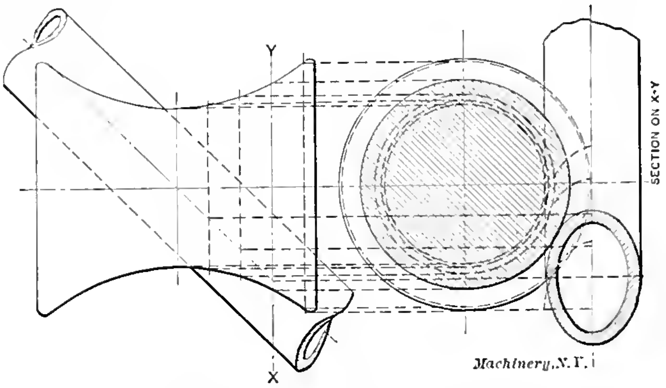

Fig. 1. Graphical Method of Laying Out Cross-roll Curve.

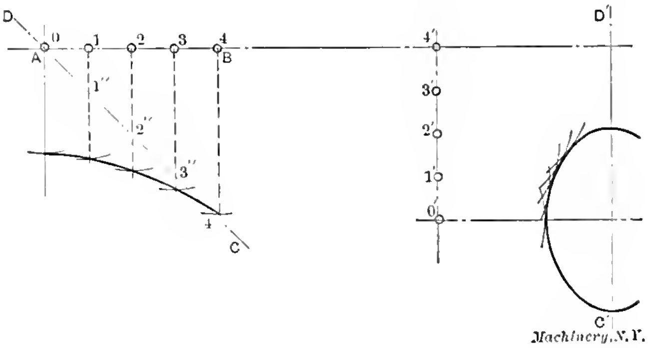

Fig. 2. Method in Fig. 1 Simplified.

The amount of work required for this construction may be reduced, and the accuracy of the construction increased, by arranging the sections so that all the sections of the pipe coincide, noting, of course, the corresponding change in position of the axis of the roll in each case. Such a construction is shown in Fig. 2. When this method is used the ellipse need be drawn but once. The line *AB* represents the axis of the cross-roll, and the line *CD* the center line of the pipe. The ellipse is the section of the pipe intersected by a plane perpendicular to the axis of the roll at 4.

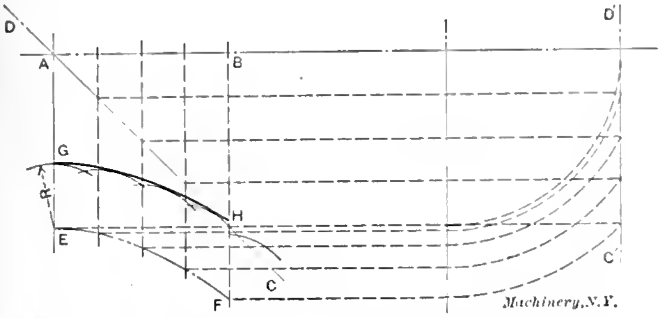

Fig. 3. Another Graphical Method for Laying Out the Cross-roll Curve.

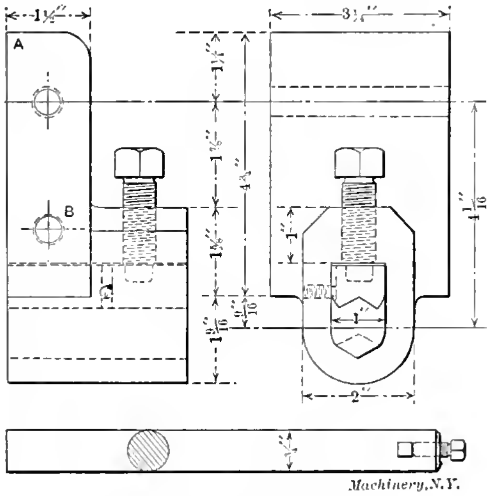
Radii of arcs tangent to the ellipse having centers at 0', 1', 2', 3', and 4' are laid off from 0, 1, 2, 3, 4 upon lines at right angles to *AB*. These radii determine the shape of the curve. The points 0', 1', 2', 3', 4' are so located that the distance 0'1' = 1''1, 0'2' = 2''2, etc.

The construction shown in Fig. 3 is based on the fact that if the pipe were of zero diameter, the cross-roll would be in hyperboloid of revolution generated by the revolution of the center line *CD* about the axis *AB*. The curve *EF* for this hyperboloid is determined as shown. For a pipe of given diameter the form of the cross-roll is a curve parallel to the curve of this hyperboloid, and at a distance inside of it equal to the radius *R* of the pipe. The curve *GH* is therefore the required cross-roll curve. E. H. WOOD.

Ithaca, N. Y.

EXTENSION TOOL HOLDER.

The extension tool holder for the shaper, which is shown in the engraving, is extremely convenient and useful, and can be made at small cost. The one shown is for a 16-inch shaper, and will hold cutter bars from 1 inch down to ⅜ inch in diameter. The holder is fitted into the clapper box, and takes the place of the clapper. When putting it in, it is necessary to drive out the taper pin and remove the clapper, then when the holder is in place and the pin driven in again, the upper square corner at *A* prevents its turning and makes a solid fixture of it. The opening for holding the cutter bar is low enough so that the bar can be extended backward under the tool head, which enables the length of the working part of the bar to be changed to any length desired. With this arrangement there is no "blocking down" of the tool, no tool-post to interfere, and the bar can be rotated so as to bring the cutter into any position. I have found it to be an advantage in doing work with an extension tool of this kind to reverse the position of the cutter, so that it will take a draw cut. If used in this way, there should be an additional taper pin put through in some such position as *B*, so as to make it more rigid for the draw cut. As the ordinary shaper head is not very strong for draw cutting, great care must be exercised when using it this way. The tool cuts smoother, however, and is not nearly so likely to "hog in"; the lines on the work are in front, and it is altogether a more satisfactory way to work. W. A. KNIGHT.



Extension Tool Holder for the Shaper.

Columbus, O.

GAS ENGINE VALVES.

The accompanying engravings illustrate the method used by one of the most progressive automobile concerns in the East, of making gas engine valves. The stock is first taken in bar form and blocked down under a trip hammer; then it is reheated and finished, as shown in Fig. 1, with one heat between dies *A* and *B*, Fig. 2. These dies produce a finished head and stem, to forging dimensions, also a screw-driver slot and center impression. *A* is the body of the top die; *C* is the inserted center die which contains the centering plug *F* and blades *E*, and the screw *D* which forms a backing for the plug *F*; hole *O* in *A* is to facilitate easy removal of *C* for renewal of center plug *F* and blades *E*. These blades form the screw-driver slot *G* in the valve head, as shown in Fig. 1. The dies were designed with the idea of doing away with two operations; milling the screw-driver slot, and center punching the head end of the valve, also for making it an easy matter to center the head end for turning in the lathe. The slot is used to drive or rotate the valve when grinding in the seat after cylinder and valve have been machined.

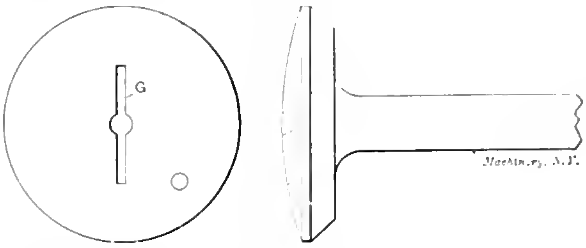


Fig. 1. Gas Engine Valve which is formed by the Dies shown in Fig. 2.

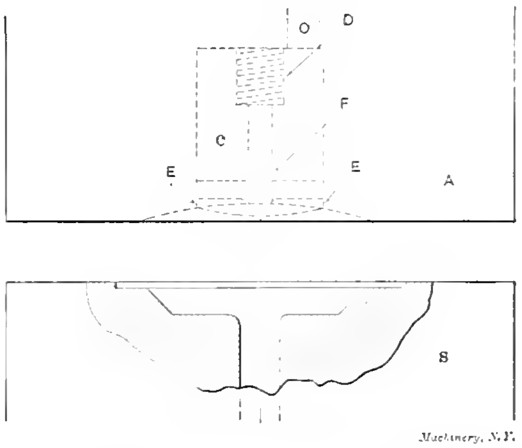

Fig. 2. The Upper and Lower Dies for Forming the Valve Head and Stem.

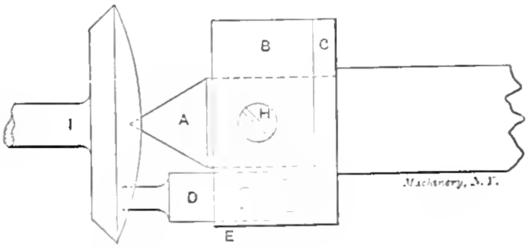

Fig. 3. Method of Driving the Valve when Turning.

In Fig. 3 is shown the driving head for turning. *A* is the center which fits the lathe spindle and *B* and *C* are two rings or collars which are an easy fit on the straight portion of *A*.

D is the driver which fits into a part round and part elongated hole in *B*, and is kept in place by pin *E*. The large diameter of *D* is a little smaller than the elongated hole in *B*, so that it will have a radial motion to allow for any variation between the center and the driving hole in the valve. There is some variation in the distances of these holes owing to the oval surface of the valve which causes the drill to crawl a little. The screw *H* holds the rig firmly in place, a flat being milled on *A* which it seats against. In Fig. 4 are shown elevations of the jig used for drilling the driving hole. *A* is the body of jig, *C* the bushed drill hole, and *B* the clamping screw with a 60 degree point which locates and clamps the valve in position while the drive hole is being drilled.

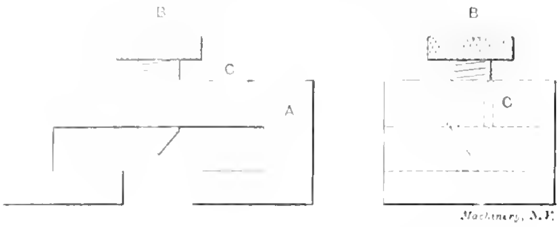

Fig. 4. Jig used for Drilling Holes for Driver.

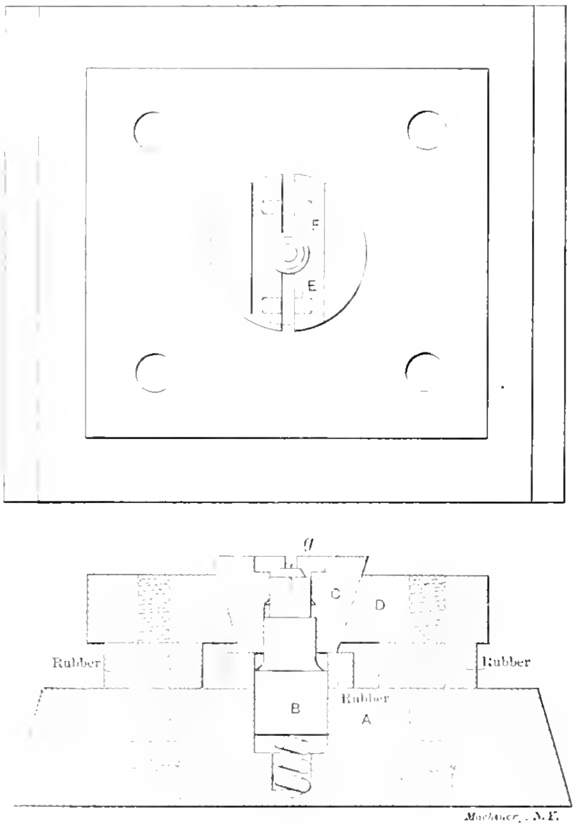
E. S. Wheeler.

DIE FOR COUNTER-SINKING HOLES IN CORNER IRONS.

In the engraving is shown a die used for counter-sinking holes, previously pierced, in corner irons of five different sizes: 5/8, 3/4, 7/8, 1, and 1 1/8 inch inside, and 3/32 and 1/8 inch thickness. The work is done by this device much quicker than it can be done in a drill press. The work is placed in the groove in the part *C*, shown in the sectional view, and the plunger *B*, which has a sliding fit in the base-plate *A*, counter-sinks the metal around the holes in the work, by being pressed into it. The bevel on the point of this plunger *B* is made the same as the angle of the screw-head to be used for the corner irons, but the distance *g* is somewhat less than the thickness of the stock, so that the point will not project through the stock and strike the punch. The punch used is simply a flat-bottomed plunger, 2 inches square, having a perfectly smooth bottom surface, and hardened.



Die for Counter-sinking Holes in Corner Irons.

The sleeve *C* is made in five different sizes, one for each size of corner iron, and is turned tapered on the outside to fit into the holder *D*. The sleeve *C* is split, and after being split is drawn to a purple and hardened. There are two holes in each of the halves of the sleeve *C*, at *E* and *F*, as shown in the plan view. These holes contain springs which hold the two parts of the sleeve apart, so as to admit the stock. When the stock is placed in the groove in sleeve *C*, it is located by the point of the counter-sink *B*, and, as the punch descends, it first forces the sleeve *C* into the holder *D*, thus clamping the stock and preventing it from bending. The annular rings, shown under both *D* and *C*, are rubber pads, permitting a springing action, as soon as the stock is firmly held in sleeve *C*.

The spring under the plunger *B* holds it up against the work, and makes it possible for the point to locate the hole in the work before the punch has descended far enough to force it into the work, forming a counter-sunk hole. Plunger *B* should be left as hard as possible, because it is subject to considerable wear.

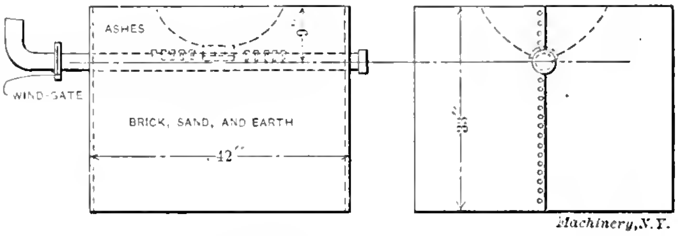
Aurora, Ill.

A CHEAP HOME-MADE FORGE.

To make a cheap forge, a cylinder is first made about 3 feet 6 inches in diameter and about 2 feet 9 inches high, from 1/8-inch sheet steel, as shown in the engraving. Then two holes are cut in this cylinder opposite each other about 9 inches from the top edge. These holes should be large enough to allow a 2½ or 3-inch common steam pipe to pass through freely. For a forge intended for heavy forging, a 3-inch pipe is to be preferred. The pipe should be long enough to pass through the cylinder and extend about 2 inches outside on one side, and 6 or 8 inches on the other side of the cylinder. The end of the pipe that extends out about 2 inches should be threaded, and a cap should be screwed on this end in such a way that it can be removed or put on by hand. A wind gate is now put on the other end of the pipe, and this is then attached to the blast pipe. After having laid the pipe in place temporarily, a 1¾-inch hole is drilled into the pipe on one side, and on each side of this hole three ¾-inch holes, followed by two ⅝-inch holes, about 3 inches apart, are drilled. A piece of steel, one inch thick, about 4 or 5 inches wide, and long enough so that it will go at least one-third around the pipe, is now made. In the center of this piece a 1¾-inch hole is drilled, and the piece is bent so that it will fit the outside of the pipe. This piece is placed directly over the 1¾-inch hole in the pipe, being attached with some fire clay. It serves the purpose of prolonging the life of the pipe, and keeps the pipe from burning out at the hole. After the forge constructed in this manner is leveled up, broken brick, sand, dirt and cinders are dumped in and packed firmly up to the lower side of the pipe. One-half inch bolts or rivets, about 1½ inch long, are put in the small holes, and then the remaining part of the cylinder is filled up with cinders and packed firmly, space being left to form a pit for the fire. The forge is now ready for use.



Serviceable and Inexpensive Forge.

The advantages of this forge are: It is possible to make a large or small fire, according to the requirements; if a long fire is required one can pick out enough of the cinders and take out the bolts or rivets mentioned; the length of the fire can be adjusted to the requirements by taking out more or less bolts; there is no brick or fire clay lining to be set before the forge can be used. The writer has built several of these forges in various shops, and they give the best of satisfaction. The forge will work well until the pipe rusts

out, and then another pipe is made and put in place at very small expense, and very little loss of time.

When the fire gets dirty, use the poker and poke the dirt down through the hole. Take off the cap at the end of the pipe and open the wind gate and blow out the cinders inside of the pipe. It takes no more than two minutes to clean a fire in one of these forges. The writer prefers this forge to any other as the most serviceable and inexpensive one to use on any class of work. It is adapted to a great variety of forging. The writer has made big blanking dies, welded 8-inch diameter shafts, and put ¼-inch links in chains, on the same forge. **Geo. T. Coles.**

Decatur, Ill.

ON OBTAINING APPROXIMATE FRACTIONS.

Referring to the article contributed by me on the subject "How to Obtain Approximate Fractions by the Method of Continued Fractions," which was published in the August issue of Machinery, I would say that before trying to obtain the approximate fractions of a fraction, one should first attempt to factor said fraction. In the selection of 729/1,000, as shown in the article, it was resolved into approximate fractions to serve as an illustration of how the work was done, yet it might have been factored thus: 729/1,000 = 81/100 × 9/10. Retaining the 81/100 and raising the 9/10, for instance, to 36/40, we should then have 81/100 and 36/40 as fractions indicating gears that might be used, and which would give the required lead exactly.

Providence, R. I. **Mitchell Dawes.**

SPECIAL BORING-BAR.

A special boring-bar for use in either lathes or horizontal boring mills is illustrated in Fig. 1. This bar is adapted for boring taper holes or cutting grooves in bearings, as well as for other classes of work that it is profitable to do with a single-ended cutter. The bar is made of ordinary machine steel, and has a taper shank to suit the spindle of the boring mill. Length *A* is made twice the length of the hole that is to be bored and is chased 16 threads per inch the full length. Collar *C* is made of machine steel, threaded to suit bar, and case-hardened so as not to allow it to cut where it comes into contact with the steel bevel key *E*. This key is case-hardened, and is made the exact bevel of half the difference of the diameters of the two ends of the taper hole to be bored, and is a sliding fit in a ¾-inch keyway. The key should be not less than 1 inch longer than the length of the hole which is to be bored, so as to allow for starting the ½-inch square tool, which is held in collar *F* by a slotted set-screw *G*. The tool is a sliding fit in a square hole in the collar and the collar is shrunk on the bar.

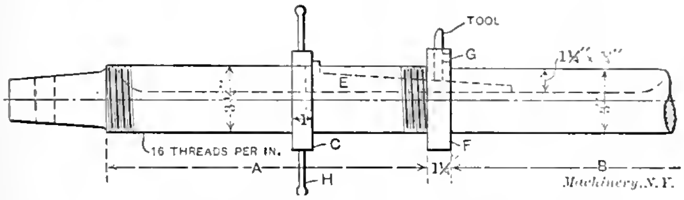


Fig. 1. Special Boring-bar for Taper Boring or Groove Cutting

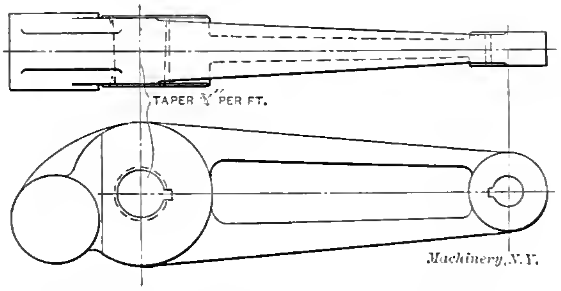

Fig. 2. Example of Taper Boring done with the Bar.

In operating the bar, the boring mill is geared to cut 16 threads per inch, and the tool set to the amount of cut desired to be taken. A parallel strip is then clamped to the table, upon which one of the four handles *H* is rested. When the machine is started the threaded collar *C* is forced to travel on the bar and as the bevel key *E* moves inward the tool is fed into the cut, the result being a taper hole the exact taper of the key. As long as the key is retained the hole can be duplicated exactly, and there need be no fear of its not fitting the same as the original, which is very often the case. The feed of 16 to the inch would leave a rather rough finish, but this is easily overcome by using a broad nose finishing tool.

When desiring to cut a groove, a tool is inserted in the collar *F* the exact shape of groove to be cut, and the bar is revolved in a stationary position. The collar *C* is then turned by the handles *H* so that the taper key forces the tool into the cut, and when the required depth is reached, set-screw *G* is slacked off and the tool drops back into the slot; the bar can then be removed. The four handles *H*, which are tapped into the threaded collar *C*, give a momentum to the collar which facilitates removing the taper key *E* after each cut, thereby saving much time. It is only necessary to make the length *B* of the bar long enough to reach the yoke of the boring mill. On the lathe, the bar is used practically the same as on the boring mill with the exception that the work moves instead of the bar. The bar is especially adapted to performing work on castings too large to swing in the lathe or vertical mill. It proved to be very economical for finishing twelve cast steel levers similar to the one shown in Fig 2, which were too long for any lathe or vertical boring mill to swing, in the shop where the bar was made. Fig. 3 shows a plan of a large thrust bearing which has thrust grooves. The bar was very useful in cutting these grooves, which were required to have a fine finish and be very accurate. This would have been a very difficult job to do with the ordinary boring-bar. This bar can be put to various other uses, and, owing to its simple construction, is quite inexpensive. It can, of course, be made in various sizes to suit very small as well as large work. **R. S. F.**

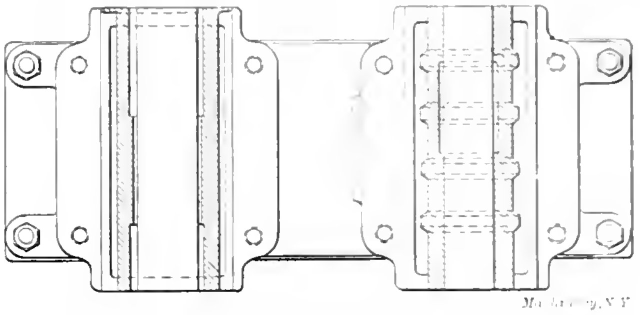

Fig. 3. Plan of Thrust Bearing showing Thrust Grooves cut by the Bar

AN ADVANTAGE OF IGNORANCE.

A variation of Billy's experience related in the May issue may be worth while telling. A farmer who needed a few repairs done on some of his implements, requested a local repair man to permit him to use a drill press, himself, in order to save time on his own work. Permission being granted, some smart Jimmy, as usual, crossed the belt, but the farmer, not being as nearsighted as poor old Bill, promptly reground the drill to suit the drill press. Needless to mention, the Jimmy figuring in this case was dumbfounded, and attended unusually well to his own business for the balance of the day, excepting, of course, that he spent some time trying to find out "how it was done." **Alfred N. Hammond.**

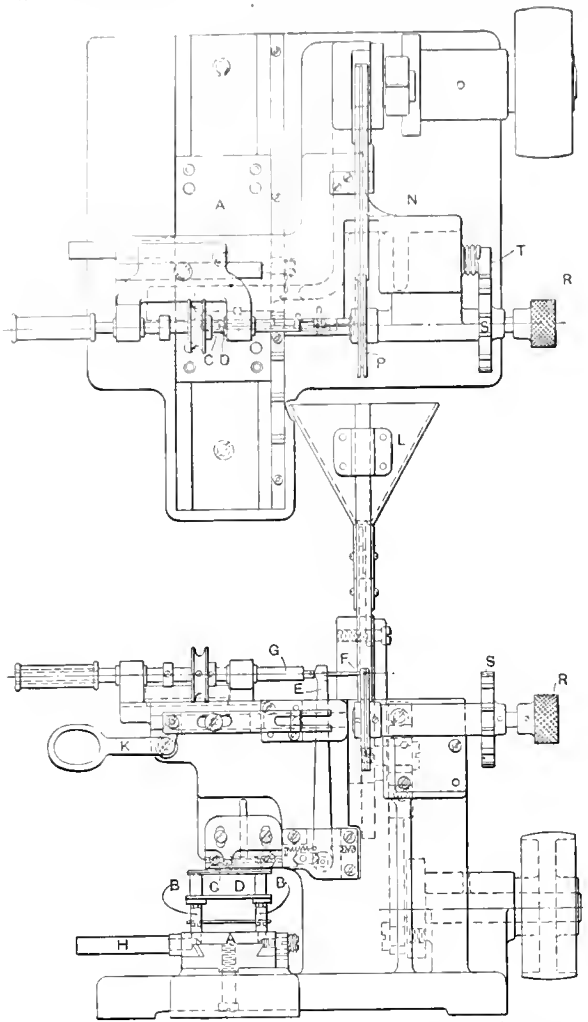
Erie, Pa.

SEMI-AUTOMATIC REAMING MACHINE.

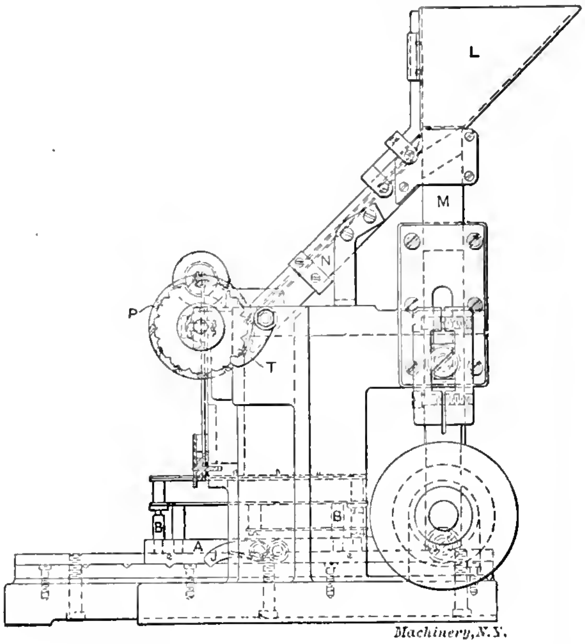
The accompanying illustration represents a small bench machine, designed for reaming holes in the pointers used on an electric meter. These holes are tapered 0.01 inch per inch, and are forced onto taper shafts after the latter are assembled in the register. The taper shafts vary in diameter so that it is necessary to ream each pointer to fit the shaft on which it is to be used. The usual method of fitting these is to use, when assembling, a hand reamer with which the pointers are reamed until they fit the shaft at the proper dis-

tance from the end. This method requires a great deal of reaming and fitting, and thus is not very satisfactory where a large production is required.

It will be observed that the device here illustrated is fitted with a slide *A* on which pins *B* are provided to hold the register, after the latter has been assembled with the pointer shafts and is ready to be fitted with the pointers. Directly above slide *A*, and in line with the pointer shafts, are located two gage points *C* and *D*, one fixed, and one movable, the latter operating a lever or indicator *E* on the same principle as a multiple gage. The upper end of the indicator *E* is split, forming a fork which straddles the taper reamer *F* thus forming a stop for spindle *G* as shown in the front elevation. Slide *A*, which carries the register, is operated by handle *H*, and the pointer shafts are stopped in alignment with the gage points by means of a pawl *J* which engages with the four notches as shown. Spindle *G* slides in its bearings, and is driven by a small grooved pulley. The back end of the spindle is provided with a spool by means of which the spindle is operated back and forth. Lever *K* operates a friction clamp, which in turn locks the indicator *E*, thus forming a positive stop for the spindle. It will be noticed that this machine is provided with a magazine feed, by means of which the pointers are automatically carried in position to be reamed. The method of accomplishing this will be readily seen. Hopper *L* forms a receptacle for the pointers. Plunger *M*, which is operated up and down through the center of the hopper, is slotted in the end so as to pick up the pointers and carry them down in the proper position to drop into the magazine *N*, from which they are conveyed to the revolving chuck *P*. The magazine and chuck are so constructed as to prevent the work from entering in any but the right way. The chuck has twelve slots to receive the work, and is indexed by means of handle *R*. The index plate *S* is fastened to the same shaft as the chuck, and locates the work in alignment with the spindle by means of the pawl *T*. A small pulley drives a crank, which in turn operates the plunger *M*.



Machinery, N.Y.



Machinery, N.Y.

Elevations and Plan of the Semi-automatic Reaming Machine.

As before stated, the size of the reamed hole is governed directly by the size of the taper shaft, the idea being to remove the pointers from the chuck as fast as they are reamed, and place them on the shaft for which they were gaged. In setting up this machine for the operator, it is necessary to adjust the taper reamer to the proper depth. The register is first placed on the slide *A*, the latter is then brought forward until pawl *J* engages the first notch as shown in the side elevation, thus bringing the first pointer shaft between the gage points *C* and *D*. This operation causes the indicator *E* to assume a vertical position, which is not very important, although it should stand about vertical. The indicator is then locked by means of the lever *K* and friction clamp, as formerly described. It is then in position to stop the spindle. The reamer has a straight shank, and is held in the spindle *G* by a small set-screw by means of which it is adjusted to the proper length. The simplest way of doing this is to set the tool out gradually, trying the pointer on the shaft each time until it fits at the proper distance from the end. When it is set for one, the rest are bound to come right for the reason that the ratio of the indicator arms is such as to correspond with the taper per inch, which in this case is one-hundredth inch.

Gt. Barrington, Mass.

THE EFFECT OF ROLLED BELTING ON ITS APPLICATION.

Perhaps the method adopted by the manufacturers, of rolling up leather belting, has been discussed in the columns of Machinery, but if it has not, we wish to call attention to a fault of the present practice. This fault has been forcibly brought to our attention lately while equipping our new machine shop. Obviously, belting should be rolled just opposite to the way it is now rolled if we are to apply the belting with the hair side next to the pulleys. It is the verdict of all good mechanics that belts wear best applied in this way, but belting is universally rolled with the smooth or hair side on the outside. This gives the belting a natural set or curve which is a great inducement to the mechanic to apply it to the pulley in the same way. Why do not the manufacturers roll belting the way it should go when in use?

G. R. Lang,
G. R. Lang Co.

Meadville, Pa.

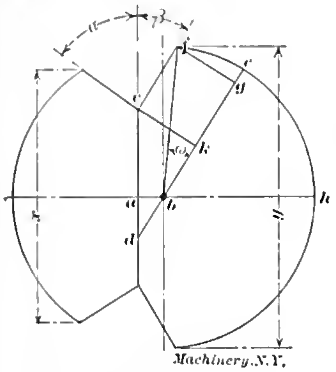
[The point made by our correspondent is important, and is one that should be taken into consideration by belting manufacturers, generally. Obviously a roll of belting looks best when made up with the smooth or hair side out, but as our correspondent says, the belting acquires a set when rolled in this direction that is hard to overcome when applied to pulleys with the hair side next to the pulleys, as it should be. Belting manufacturers who are desirous of having their belt-

ing applied so as to give the best results should give the matter their attention. Doubtless they will find that the mere matter of appearance is not nearly so important as convenience of application.—EDITOR.]

SIMPLE SOLUTION OF "A PROBLEM IN TRIGONOMETRY."

The following is a simple solution of "A Problem in Trigonometry," published in the How and Why section of the August issue of MACHINERY.

Let the given length $ac = A$; the given length $ab = B$; the given radius $= R$; and the given angles $= \alpha$ and β. Draw de parallel to cf, through the center of the circle; and ck and fg at right angles to de.



$$\text{Then } ad = \frac{B}{\tan\beta} \qquad (1)$$

$$cd = ad + A = A + \frac{B}{\tan\beta} \qquad (2)$$

$$fg = ck = cd \sin\beta = \sin\beta\left(A + \frac{B}{\tan\beta}\right) \qquad (3)$$

$$\frac{fg}{R} = \sin\omega = \frac{\sin\beta}{R}\left(A + \frac{B}{\tan\beta}\right) \qquad (4)$$

$$\text{Angle } fbh = 90^\circ - \beta + \omega \qquad (5)$$

$$y = 2\,R \sin fbh \qquad (6)$$

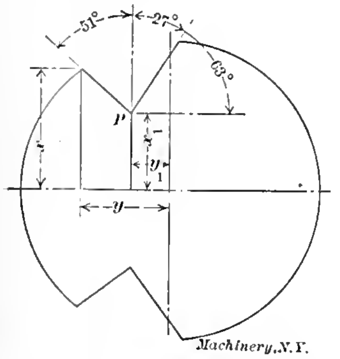
The length x is determined in the same manner. When the formula (4) has been obtained, this solution requires but three steps for finding the chord, although one step involves two divisions, one addition, and one multiplication.

Philadelphia, Pa. LOUIS J. SCHROEDER.

SOLVING "A PROBLEM IN TRIGONOMETRY" BY ANALYTICAL GEOMETRY.

The solution of S. S. Y.'s problem in the How and Why section of the August issue is an interesting practical exercise in trigonometry, but it may be solved more simply by analytical geometry. The object is to find the co-ordinates x and y of the points of intersection of the circle and the inclined lines passing through the point p.

The equation of a circle is $x^2 + y^2 = R^2$ if the origin of coordinates is at the center; and that of a line passing through a given point is $y - y_1 = a(x - x_1)$, in which $y_1 x_1$ are the coordinates of the given point, and a is the tangent of the angle the line makes with the axis of abscissas. Substituting known values in these equations, and combining them so as to eliminate y, we get the value of x, and *vice versa*. In the first of the two cases, the writer has changed the usual position of x and y, so as to get the angle 51° in the first quadrant, and thereby obtain a positive value of a.



The known values in the first case are: $R = 0.196$; $R^2 = 0.038416$; $x_1 = 0.1$; $y_1 = 0.03125$; $a = 1.2349$.

$$y - 0.03125 = 1.2349\ (x - 0.1)$$
$$y = 1.2349x - 0.09224$$
$$y^2 = 1.525x^2 - 0.2278x + 0.00851$$
$$R^2 = 2.525x^2 - 0.2278x + 0.00851$$
$$2.525x^2 - 0.2278x = 0.0299$$
$$x^2 - 0.0902x = 0.01185$$
$$x = 0.0451 + 0.1178 = 0.1629$$
$$2x = 0.3258$$

In the second case we put x and y in their usual position. We have given $a = tg\ 63^\circ = 1.9626$; $x_1 = -0.03125$; $y_1 = 0.1$.

$$y - 0.1 = 1.9626\ (x + 0.03125)$$
$$y = 1.9626x + 0.1613$$
$$x = 0.5094y - 0.0822$$
$$x^2 = 0.2595y^2 - 0.0837y + 0.0067$$
$$R^2 = 1.2595y^2 - 0.0837y + 0.0067$$
$$y^2 - 0.0665y = 0.0251$$
$$y = 0.19525$$
$$2y = 0.3905$$

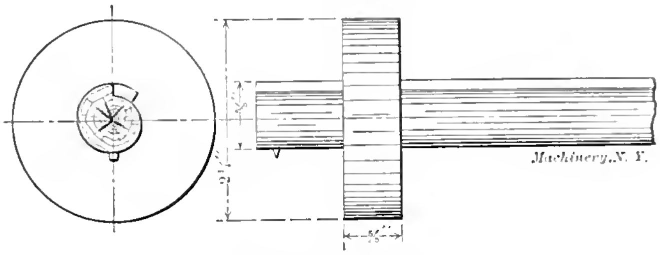
This is a good exercise for students in analytical geometry, and a test of the accuracy of their arithmetical work.

Syracuse, N. Y. WILLIAM KENT

[While the above solution may be more elegant than a trignometrical one, and seem preferable to the mathematician for that reason, it involves considerably more arithmetical work, and requires more time for working out than the trigonometrical solutions offered in the August issue and in the present number. From a practical point of view, therefore, and for practical purposes, it seems that the trigonometrical solutions are to be preferred.—EDITOR.]

PATTERNMAKERS' SCRATCH GAGE.

The illustration below shows a patternmaker's scratch gage. This scratch gage is constructed entirely of hardwood (black walnut preferred). The stick is made the full length in the shape of a cam, in a uniformly increasing involute curve. The hole in the guide is made of the same shape as the outside of the stick, but the curve is carried about 5/16 inch farther around, which makes it a little larger than the stick. Now, if the stick is slid into the guide, and then the guide revolved around the stick a quarter turn, it will clamp tightly. This makes a simple, neat, quick-adjusting tool for the patternmaker or carpenter. This gage is the invention of Mr. Ed. Therrian, of Two Harbors, Minn., and he has used it for years with great satisfaction. AUSTIN G. JOHNSON.



Quick-adjusting Scratch Gage.

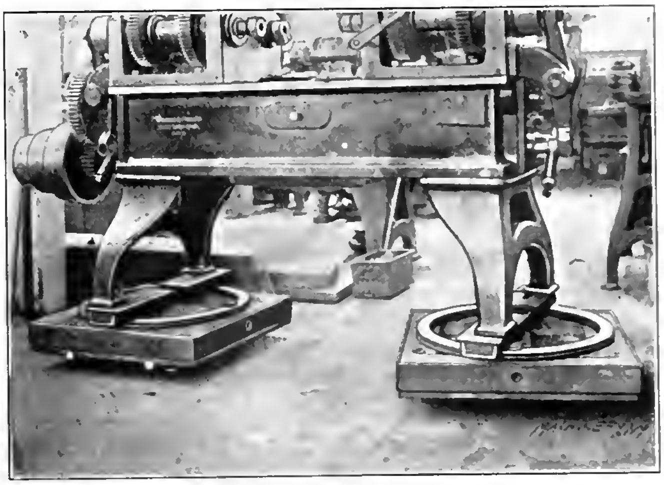
TRUCKS FOR MOVING MACHINERY.

In the September issue of MACHINERY we published an article by Mr. Ethan Viall, under the above title, descriptive of a small truck used for moving machinery, heavy castings, etc., about the shop, together with a drawing giving its principal dimensions. The accompanying illustration gives an idea of the usefulness of a pair of these trucks in a shop. As the top of the truck platform is comparatively close to the floor, heavy tools can easily be placed upon them and moved from one place to another.



Machine Tool mounted on a Pair of Trucks.

SHOP KINKS.

A DEPARTMENT OF PRACTICAL IDEAS FOR THE SHOP.

Contributions of kinks, devices and methods of doing work are solicited for this column. Write on one side of the paper only and send sketches when necessary.

STAMPING TRACINGS.

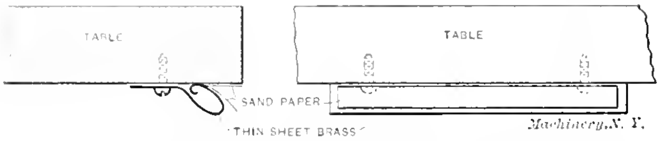
To stamp names or headings on tracing cloth, use a rubber stamp with the ordinary red, blue or green ink found in inking pads. Before the ink has a chance to dry, sprinkle lamp-black over it, using an insect powder sprayer for the purpose. When dry, brush off with a piece of chamois skin. Stamping done in this manner will be found light-proof.

Aurora, Ill. JOHN B. SPERRY.

PENCIL SHARPENER.

The accompanying engraving represents a pencil sharpener or pointer. As seen from the illustration, it consists of a piece of thin spring brass bent to the form shown and fastened under the table near the edge by two round-head wood screws. The sandpaper is held between the table and the brass spring. To sharpen the lead of the pencil, slip the point between the leaves of the sandpaper and move it back and forth. JOHN B. SPERRY.

Aurora, Ill.



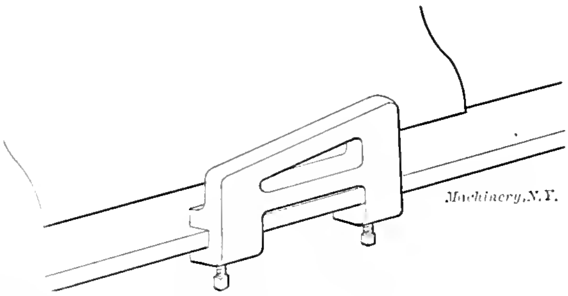
HARDENING DRILLS FOR DRILLING SPRING STEEL.

The difficulty of making a drill stand up when drilling spring steel is probably well known to all of the readers of MACHINERY who have had to do with this kind of work. The writer has been using the following method for hardening drills, with much success. A hole is drilled about ¼ inch deep in a piece of lead with the point of the drill to be hardened, care being taken that, when the drill is removed, the hole is not enlarged more than necessary to get the drill out. Then, the point of the drill is heated cherry red, and again placed in the hole and given a light blow with a hammer, and permitted to cool in the lead. It then will stand up much longer than otherwise. Turpentine is a good lubricant when drilling this kind of material. WILLIAM DAVIS.

Philadelphia, Pa.

HANDY ATTACHMENT FOR LATHES.

The accompanying illustration shows a handy attachment for lathes. The tapered slot in the casting holds the head of the set-screw in the dog when tightening it on stock. No machine work is necessary in the construction of this tool, save the drilling for two set-screws; and the device saves many steps when wrenches are scarce and hard to find.



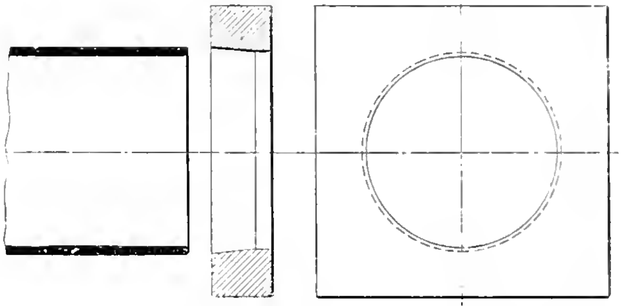
Middletown, N. Y. DONALD A. HAMPSON.

SAVING A TAP WARPED IN HARDENING.

The following method of saving a tap warped in hardening may be of special interest to those having to do with tools of this or similar description. The tap in question was of the expansion type, with a hole drilled longitudinally through its center, and reamed for a taper pin, which latter was used for expanding the tap. The total length of the tap was 20 inches, the diameter being 1¼ inch. A length of 4 inches in the center was threaded, leaving 8 inches on the one end for a guide and 8 inches on the other end for the shank. The tap was hardened, but when tried on its centers after hardening, it was found that it had warped and that there was not enough left on the shank and guide for grinding, so that the thread would run true with its guide bushings. To remedy this defect, a piece of brass was soldered onto each end of the tap, and after this was done, a piece of cast iron was chucked in the lathe and a hole bored and a thread cut to fit the tap, which was then screwed into this cast iron piece backwards, so that it would not cut its way through. The end which projected was then centered, the center being cut, of course, in the piece of brass fastened to it. When this was done the tap was screwed through the casting, the chuck was taken off and reversed, and the tap was screwed in from the back of the chuck, and the other end centered. The tap was now put on the new centers in the brass pieces and the threaded part, when tested, ran absolutely true. F. M.

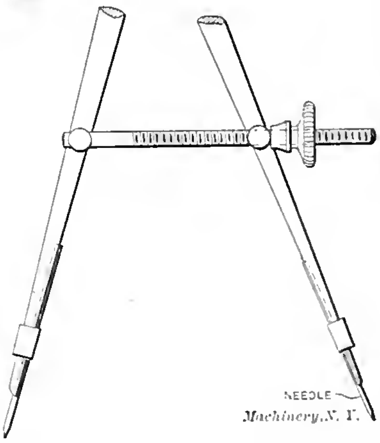
TIGHTENING A BUSHING FOR PAPER ROLLS.

To the left of the accompanying line engraving is shown the end of a brass bushing placed on rolls used in paper mills for feeding the paper through the machines. The rolls are about 2 feet in diameter and 10 feet long, and the brass bushing, which is about 3/8 inch thick, became loose on one roll. The following method of tightening it proved very satisfactory, and may be of interest to others. In order to diminish the size of the bushing so as to tighten it on the roll, a cast iron collar, shown to the right, was made, the smaller end of the taper hole bored in the collar being about 0.009 inch smaller than the outside diameter of the bushing on the roll. The brass bushing was next removed from the roll, and was forced through the collar, and then again pressed on the roll and turned true. E.



NEEDLES USED AS DIVIDER POINTS.

The engraving herewith shows the kind of divider points which I have on all my dividers and compasses. The inside of each divider leg is grooved about the depth of the diameter of an ordinary sewing needle, a needle is placed in the groove, and around the caliper leg and needle is fitted a band of brass. This band secures the needle to the leg as firmly as if they were one piece. This gives a hard, sharp, round point which can be thrown away when dull or broken. Die sinkers, tool-makers and machinists will find these the best divider points ever used. DIE MAKER.



[Sewing needles also make superior scribers for marking around templets on work requiring very exact duplication of outline and size. The points are much better than can be made by the average mechanic, being sharp, round, nicely tapered and of a fine temper. Of course, a suitable holder must be provided, but that is easy to make or buy.—EDITOR.]

NEW MACHINERY AND TOOLS.

A MONTHLY RECORD OF APPLIANCES FOR THE MACHINE SHOP.

CONSTANT-SPEED DRIVE FOR BROWN & SHARPE AUTOMATIC SCREW MACHINE.

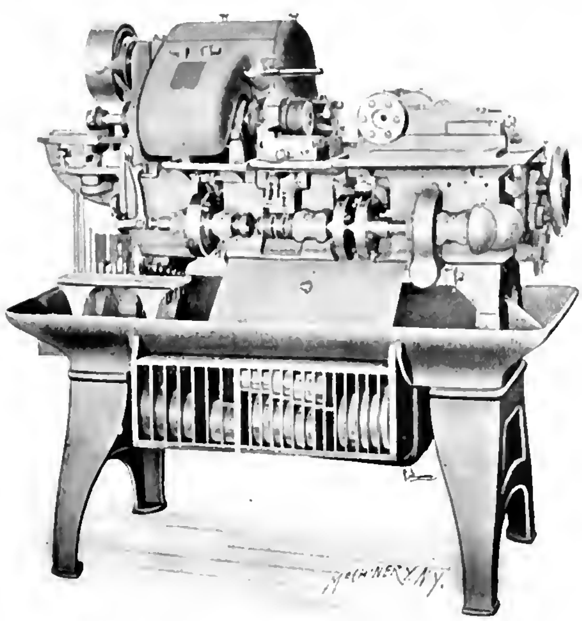


Fig. 1. Brown & Sharpe Automatic Screw Machine, Fitted with Geared Drive, Operated by a Single Conatant-speed Belt.

The automatic screw machine, of whatever design, has usually been driven from the counter-shaft by at least two belts, one for the spindle and the other for the feed mechanism, with sometimes a third for driving the oil pump. The counter-shaft also has usually been provided with two shafts, one of constant speed, receiving power from the line-shaft and driving the feed mechanism, and the other for the variable speed drive of the spindle, the two being connected by a belt over suitable cone pulleys. As a consequence of this complication, the ceiling of a screw-machine shop is completely covered with a mass of shafting, darkening the room, and causing trouble in the maintenance of the multitude of loose pulleys, hangers, clutches, etc. A large quantity of belting is also required. Besides this, the speed change, being made in the counter-shaft, is unhandy to operate, and rather difficult to keep in order, owing to the shortness of the belt on the cone pulleys.

The Brown & Sharpe Mfg. Co., of Providence, R. I., has recently designed for its automatic screw machine a constant-speed drive which does away with the various difficulties just mentioned, and gives to the screw machine, in addition, the same advantages that result in the application of the geared drive to other machine tools. The advantages include those of positive, strongly-driven feeds, self-contained mechanism, convenient manipulation, decrease in first cost and maintenance of belting and convenient provision for applying a constant-speed motor drive.

Fig. 1 shows a No. 2 automatic screw machine arranged with the constant-speed pulley drive, the construction of which is shown in Fig. 2. Flange pulley A is driven from the counter-shaft (or direct from the line-shafting, if preferred) by a constant-speed belt. This pulley, which is bronze bushed, revolves loosely on shaft G. A clutch, operated by a lever seen at the front of the machine at the rear end of the head-stock in Fig. 1, engages or disengages sleeve B and pulley A as required, to start or stop the machine. Sleeve B has formed in it pinion teeth engaging gear C, keyed to back-shaft D, which is thus driven at constant speed. Change gears E and F connect shafts D and G, giving a choice of six speeds for the latter.

On shaft D is mounted a bronzed bushed quill having a pinion formed on it at R, and a larger gear at O, and having keyed to it a sprocket P. Gear O meshes with a mating gear K of the same diameter, which is pinned to sprocket wheel L and a clutch member M, which normally revolve loosely on shaft G. Sprocket wheels P and L are thus constantly connected with each other, and revolve at the same rate of speed in opposite directions. Pinion R meshes with gear teeth on the periphery of clutch member J. A suitable clutch mechanism, operated automatically, may be made to engage either J or M, through H or I, with shaft G. When J is engaged, sprockets P and L revolve in opposite directions at a high rate of speed. When M is engaged, the sprockets receive movements in the same directions as before, but at a slower rate.

The spindle of the machine has mounted on it, on roller bearings, sprockets Q and N, which are connected by chains with corresponding sprockets P and L in the driving mechanism. To Q and N are keyed the heavy clutch members Z and X, either of which, as required, may be engaged with the spindle by the movement of clutch YY, which is automatically operated. The rims X and Z are made heavy enough to have a balance-wheel effect, as shown. This relieves the strain on the chain and the driving gearing in the very sudden spindle reversal which is a feature of this machine. The throwing of clutch YY thus serves to reverse the spindle, while the operation of clutch HH changes the speed from fast to slow, or *vice versa*. This combination of automatic reversal and speed change has a special value in threading and work of similar character, where it is an advantage to employ one speed for turning and a slower one for threading. The

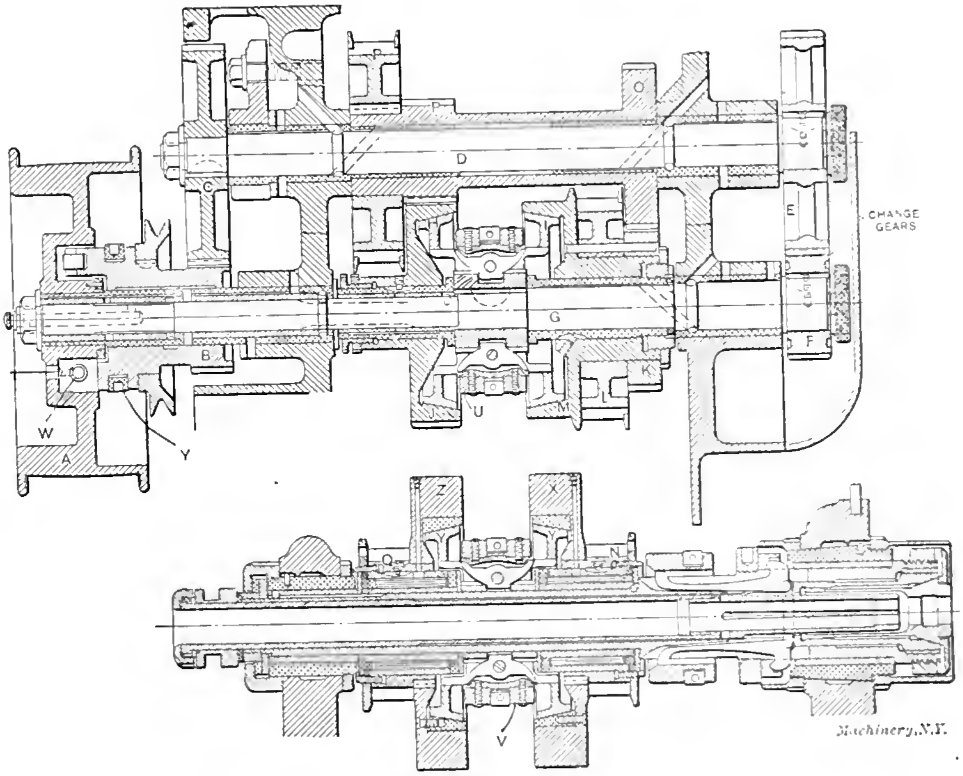

Fig. 2. Details of Construction of the Driving Mechanism, showing Provision for Automatic Reversal and Change of Spindle Speed.

speed change may also be employed in cases where the range of diameters turned, formed or drilled on a given piece is quite large, to permit all the operations to take place at suitable cutting speeds.

The feeding, operative, and idle movements of this machine, other than the revolving of the spindle, are driven by a shaft at the rear which runs at constant speed. This shaft is driven by a train of gearing, receiving motion from constant-speed gear *C* in Fig. 2. This connection includes a positive clutch thrown out by a lever at the front of the machine, so as to stop the feeding movements independently of the spindle. The power is transmitted through a shearing pin which furnishes a safety device in case of an accidental over-strain of the mechanism. On the back shaft, thus driven, is mounted a series of automatic throw-out clutches, similar in action to those used in punch presses. They operate various cams for controlling the feeding of the stock, the opening and closing of the chuck, the revolving of the turret, the reversing of the spindle and the change of speed from fast to slow or *vice versa*, the two latter movements being effected as previously described. Change gearing connects this back shaft *H*, see Fig. 3, through a worm drive, with a slow moving cam shaft *A* at the front, on which are mounted the cams for the turret and cross-slide movements, and a series of dog carriers and dogs which control the action of the various clutches on the back shaft. The change gears just mentioned determine the duration of the cycle of operations, and consequently the length of time it takes to make a given piece. The whole mechanism, as described, furnishes complete means for providing the various movements required in producing the parts for which the machine is set up.

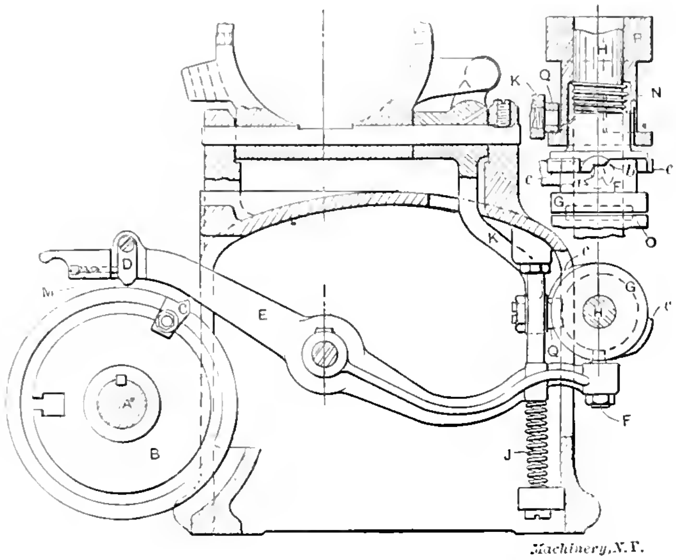

Fig 3. Cross-section through Bed, showing Reversing Mechanism.

In Fig. 3 is shown a section through the bed of the machine beneath the head-stock, which indicates the way in which the reversing movement is effected. There is a perplexing mechanical problem involved here which is solved in a very neat fashion. At *A* is shown the cam shaft at the front of the machine, to which is keyed dog carrier *B* provided with a T-slot in which are adjustably mounted dogs like the one shown at *C*. These dogs engage a tappet *D* on lever *E*, the rear end of which carries a screw *F* (locked by a nut) whose cylindrical point enters a cam groove in clutch *G*, mounted loosely on the constantly revolving back shaft *H*. A top view of the cam is shown in small detail above the position on the sectional view. The cam groove is exactly the same on the other side as on the side shown, the clutch being arranged to engage each half revolution and then automatically disengage. The normal position of the pin *F* is in the recess at *a*. When it is lowered entirely out of the groove by the action of dog *C* on tappet *D* against the pressure of spring *J*, this releases clutch *G*, which is forced forward by a spring *N* coiled about the shaft, until it engages a mating member *O*, fastened to shaft *H*, and is thus started to revolve. Meanwhile dog *C* has passed tappet *D*, allowing pin *F* to drop into the cam groove again. The clutch *G* as it revolves brings inclined face *b* of the groove (or a similar incline on the opposite side) into contact with *F*, and the continued revolution of *G*, through the action of this inclination on the pin, forces the clutch teeth out of engagement, stopping *G* again with the pin in position *a* as at the start. A cam *P*, also loose on the shaft *H*, is keyed to *G*. This cam engages a roll *Q* on the end of lever *K*, which operates a clutch fork, controlling *V* in Fig. 2. When it comes time to again reverse the spindle, another dog *C* is set in the proper position, and the clutch is again tripped, revolving for a second time a half revolution and stopping, operating lever *K* and the clutch fork to change the direction of rotation of the spindle back again.

This represents the normal procedure in cases where the time taken to make one piece is short enough so that the rotation of dog carrier *B* is reasonably rapid. For many pieces, however, this movement is so slow that dog *C* does not come out from under tappet *D* in time to allow pin *F* to drop into the cam groove before the clutch has made the required half revolution. In such cases, incline *b* having been passed without raising the clutch out, the pin can not drop in until the next recess comes along, and the next incline *b*, thus stopping the clutch at the end of one revolution instead of a half revolution. This difficulty has been very simply overcome by the following means:

Tappet *D* is pivoted to lever *E* as shown, and is forced back against a shoulder to the position indicated, by a spring *M*, located in a drilled hole, and pressing against a plunger bearing on *D*. This spring is of such strength as compared with spring *J* that the first effect of dog *C*, when it strikes *D*, is to move the latter backward without raising lever *E*. When *D* has been pressed so far back that it strikes the shoulder at the left, further movement being impossible, *E* is raised, pin *F* is withdrawn from the cam slot in the clutch *G*, and the latter is allowed to engage fixed member *O* on the shaft *H*, and starts to revolve. A cam surface *c* is provided on *G* which, immediately after the commencement of the rotation of the clutch, strikes pin *F* and depresses it still further, thus raising tappet *D* clear above the point of dog *C*, and allowing it to swing back to its normal position against the shoulder at the right under the influence of spring *M*. Lever *E* is then at once ready to drop, *D* and *C* being entirely clear of each other. As soon as the end of cam projection *e* passes, *F* drops into the groove and the rotation of the cam is arrested on the half revolution as required. When it is stated that shaft *H* revolves at 120 revolutions per minute, so that the half revolution of *G* occupies but ¼ of a second, it will be seen that the device has a difficult duty to perform. It performs it in a very satisfactory manner. Dog carrier *B* may even be arrested as soon as the clutch is tripped, but the springing back of dog *D*, affected by the mechanism just described, will bring the points of *D* and *C* clear of each other, so that the latter is allowed to drop immediately and in time to stop the clutch. A second half revolution clutch and connected cam (similar in principle though somewhat differently arranged) is provided for controlling the fast and slow movements, as determined by the position of clutch *HI* in Fig. 2. A second set of dogs and a second lever are provided on the other side of dog carrier *B* for controlling this action.

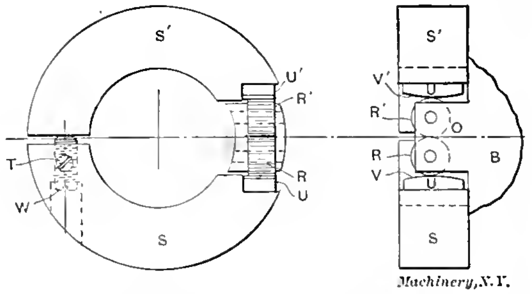

Fig. 4. Detail of Clutch Mechanism.

The friction clutch in the machine driving pulley (see Fig. 4) is entirely new in design and differs greatly from the usual type of friction employed for this purpose. The driving pulley *A* carries a split friction ring *S* and *S'*, which is

expanded by two hardened rolls *R* and *R'* on the end of the sliding pinion sleeve *B*. These rolls operate against the hardened shoes *U* and *U'*, the inner surfaces of which are arcs of circles. The sliding sleeve *B* is operated by a hand lever, conveniently located, whose fork engages the ring *Y*. To operate the friction, the rolls are forced in between the shoes a little beyond the centers of the arcs, thus expanding the ring and clamping it to the pulley. As the rolls are beyond the centers of the arcs, they remain locked in position. This rolling movement effects a powerful expansion of the ring, with but a very slight expenditure of force on the part of the operator. To compensate for wear, the friction ring is adjusted by the screw *W* and clamped by the set-screw *T*.

The grooved pulley, which is shown keyed to the hub of sleeve *B* in Fig. 2, is used for driving the various attachments with which this make of automatic screw machine may be fitted. This line of attachments includes those for automatic screw slotting, high-speed drilling in the turret, cross drilling on the cross-slide, and other similar devices. They are driven by a self-contained counter-shaft mounted as shown in Fig. 5, being attached to pads on the back of the headstock prepared to receive it. These pads are machined, drilled and tapped to accurate dimensions when the machine is sent out, so that the counter-shaft may be supplied and attached at any time by the purchaser. The various grooved pulleys shown, of different diameters, may be used as required to give the desired speed to whatever attachment may be in use at the time.

As may be seen from the details shown in Fig. 2, the whole mechanism is carefully designed to give an efficient and durable construction. The wearing surface and spindle bearings are amply proportioned to withstand the most severe service which a machine of this size and capacity should be subjected to. All the working parts are easy of access and readily adjusted, though carefully protected from chips and dirt. The driving chains are of the silent running design, operating quietly and efficiently at high speed. All the bearings in the spindle drive are bushed with phosphor bronze and, wherever considered advisable, the shafts are hardened.

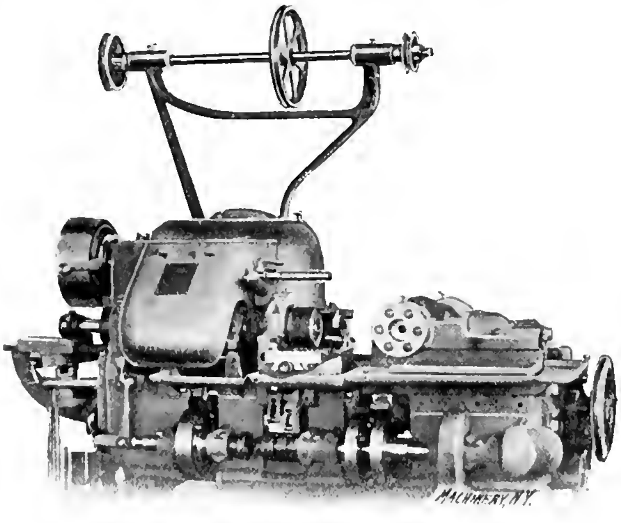

Fig. 5. Self-contained Counter-shaft for Driving Attachments.

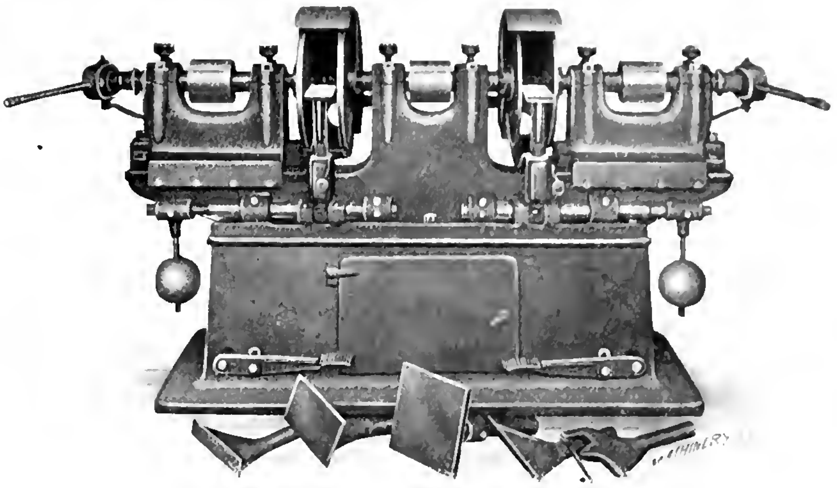
FOUR-DISK GORTON GRINDER.

The maker of the Gorton disk grinder (The Diamond Machine Co., Providence, R. I.) has designed a form of that machine which carries four disks, and is adapted for grinding in two stages, work having parallel sides or sides at a slight angle with each other. One pair of disks does the roughing and the other pair the finishing, there being opportunity for using two operators on work of this kind.

The machine is provided with a heavy base on which the bed of the machine is mounted. Supported in bearings in the center of this bed is the main spindle, driven from the counter-shaft by a pulley between the bearings, and provided with a grinding disk at each end. The ends of the bed are machined to form ways on which slide the adjustable grinding heads, each of which carries a spindle and a grinding disk facing the corresponding one on the central spindle. These heads are adjustable on the bed to give any distance between the disks up to 12 inches. The heads are not mounted directly on the base, being clamped to saddles on which each has a swivel adjustment for any angle up to 10 degrees. This allows small angles to be ground at one setting.

The outer spindles have a longitudinal movement for feeding in against the work. This movement, which is limited by a micrometer stop, reading to 0.001 inch, may be effected either by the hand levers at the end of these spindles, or by the treadles shown on the base of the machine, the latter being connected with the hand levers by suitable link work. This foot-operated feed can be disconnected if necessary, though it does not interfere with the regular hand-operating device in any way. The work tables (which are furnished in various widths, or can be made specially to suit work difficult to hold otherwise) are adjustably mounted on counter-weighted rocking bars, as is usual in disk grinders, and may be swung in and out between the faces of the disks by hand levers projecting toward the front. The adjustable heads may be removed entirely if desired, and swiveled tables provided for the work, in which case the machine has all the adjustments of the standard machine.



A Four-disk Grinder especially adapted to Two-operation Work.

While this machine was originally designed and is here shown as a regular disk grinder, the disks may be replaced with chucks for holding emery rings, so that heavy grinding can be done. It will sometimes be found convenient to use a set of emery rings on one end of the machine, for roughing work which is finished between a pair of disks at the other end.

HAMILTON VARIABLE SPEED PLANER.

The two accompanying engravings show an improved form of planer drive built by the Hamilton Machine Tool Co., Hamilton, Ohio, which gives four changes of forward or cutting speed with a constant return, thus giving the machine the advantage of a variable cutting speed the same as has always been provided for other machine tools, such as lathes and milling machines. The changes are made entirely in the machine itself, and require no complication in the construction of the counter-shaft. Fig. 1 shows the general appearance of a planer so equipped.

The driving shaft has mounted on it four pulleys, only one of which, that for the return movement, is keyed to it. The others are: the loose pulley for the return motion, the loose pulley for the forward motion, and the forward driving pulley. The latter, as may be seen at the left of Fig. 2, is connected by gearing on the outside of the frame with a

secondary driving shaft parallel with and close to the main driving shaft. Inside the bed the main driving shaft has keyed to it a series of four gears of different diameters. The secondary driving shaft carries two sets of double mating gears, controlled by forks pinned to sliding rods. These rods may be manipulated by two handles shown on the outside of the bed at the left, so as to bring any one of the four into engagement with the mating gear on the driving shaft. The handles are so interlocked that it is impossible to engage more than one gear at a time.

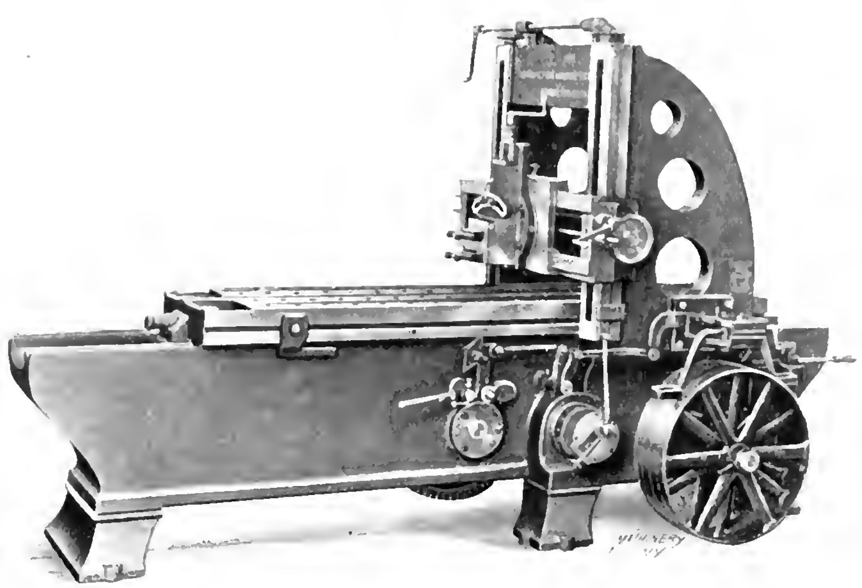


Fig. 1. 24-inch Hamilton Variable Speed Planer.

With any one of the four combinations of gearing in action, the drive is from the loose driving pulley through the outside gearing to the secondary driving shaft, and thence to the main driving shaft, through whichever one of the four pairs of gears happens to be engaged. From here the gearing connection is of standard form found on planers of the usual construction. On the reverse drive the movement is transmitted directly to the main driving shaft, to which the reverse pulley is keyed, the driving pulley running idly, meanwhile, from its connection through the change gearing and the outside gearing. One of the pair of outside gears is raw-hide, making a quiet running mechanism. The driving gears are of wide face and coarse pitch, running at comparatively slow speeds, and since only two of them are engaged at any one time, the action is smooth and durable.

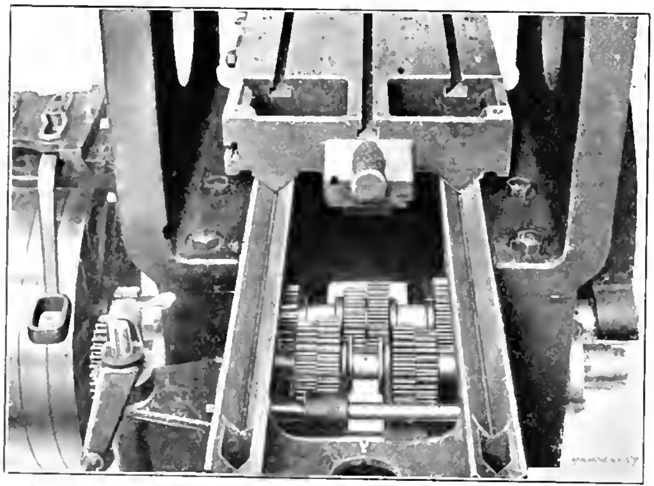

Fig. 2. Table run out to show Driving Change Gears in the Base

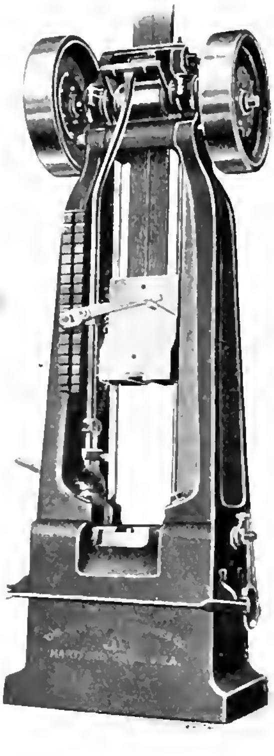
The placing of the gearing in the bed instead of on the housings overcomes any tendency to vibration, and locates it in a position which is out of the way and thoroughly protected, and yet easily accessible at any time. It is not intended that a speed change shall be made while the planer is running. While this is an advantage on some kinds of machinery, it is unnecessary on a planer, which has to be stopped to remove the work, rechuck it, or reset the tools prior to changing the cutting speed. For this reason the simple arrangement here provided can be used, giving, the builders believe, a much more satisfactory service than the complicated friction or tooth clutches sometimes used for such devices.

For the 24-inch machine, which is here shown, the forward cutting speeds usually provided are 20, 25½, 32, and 40 feet per minute, respectively, with a constant return of 80 feet per minute. Any reasonable variation may be obtained from these speeds by increasing or decreasing the speed of the countershaft, or by special modifications in the speed changing gears themselves made at the time the machine is built. By providing a two-speed countershaft, the number of cutting speeds may be increased to eight, though the four regularly furnished should be sufficient for the usual run of work. An index plate is attached to each machine, showing the different speeds provided and the proper location of the levers for each speed.

This variable speed drive, for which patents are pending, will be applied by the makers to any size of their line of planers of both the regular and widened patterns. It may be used for motor drive as well as for belt drive.

BILLINGS & SPENCER MODEL C DROP HAMMER.

The Billings & Spencer Co. of Hartford, Conn., has been making drop forgings for a period of about forty years. The firm has in that time used practically all the various forms of drop hammers on the market. The experience with these various hammers has, from time to time, given the company an opportunity to note their defects, and has suggested improvements. This led some twenty years ago to the building of hammers for use within the factory, and in this the firm has continued to the present time, bringing out successively the original Model A, a later design, Model B, and, finally, the machine here shown, Model C, which incorporates all the improvements suggested by the experience of the company in building drop hammers and using them. The new machine is intended to meet the demand for the much heavier work met with in the modern forging plant, where larger parts and harder materials are constantly being called for. This machine is not only much stronger than the old one for a given weight, but it also incorporates a number of distinctive features which will be mentioned in the description.



Billings & Spencer Model C Drop Hammer.

As shown in the accompanying half-tone, this hammer is of the board drop type, in which the weight is hung from a board which is raised by being clamped between revolving rollers. An improved board clamp catch is employed which

does away with the latch and connections at the side for holding the ram aloft. This clamp is located at the extreme top of the machine, above the friction rolls, where it is impossible for the oil to get between the gripping surface and the board, thus avoiding a most serious difficulty hitherto met with in some devices. This clamp, which is positive in its action, is controlled by clamps or eccentrics connected to a foot lever attached to the base of the machine. Another important feature of the tool lies in the adjustment provided for the rear friction roll. This adjustment is effected by means of an eccentric duplicating that used for the front friction roll. These two rolls, with their eccentrics, are therefore interchangeable. Owing to this construction, a true alignment between the lifting board and the rolls may always be preserved. A new form of bronze bushing is provided for these eccentric bearings, which may be easily and quickly removed and replaced. The attachment of the rear friction roll and the rear board clamp, which is also effected by an eccentric, are controlled by bars attached to the eccentrics and running down parallel with the uprights within easy reach of the operator on the floor. These bars are on the back of the machine and do not appear in the engraving.

The uprights used on the new model are of special design and greatly reduce the possibility of breakage, the distribution of metal being such as to afford a maximum of strength for the weight. The cross-section is that of the letter V, the apex, which is machined, forming the guide for the ram. A longitudinal rib running the entire length adds to the strength of the uprights. A feature of their construction is the fact that they are solid throughout their length, no weakening perforations being made for the fastening of attachments. The uprights are adjusted longitudinally on the base by a new and improved method, affording easy means of setting the dies. The releasing arrangement is attached to the front of the left-hand upright as shown. This may be placed in any one of a number of vertical positions at intervals of $1\frac{1}{2}$ inch, allowing the ram to be released at any desired height.

COCHRANE-BLY AUTOMATIC SAW SHARPENER.

The metal-sawing machines made by the Cochrane-Bly Co., of Rochester, N. Y., employ a saw blade having teeth ground in the manner shown in Fig. 2. As may be seen, they differ from ordinary milling saws in that every alternate tooth is beveled on each side to make a narrow cutting edge slightly higher than the other teeth. This high and narrow tooth takes a chip from the center of the cut while the following wide tooth takes two, one from each side. The chips drop freely from the slot, reducing the heat and friction of cutting and permitting greater feeds and increased production. While this form of tooth is thus a very efficient one, it is rather difficult to grind properly without special fixtures, and, to obtain the best results, the grinding should be performed automatically, so as to give uniform spacing and height to the teeth. The interesting tool shown in Fig. 1 has been designed by the builders to effect this conveniently and accurately.

Fig. 1. A Machine for Automatically Sharpening and Beveling Metal-cutting Saws.

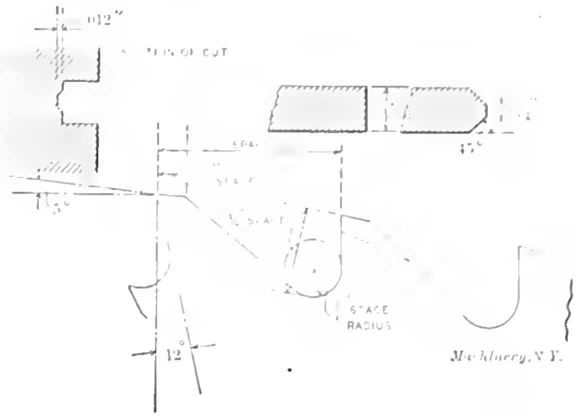


Fig. 2. Shape of Tooth produced by the Machine shown in Fig. 1

The saw blade is mounted on a spindle, with an index plate of the same number of teeth as the saw. The main emery wheel spindle is carried by a swinging frame, operated by cams and levers which give it two movements, one of which feeds the emery wheel toward the center of the saw, grinding the face of the teeth, after which the wheel is backed out and fed across the top of the teeth to grind the land. The frame is, of course, set to give the proper angle of tooth for each of these faces, and as the feeding movement starts at the point, it leaves the cutting edge sharp and free from burrs. This action takes places on every tooth with identically the same movement, except that each alternate tooth is ground about 0.012 inch lower, the high teeth being the ones that are subsequently beveled.

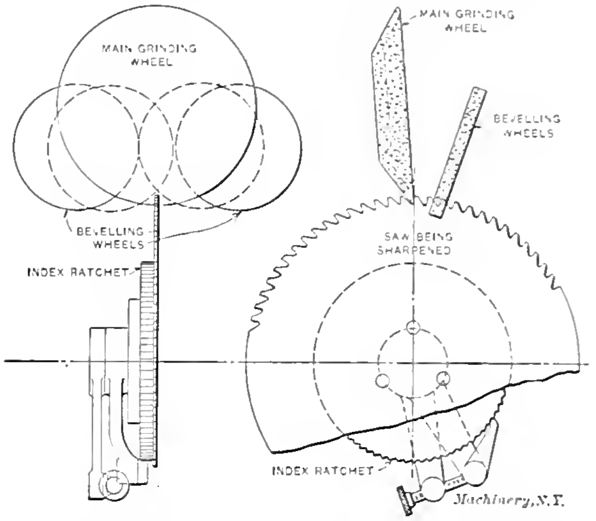

Fig. 3. Arrangement of the Grinding Wheels and the Saw to be Sharpened

The beveling is done by a pair of wheels mounted on a standard at the back of the work spindle support. They are attached to a slide which is reciprocated vertically on the standard by a cam, so as to alternately grind the upper and lower beveled corners of the alternate teeth. This is done while the main grinding wheel is working on the preceding tooth. The beveling wheels are raised from the work on each alternate low tooth. After each tooth has been ground, the saw is indexed by means of a cam-operated index lever engaging the ratchet wheel indicated in Fig. 3, and shown in Fig. 1, each tooth being thus brought to a certain fixed point, insuring even spacing. Fig. 3 shows plainly the relative positions of the wheels and the saw.

The spindle carrying the saw and index plate is set in a slide mounted on a bracket attached to the frame of the ma-

chine. This slide is adjusted by the hand screw on the bracket to accommodate the saws of different diameters. An adjustable automatic movement is provided for feeding the blade toward the emery wheels after each revolution of the saw, until enough stock has been removed to sharpen all the teeth properly. A special saucer shape is used for the main grinding wheel, which keeps its outward shape as it is worn down, and does not require constant dressing to produce the proper form of teeth. The cam movement of the machine governs the shape of the teeth.

The design of the machine shows evidences of having been carefully worked out. All the working parts are well protected from dust and dirt, the bearings being provided with covers and felt washers. The spindles are hardened and ground and the fitting is carefully attended to throughout the machine. There is but one adjustment, that which governs the depth of the teeth. This should vary according to the pitch and diameter of the blade. The capacity of the machine is for saws from 10 inches to 24 inches in diameter. The main emery wheel is 8 inches in diameter, while the beveling wheels are 5 inches in diameter. The net weight of the tool is 388 pounds.

HACKETT TWISTED DRILL.

Twist Drill made from a Flat Bar of Stock throughout its Entire Length

The drill shown in the accompanying engraving is made from a twisted flat bar of stock throughout its entire length, and may be held in a socket or machine spindle finished to the regular Morse taper standards. This, as shown, is accomplished by increasing the twist at the shank of the drill so as to form a good bearing, and grinding the spiral which is thus formed to fit accurately a Morse taper hole. The extreme end of the twisted bar is left straight and serves as a tang entering the slot in the socket, thus driving the tool in the same way as is done with a drill of the usual construction.

The construction of the tool is so obvious and so simple that little more need to be said about it. It can be made very inexpensively and of any suitable grade of steel, carbon or high-speed. It is lighter, and therefore easier to handle, and less expensive for stock than drills as commonly made, milled as they are from the solid bar. It will be noted that there is a tendency on the part of the tool to grip firmly into its taper seat under the pressure of the cut, as this causes the spiral to unwind somewhat, thereby increasing its diameter and causing it to expand tightly in the hole. These drills are sold by George E. Hackett, 90 West Street, New York City.

CORBIN-CHURCH HIGH-SPEED DRILLING MACHINE.

The Corbin-Church Co., New Britain, Conn., has designed a 13-inch high speed drill which is built in two different styles to suit the requirements of the purchaser. These two styles are shown in the accompanying half-tones, Fig. 1 showing the machine as a sensitive drill, and Fig. 2 the same machine with power feed applied. These drills are designed especially for the use of high speed tools.

The column is a solid casting with supports for the spindle and the various shafts required for the drive. The counter-shaft is contained in the machine and is provided with 8-inch tight and loose pulleys for 2-inch belt. A 3-step cone in the counter-shaft is connected by a belt with an idler cone, which in turn drives the spindle pulley by a quarter-turn belt running over suitably placed idlers. The strain of the belt on the driving pulley is taken by the sleeve on which it is mounted, leaving the movement of the spindle sensitive to the slightest touch. The large diameter of the pulleys used permits running the belt at a low tension while still furnishing sufficient driving power, thus prolonging the life of the belt greatly.

The spindle is balanced and is provided with a micrometer adjustment stop-collar on the sleeve for drilling to suitable depths. This stop-collar may be adjusted without stopping the machine. A special index is provided for measuring the depths of holes. The spindle is of tool steel and provided with a ball thrust bearing. The table is balanced by a weight inside the column. An index line is provided on the column for bringing the center of the table in line with the center of the spindle.

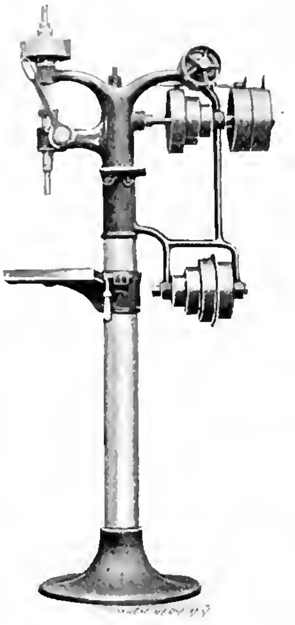

Fig. 1. Corbin-Church High-speed Sensitive Drill.

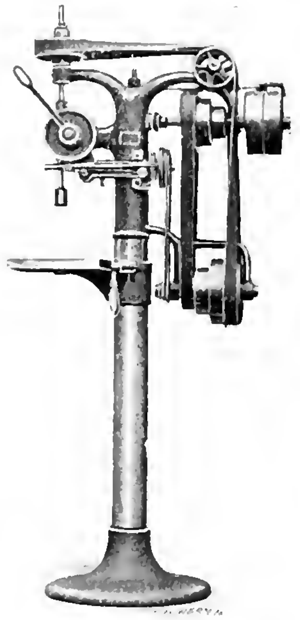

Fig. 2. High-speed Drill with Power Feed Attachment.

The power-feed attachment, shown applied in Fig. 2, is driven by a round belt from the idler cone-shaft, over a pair of 3-step cones which give a corresponding number of changes of feed. A drop worm and worm-wheel delivers the power to the feed pinion-shaft and furnishes means for providing an automatic stop. A special feature of the power-feed machine is the overbalancing of the spindle, and the automatic release of the feed, which allows the spindle to fly back to its starting position again at the conclusion of each cut. This leaves the operator nothing to do but put in and remove the work, and start the feed. This attachment is particularly useful on the multiple spindle type of this tool.

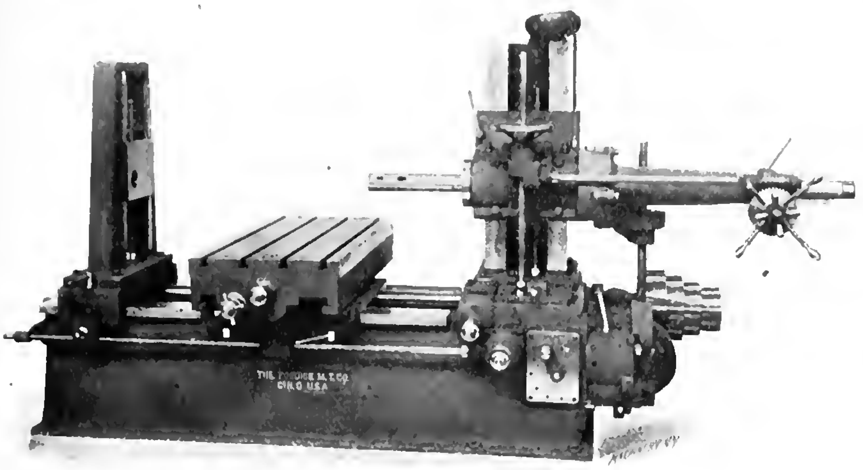
This machine gives the maximum range of 33 inches from the end of the spindle to the table, and a distance of 6⅝ inches from the center of the spindle to the column. As a single spindle machine it weighs about 325 pounds. It will be furnished with any number of spindles up to six. The makers invite comparison in design and workmanship with any other similar drills made.

FOSDICK HORIZONTAL BORING, DRILLING, AND MILLING MACHINE.

The accompanying illustration shows a horizontal boring, drilling, and milling machine brought out by the Fosdick Machine Tool Co., Cincinnati, Ohio. The illustration shows very plainly the general features of the design of this machine. The builders have particularly endeavored to make the machine convenient to operate, as this factor governs the output of any machine to the very largest extent. All levers and hand-wheels have consequently been placed on the operator's side, and within easy reach. The safety feature of operation

has also been given due attention, and all gearing and moving parts have been thoroughly encased. All the gears are made of steel, and provisions made for adjustment for wear of the spindle and alignment of the spindle with the outer support bearing. The outer support can be entirely removed if required, and independent adjustment provided for alignment if the operator should change the position of the head while the support is removed from the machine.

The spindle travel and the cross-feed of the table are actuated by power in either direction, and are equipped with graduated dials for micrometer adjustments. The diameter of the spindle is 3 inches in the driving sleeve, and 1½ inch in the rear sleeve, the end thrust being taken by ball bearings. The spindle is provided with a No. 5 Morse taper socket. There are eight spindle speeds, ranging from 12½ to 155 revolutions per minute, all being reversible. The feed changes are eight in number, varying from 0.007 to 0.250 inch per revolution of spindle. The spindle travel is 22 inches, and the vertical head travel, 21 inches. The lateral travel of the table is 36 inches, and the cross-feed, 28 inches. The working surface of the table is 50½ by 23½ inches. The table is provided with four T-slots and six stop holes.



Fosdick No. 0 Horizontal Boring, Drilling, and Milling Machine.

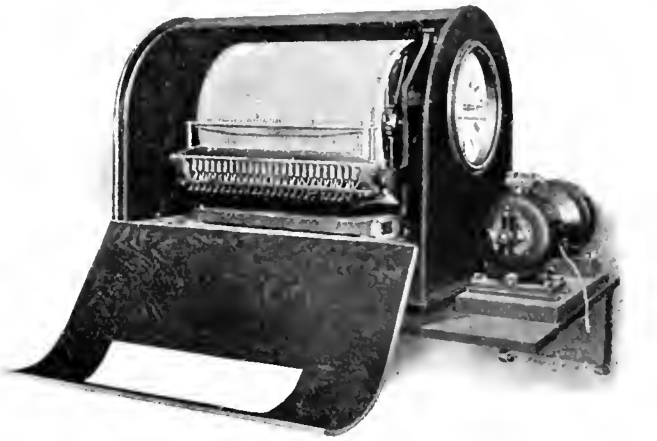
The drive is positive throughout and two mechanical changes are made with positive clutches. A 3-inch double belt is used on the cone pulley or on the constant-speed driving pulley. The counter-shaft has friction pulleys for forward and reverse, and is run at 400 revolutions per minute. When motor-driven, a 5-horse-power motor is recommended, and the motor can be direct connected to the machine through spur gearing. A constant speed motor can be applied to the machine in connection with the regular gear box for speed changes, or a 3 to 1 variable speed motor can be applied. The machine illustrated in the accompanying half-tone is termed by the makers as style No. 0. This machine requires a floor space of 13 feet in line with the spindle by 7 feet 8 inches traverse width, this latter dimension permitting the table to travel to its extreme limits. The net weight of the machine is 7,500 pounds. In addition to the No. 0 machine, two larger size machines, Nos. 1 and 2, are also built.

NATIONAL MACHINE RECORDER.

The instrument shown herewith, made by the National Machine Recorder Co., Marquette Building, Chicago, Ill., will automatically indicate and record the length of time that each of fifty machines is actually running, and the length of the corresponding idle periods. It consists of a revolving drum to which is attached a record sheet about 16 inches wide and 45 inches long, which is rotated evenly by clockwork and furnishes a complete record for twelve hours. Mounted in front of this rotating drum is a series of 50 metallic points or markers, each of which is controlled by an electromagnet connected in circuit with a switch attached to the counter-shaft of the machine whose working it is desired to record. When the belt shifter or clutch lever is thrown to start the machine, the circuit is connected, and the corresponding magnet, through the recording mechanism pushes the metallic point down until it presses on the paper, where it traces a line on the revolving surface as long as the machine is in operation. When the machine is stopped, the circuit is broken, and the metallic point drops back from the paper, breaking the line on the recorder. The fifty record lines are 5/16-inch apart, and the sheet is graduated horizontally in lines 1/16 inch apart, one for each minute, so that very accurate and easily read records are kept, it being possible to estimate the time as closely as within one-half minute. The device may be set up in the superintendent's office or that of any other official, without reference to the location of the machines to be recorded, except for the requirements of making the necessary wiring as short as possible.

The uses of such an instrument from the standpoint of the works manager are obvious. One of these is the matter of estimating the efficiency of the individual workman as far as concerns the wasting of time. A glance at the recorder will, in many cases, serve to show that a machine has been idle very much more than it should have been. Upon investigation, it can then be determined whether the difficulty lies with the machine or with the workman, and remedial measures applied.

The apparatus will also prove to be of the greatest value to the cost department in showing the length of time actually spent on work. In the case where the workman keeps his own record, the divisions of the time difference between jobs is notoriously inaccurate, the inaccuracies being due sometimes to carelessness and occasionally to design. The plan sometimes adopted of having men report to a time-keeper at the commencement and conclusion of each job is wasteful of time, and is not necessarily much more accurate than in the previous method. By the use of this instrument, however, in connection with the record of the work given out to the operator, it is possible to determine the time for commencement and completion of each job with the utmost accuracy, with the added advantage of knowing how much was spent in the changing from one operation to another. Having this accurate record on even the shortest jobs, it is possible to compare the time of the same operation in different lots, and by different workmen, and thus arrive by course of comparison and analysis at an estimate of the proper cost for given operations and given parts.



Instrument for Recording, Automatically, the Length of Time Machine Tools are Idle or in Operation.

This leads to the consideration of what would undoubtedly be the most useful function of the device in shops where the piece-work system is in vogue, namely, the setting of suitable rates for piece-work. In some plants, tests are made to determine what time should be required for each operation, and so establish piece rates. In most plants, however, owing to the complication of operations and the impossibility of properly forecasting the time without special training, this is done in a more or less haphazard manner. In such plants

there exist what are known among the piece-workers as "good" and "bad" jobs, evidencing the fact that the piece rates in force are either too high or too low. The common method followed in such places is to determine the length of time consumed in producing a certain output by day work, increase this output 10 or 15 per cent, and divide the quantity into the amount earned, the result being the piece-rate. This might be accurate if some workmen in the modern factory did not anticipate a piece rate on operations which are now being performed by day work, and did not use their ingenuity to curtail production, and keep the manager in ignorance as to what the actual output should be, so that when the piece rate is established it would be one at which it would be easy to make regular day wages.

With this machine, however, the actual length of time the machine has been producing, the duration and time of day of each producing period, and their idle moments are recorded. As the speeds and feeds are always subject to the foreman's supervision and the record shows whether or not a machine has been kept in operation for a suitable length of time, it is possible from the start to set an equitable rate of production for any given operation, and piece rates may be established with a reasonable degree of confidence.

The device should also prove a spur to the works manager himself. When the records are examined, the idle periods will doubtless seem unnecessarily long and it will be his place to investigate the reason for the delays in getting started on new work, in changing work in the machine, sharpening tools, and performing the other operations that detract from the cutting time of the machine. Such an investigation would naturally lead to a better system of shop management down to the smallest details. Since the record is made while the operation is in progress, it is possible to stop leaks of this kind at their inception. Without such a record most of the irregularities would never be discovered, while those that would be found out would come so late that investigation would be practically fruitless. This device was originally designed for the use of engineers interested in increasing production, and has proved a most valuable adjunct to that work.

STURTEVANT TYPE H ELECTRIC MOTORS.

The B. F. Sturtevant Co., Hyde Park, Mass., has designed a line of motors especially adapted for direct connection to the blowers and exhausters built by the same firm. They are of the 4-pole type, simple and compact in design and pleasing in appearance, as may be seen by reference to Fig. 1, which shows one of them connected to the blower.

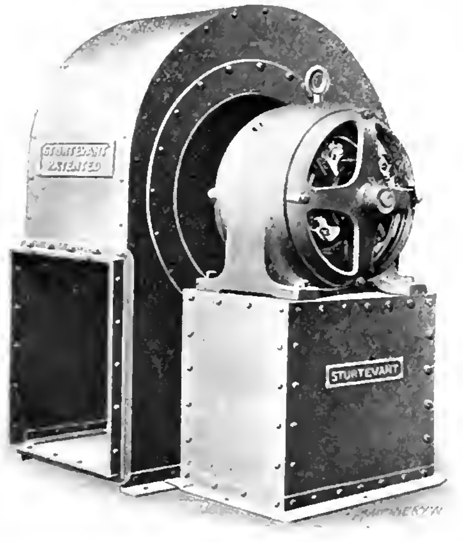


Fig. 1. Sturtevant Type H Electric Motor, connected to Blower.

The magnet frame is of cast iron with pole pieces bolted to the frame and located off center to permit the use of duplicate bearing brackets on each end. By taking out the through-bolts, the pole piece with its field coil may be removed without disturbing the armature or dismantling the motor. The pole pieces are built up of soft steel punchings secured between end plates while under pressure. They are of such shape as to afford a support to the field coil and so distribute the magnetic flux as to produce sparkless commutation under wide variations of load. Cast iron horns are provided to eliminate the disagreeable humming noise otherwise consequent to the use of laminated pole pieces. The field coils are machine wound, carefully insulated, and protected in the most improved manner against moisture or mechanical injury. The view of the machine dismantled in Fig. 2 will show the construction of these parts very plainly.

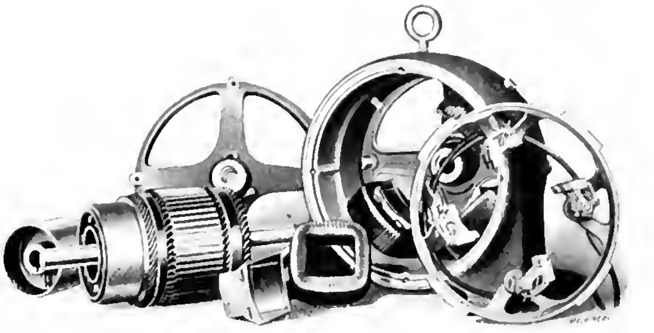

Fig. 2. View of Dismantled Motor, showing Construction.

The armature is of the iron-clad, slotted-drum type built up of soft annealed steel punchings, each insulated by a coating of japan. The punchings are assembled on a cast iron sleeve provided with openings for the full circulation of air. This is shown better in Fig. 3, where the direction of the current is indicated by arrows. The whole arrangement forms a fan exhauster between the armature and the commutator, taking in air at both ends. As may be seen in Fig. 3, the sleeve has an extended hub for the reception of the commutator shell, thus making the armature and the commutator a self-contained unit: The coils are of double cotton-covered copper wire or strap held in the slots by fiber wedges, thus preventing the stripping of the bands. The commutator is built of bars of hard drawn copper held in a cast iron shell of spider construction. Great care is exercised in selecting the mica, to have it of the same hardness as the copper, so that the wear of the two substances will be uniform. The whole commutator is assembled while hot under great pressure; thus each bar is held firmly in place, and the liability of its working loose reduced. The brushes are of carbon, and are held in holders of the sliding socket type provided with a braided copper pigtail, which relieves the brush holder body and springs of the necessity of carrying the current. The holder is supported by a ring seated in the machined recess in the magnet frame and clamped in position by the front bearing bracket. There is thus no danger of the brushes being thrown out of position or tilted, as is the case when the brush rigging is clamped by set-screws.

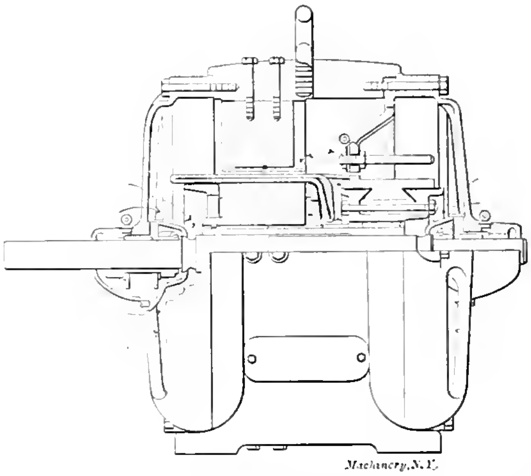

Fig. 3. Half-section illustrating the way in which a Free Circulation of Air is obtained.

These motors are designed to be as efficient as any motors built of the same size and speed, but have capacity for great

over-load. They will carry 50 per cent over-load for an hour without destructive sparking or heating, and will carry 100 per cent over-load for 5 minutes. These characteristics show their great adaptability for driving fans, particularly in factory service, when the fans are often over-loaded. Special pains have been taken to keep the heat-rise low. Tests made in clean dry places have shown the heat-rise for open and semi-enclosed motors less than 72 degrees F. at normal speed and output. These motors are made in a complete line from 1 to 100 horse-power in order to meet the requirements of all installations. Though primarily fan motors, they are applicable to the regular work of driving machine tools, etc.

THE NUTTER & BARNES AUTOMATIC SAW AND CUTTER SHARPENING MACHINES.

We show herewith in Figs. 1 and 2, illustrations of two machines made by Nutter & Barnes Co., 326 A St., Boston, Mass., for automatically sharpening gear and milling cutters, and for sharpening and beveling saw teeth. In these machines the cutter or saw is clamped in place, and automatically indexed, the machine spacing the teeth past the grinding wheel and feeding the latter back and forth across the face of the saw, or cutter. At the completion of each revolution of the latter, the wheel is fed in by hand until all the teeth are sharpened.

The saw and milling cutter sharpener, shown in Fig. 1, is an inexpensive machine intended for general shop and factory use wherever milling saws and cutters of various kinds within the range of the machine have to be sharpened. Saws from 2½ to 6 inches in diameter, and of any ordinary thickness, may be ground. Those which are badly worn may have a new set of teeth ground in them at very little expense, as the machine does not require close attention after being started. Old milling cutters of any diameter ranging from 2½ up to 6 inches, and for straight faces as wide as ⅝ inch, may also have their teeth renewed. An attachment at the rear of the machine is provided, by means of which the teeth may be easily backed off.

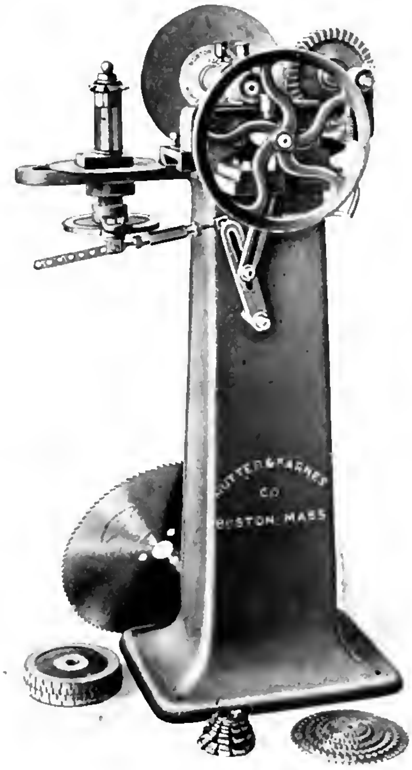

Fig. 1. Automatic Saw and Milling Cutter Sharpening Machine.

A feature of the machine is the indexing of the work by accurate index plates 6 inches in diameter. The use of these insures accurate spacing in the grinding, and permits the reshaping of teeth as described. They are also particularly useful in sharpening gear-cutters. This may be done with absolute correctness, so that the teeth will be spaced regularly and radially from the center line. This it is difficult to do in the ordinary manner without an index and means of holding the cutter central with the grinding wheel. Two index plates cut with any desired number of teeth are furnished with the machine. All the change necessary in going from one cutter to another is to change the arbor bushing and the index plate and this is a small matter, but very few minutes being required. The machine should be particularly profitable in the matter of reshaping old saws and cutters which have been abandoned on account of the teeth having become too shallow. These can have new teeth ground at much less expense than would be required for annealing, re-milling and re-hardening them.

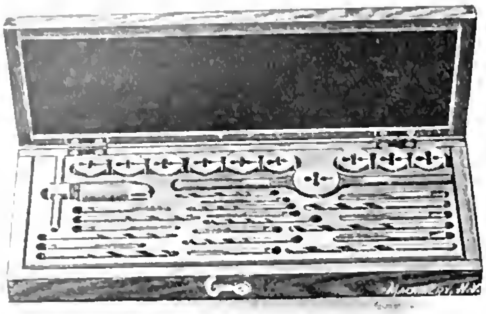
Fig. 2. Automatic Saw Sharpener and Tooth Beveling Machine.

In Fig. 2 is shown an automatic saw sharpener and tooth beveling machine of somewhat similar construction. In this case, also, the spindle is indexed from a ratchet wheel cut accurately to a number of spaces corresponding with the number of teeth in the saw. The reciprocation of the grinding wheel and the indexing are automatic. The feeding of the wheel to depth, however, is done by hand. Two index plates, one for sharpening and one for beveling, are furnished with the machine, covering the saws provided with the builder's cutting-off machine. For special index plates an extra charge will be made. At the rear of the saw-sharpening arrangement is placed the tooth beveling device, by means of which every other tooth may be beveled on opposite sides, thus relieving them of half of their thickness, while the cutting face remains the full thickness of the blade. This form of tooth breaks up the chip and allows the saw to run much more freely, practically eliminating the liability of its sticking when cutting soft stock. In no tooth, when so ground, is the full width presented to the surface of the cut. The saw is indexed in this operation the same as for sharpening, except that the index plate is set for half the number of teeth in the saw, skipping every other one. After the bevel has been completed on one side of the saw, it is turned over and treated the same as on the other side, for the alternate teeth.

REECE SCREW PLATES.

The illustration shows a screw plate set brought out by E. F. Reece Co., Greenfield, Mass., which is supplied in six assortments. The principal feature of novelty of the new screw plate set is that a Morse twist drill is provided for each size of tap, the drill, of course, being the correct size for drilling the tap hole. This feature makes a screw plate set complete, it containing all tools required for threading screws, nuts or tap holes.

Another feature of interest is a T tap wrench for holding the taps. These tap wrenches are made with spring-tempered tool steel centers in two sizes, having a range from 1/16 to 1/2 inch. These screw plate sets are made in machine screw and

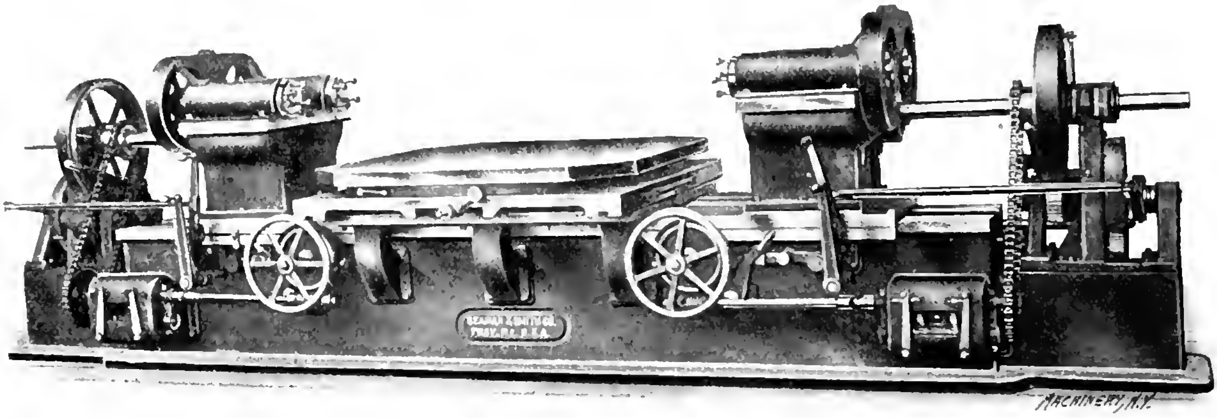


Reece Screw Plate Set, with Tap Drills.

fractional sizes. The machine screw assortment No. R. D. 3 cuts No. 2 to No. 16, inclusive, and the fractional sizes cut from 7/64 to 1/4 inch, inclusive.

BEAMAN & SMITH DUPLEX BORING MACHINE FOR AUTOMOBILE CYLINDERS.

The special boring machine shown herewith, built by the Beaman & Smith Co., Providence, R. I., combines a number of interesting features of design. It is of the type which has been called in England the "snout" boring machine, in which an overhanging rotary cutter head is fed in to the bottom of a blind cylinder bore. The operation corresponds to that of boring in the lathe, to the extent that the members of the machine are subject to a constant deflection, the tool having constantly the same over-hang from the beginning to the end of the cut. This is not the case with a boring-bar supported front and back, and fed through supporting bushings. By making the heads very strong and rigid, it is possible also to use multiple cutters, four being commonly used for roughing and six for finishing. This method of boring was described in an editorial in the May, 1906, issue of MACHINERY.



An Automobile Cylinder Boring Machine provided with a Rotating Table, permitting the Setting of Work while the Machine is in Operation.

The general construction of the machine designed by the Beaman & Smith Co. for employing this method of boring automobile cylinders, is plainly evident from the engraving. A work table is provided, pivoted so as to be swung around a cross-slide carriage, which is supported on the center of the bed. Sliding on ways on the bed on each side of this revolvable work table are two boring heads, each provided with two heavy spindles fixed in position, so far as center distance is concerned. The work is clamped to the revolving table opposite these spindles, and the heads in which they are mounted are fed forward on the bed until the boring tools have reached the bottom of the bore, when the feed is thrown out by an automatic stop. The heads are then quickly returned by power, allowing the table to be revolved and new parts to come in place to be machined.

The revolving table permits the clamping of work in place at the sides of the machine, while those presented to the spindles are being bored. At the completion of the operation, after the heads are withdrawn, the table may be indexed to bring the new pieces in position to be bored, leaving the completed parts ready to be taken off and replaced with unfinished work. This permits the machine to be in operation continuously, it being necessary to stop the boring only long enough to return the heads and index the work table. Another method of employing the revolving table, involves the use of roughing cutters on one head-stock and finishing cutters on the other; in this case, the work is indexed step by step. At the conclusion of each operation it is carried from the roughing head to the intermediate position at the rear of the machine, and then to the finishing head at the next move, finally returning to the intermediate position at the front of the machine, where it is removed and new work inserted.

Another important point in the design of the machine relates to the construction of the bearing surface on which the boring heads slide on the bed. As will be seen from an examination of the engraving, the support for the central table is raised above the bed, being mounted on three brackets attached to it on each side. The boring heads are bolted to carriages which extend for a considerable distance forward of the cutting tools, thus bringing the line of direct pressure within the bearing surface which supports the heads. This provision does away with the excessive wear at the front of the bearing surface which would otherwise take place and result in a pitching forward of the heads and a consequent disalignment of the machine.

The work table is clamped in its four positions by a lock bolt entering corresponding slots in hardened blocks, held in recesses on the under side of the table. These blocks are adjustable in their positions by screws on the upper surface of the table, so that the dividing can be done accurately at any time after the completion of the machine to make each indexing exactly 90 degrees. The carriage rotates on a ring of balls, making it very easy to swing around from one position to another. The table and the carriage are clamped together by a split reverse V-ring which brings these two parts down together firmly all around their whole periphery, and makes the table practically solid with the carriage. The short weighted lever seen just at the front of the cross slide is used to withdraw or insert the locking bolt for indexing the work table.

The carriage itself is adjustable crosswise of the machine on the base by which it is supported. This adjustment is guided by another bearing at the center to keep the movement accurately at right angles to the line of travel of the spindle. The movement is not a sliding one, there being no vertical pressure on this central bearing, and the vertical pressure at the edges being taken by a train of rollers on each side. Suitable clamps are provided for binding the carriage firmly to the base when the adjustment has been made. Instead of using fixed stops to locate the successive cross positions of the carriage required in boring multiple cylinders (or a series of single cylinders mounted side by side) a contact point and multiplying pointer are used to indicate the reaching of any desired position. Distance pieces of the required length are inserted between this contact point and the finger of the

pointer, thus providing for an accurate setting at the various cross distances desired. This is much more satisfactory than the using of stops, which probably could not be set in line with the thrust of the screw, and which would, for other reasons as well, give varying results in accordance with the degree of pressure applied to them.

The two ends of the machine are driven entirely independently. A driving shaft extends the length of the bed at the rear of the machine. This is connected by suitable gearing, as shown, with the splined shafts which lead to each of the heads. The connection with each of these splined driving shafts is through a friction clutch controlled by levers at the side of the bed in convenient position for inspecting the work, so that either may be stopped independently of the other. Each member is also provided with an automatic power feed driven by a sprocket-wheel and chain, as shown, from the driving shaft, and connected through a change gear box which gives four rates of feed. A drop worm and automatic stop are provided, so that the feed is arrested when the proper depth of boring has been reached. For the rapid handling of the head, a power traverse is provided, controlled by the lever seen just in front of the clutch lever on each end of the machine. Each head thus has independent controlling mechanism throughout.

LAPOINTE BROACHING MACHINE ARRANGED FOR BROACHING TAPERS.

The broaching machine built by the LaPointe Machine Tool Co. of Hudson, Mass., has recently been adapted by its builders to the broaching of taper holes. The machine thus arranged is shown in Fig. 1, while Figs. 2 and 3 show, respectively, the shape of the hole broached and the construction of the cutting tool by which the operation is performed. It is evidently impossible (except in the case of holes as large as in the job described in the July, 1908, issue of MACHINERY) to complete the forming of a square taper in one operation. This would require, as in the case there described, that the broach be made in sections, which must be guided in such a way as to travel in paths at the proper angle with each other to give the required taper. In the case of small work like that here shown, the plan is followed of cutting one corner of the taper at a time, and then indexing the work to four successive positions until each corner has been cut, which thus finishes the entire hole.

Fig. 1. Arrangement of Head and Cutter-bar for Broaching Tapers in the Lapointe Machine.

The work performed is indicated in Fig. 2. As shown, the hole to be broached is first finished with a taper reamer slightly larger at the large and small diameters than the width across the flat sides of the finished taper hole at the large and small ends. This gives a little clearance space for the broach to run out into on each of the operations. This round tapered hole also serves as a seat for the taper bushing on which the work is supported during the cutting operation, and as the broaching does not entirely clean out this hole, the bearing remains to the completion of the final operation. The work bushing and head may be seen in Figs 1 and 3. The work bushing, turned on its outside to the taper of the hole in the blank, is mounted at the head of the machine on a base which is inclined to the angle of the corner of the internal taper to be cut. In a groove formed on the under side of this tapered work bushing, slides the broach or cutter bar, having teeth formed in it after the usual fashion of such tools, smaller at the inner end and gradually increasing in height to the outer end until they conform to the full depth of the cut to be made. The work, of which several pieces are shown at the base of the machine in Fig. 1, has clamped to it a dog, as shown, with a slotted tail, adapted to engage any one of the four pins disposed equi-distantly about the edge of the disk which forms the base of the taper work bushing.

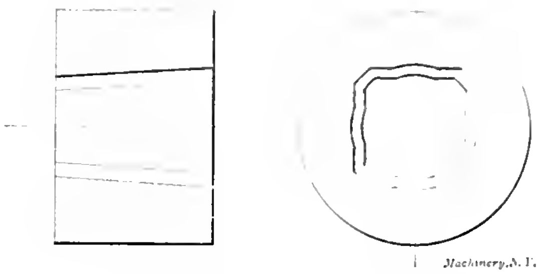


Fig. 2. The Taper Hole to be Broached.

In operation, the broach having been run out to the extreme of its travel, the work is inserted over the broach and pushed on to the taper work-holding bushing, and is located as to angular position by the engaging of the dog with one of the four pins as described. The machine is then started up and the broach is drawn back through the work, cutting out one of the corners. Then the blade is again run out, the work is drawn off by the taper bushing far enough to permit rotating it until the dog engages a second pin, when the operation is repeated, cutting out a second corner. The other two corners are successively finished in the same way, thus completing the machining of the hole to the form shown in Fig. 2.

It may be noted that while the hole shown has flatted corners, these are not required, as the broach can be made with a sharp corner if necessary. In all cases, however, it is necessary to leave a portion of the taper hole in the flat of the square, as shown in Fig. 2, so as to center the work with the bushing. Less of the circle, however, can be left than is shown in the engraving. For instance, at the large end the round taper hole need be only about 0.010 inch deeper than the square to be cut.

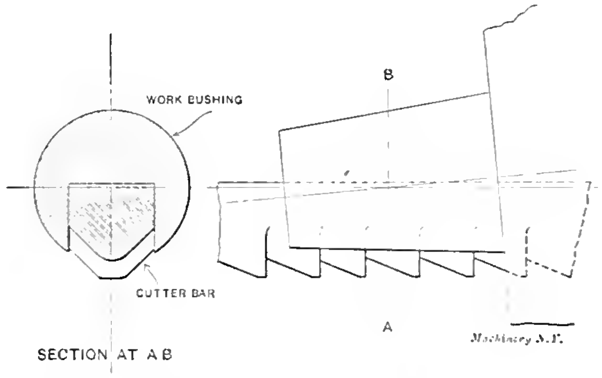

Fig. 3. Detail of Work-holding Bushing and Broach.

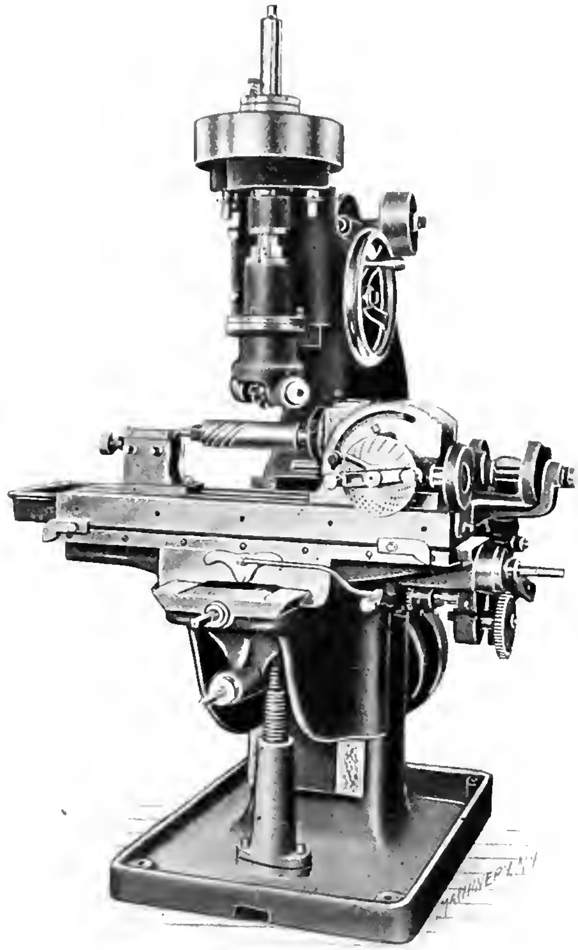
SPIRAL CUTTING ATTACHMENTS FOR THE BECKER VERTICAL MILLING MACHINE.

In the May, 1908 issue of MACHINERY, in the department of "New Machinery and Tools," we illustrated a horizontal attachment for the vertical miller built by the Becker Milling Machine Co. of Hyde Park, Mass. This horizontal attachment, it will be remembered, bears the same relation to the vertical milling machine, that the vertical attachment often furnished by horizontal milling machine builders bears to their product. It is adjustable at any angle about the axis of the spindle, the movement taking place in a horizontal plane instead of in a vertical plane, as in the case of the regular column and knee type machine. The builders of this attachment have recently designed the arrangement herewith shown, for providing a universal spiral and dividing head and connecting it with the table feed-screw. This device permits the cutting of spirals and doing other work which is strictly within the province of the universal milling machine.



Spiral Cutting Attachment applied to Becker Vertical Milling Machine.

The accompanying engraving shows the horizontal attachment and the spiral cutting arrangement mounted on the vertical milling machine, using a regular spiral head as provided with the builders' line of horizontal millers. The connection with the feed is made by means somewhat similar to that employed in the case of the circular milling attachment, with which this type of machine is often provided, except that both the table feed and the feed for the head are used simultaneously, while the ratio between them is varied by change gears to give a suitable range of spirals adapted to the general run of work of this kind. When set to the proper ratio, the operation of the table feed revolves the work spindle of the index head through the indexing mechanism, in the same way as in the universal miller.

The cutter, of course, for spiral work, has to be set at the helix angle of the groove to be cut. In the universal milling machine this is effected by swinging the table about a vertical axis. With the arrangement here shown, a corresponding effect is produced by swinging the spindle of the horizontal attachment about the axis of the spindle of the machine. This can be done with the same facility as in the universal miller, it being possible to center the cutter while the spindle is at right angles to the axis of the work and adjust it afterwards to the helix angle without altering the center adjustment. This makes the arrangement much superior to the devices oftentimes used on horizontal machines for somewhat similar purposes, where the cutter is usually mounted off the center of angular adjustment so that it cannot be centered with the work conveniently. Another advantage over the attachment for the horizontal machine, is in the simpler motion obtained, it being necessary to change the axis of the revolving spindle through but one right angle turn instead of two.

The machine is also, when thus arranged, more adaptable in some respects than the universal milling machine without attachments, since it is unlimited in the matter of angular settings, it being possible to bring the cutter spindle to positions between 45 degrees and a line parallel with the work—an adjustment impossible in the universal miller, where the table usually has 45 degrees of adjustment on each side of the center. The arrangement gives the same facility for cutting spiral tapers, etc., that the universal miller does, and would seem to cover its field quite effectively. The machine to which the attachments are shown applied in the engraving is of an older style, which is soon to be replaced with a new line, which the builders are now preparing for the market.

AUTOMATIC TRIMMING MACHINE FOR BOLT HEADS.

When ordinary machine bolts with square or hexagon heads are produced by the cold-forging process, the heads are first forged circular, and special trimming machines are employed for producing the square or hexagon heads by trimming off the superfluous metal by a trimming process. In the following, a machine for automatically trimming bolt heads, placed on the market by the E. J. Manville Machine Co., of Waterbury, Conn., is illustrated and described.

In order to make the principles of the machine clearer, a few words may be said on the subject of cold-forging of bolts. The bolt blank with its circular head is produced in a heading machine, in a manner as indicated by the three illustrations in Fig. 1. In the heading machine the wire is taken from the coil, straightened, and fed a predetermined distance until a cutting mechanism cuts it off to the required length. A die then receives and protects that portion of the blank which is to form the body of the bolt, and a punch compresses the projecting end of the blank into a preparatory cone shape, as shown in the central view, Fig. 1. Finally, a finishing punch forms the head to a circular shape.

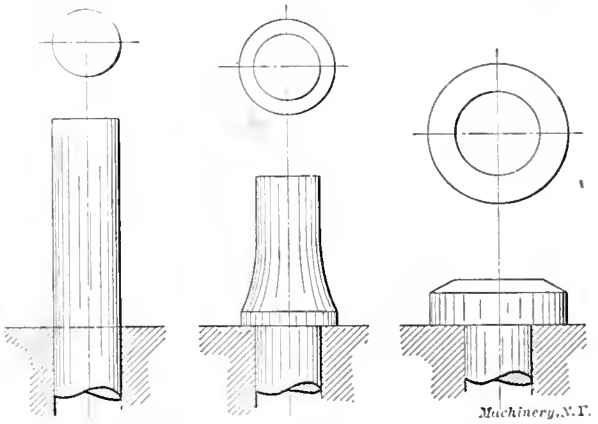


Fig. 1. Successive Steps in Cold Forging Bolts.

When the bolt blank is thus finished it passes to a trimming machine. Ordinarily the trimming operation is performed on a vertical power press, each bolt being placed by hand so that its body or shank is pushed up into a hollow punch, while the head is trimmed to the required shape. This process, however, is neither rapid nor safe, and the automatic bolt and head trimmer illustrated in Figs. 2 and 3 has been designed for rapidly carrying out the trimming operation.

The most important feature of this machine is the feeding device which must handle automatically several different sizes of work. The feeding device consists principally of a feed hopper, provided in its center with an oscillating slotted blade. This blade raises the blanks, holding them by their heads, and is pivoted at a point outside of the hopper. This lifter or blade is made of two plates of steel, riveted to a separating piece, the lower end of which is acted upon by a crank-pin and roller projecting from the face of a plate gear. This gear, in turn, is rotated by a pinion on the end of a short shaft driven by a belt on a 2-step pulley, the power being thus transmitted from the main crank-shaft, as clearly illustrated in Fig. 2. As the slotted blade passes upward through a quantity of headed blanks, several blanks will be lifted by their heads at each stroke. Owing to the incline of the blade when in its upper position, the tendency of the suspended blanks is to slide toward the lower end. A continuation of this sliding way is constructed of two stationary plates, as may be seen most clearly in Fig. 3, in which may also be seen the heads of several blanks automatically placed in proper position by the feeding device. At the junction of the stationary tracks and the lifting blade of the hopper, a device is introduced which stops the progress of every blank not properly delivered to the fixed track; this device returns such blanks to the hopper, and thereby insures a continuous action at the lower end of the race-way. A mechanically-actuated device holds back the descending column of blanks, and, at the proper moment, the lowest blank is separated from those behind it and forced outward into the spring jaws of a special carrier or transferring device as shown.

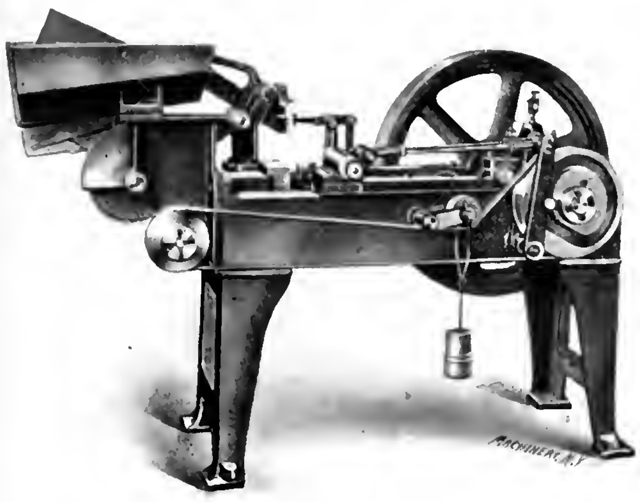

Fig. 2. Manville Machine Co.'s Automatic Bolt Head Trimmer.

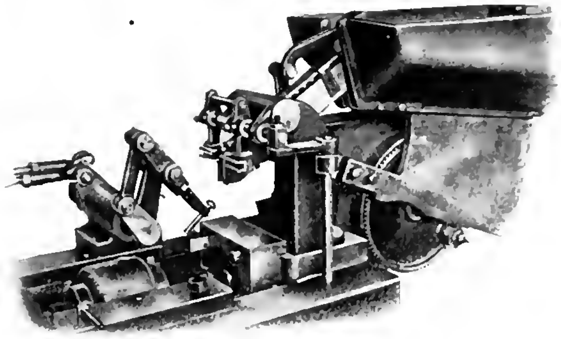

Fig. 3. Feeding Mechanism of Bolt Head Trimmer.

The blank is now transferred from the vertical position which it has had at the outlet point of the feeding device to a horizontal position in line with the punch and die for trimming the head. The mechanism by means of which this is accomplished consists of two rocking shafts working on the same center, each being moved through an arc of about 90 degrees by two cams on the crank-shaft of the machine. On the inner ends of these two rocking shafts are arms, to one of which is pivoted the finger lever holding the spring fingers which receive the blank from the feeding device and deliver it to the dies. A link joins the end opposite the spring finger and connects it with the second rocking shaft thus forming, as will be seen in Fig. 3, a parallelogram or linkage by which it is possible, with properly shaped cams, to cause a bolt held by the fingers to move in a predetermined path and place it in a horizontal position. When the bolt has reached the proper horizontal position, it comes to a rest until the hollow end of a square- or hexagon-ended punch advances a sufficient distance onto the end of the blank, at which moment the fingers move up to clear the punch.

The swinging fingers and their holders are easily removed from the finger lever and replaced by other fingers when a different diameter of bolt is to be handled. Means are provided for adjustment, so that the bolt will be placed in perfect line with the trimming tools at all times. When trimming the head, the punch advances on the shank or body of the blank until it reaches the under side of the head, when its further advance pushes the bolt head against the die and finally into it, thus shearing the head to the required shape. The punch then recedes, leaving the bolt in the die until, at the backward stroke, the bolt head is pushed out of the die by a knock-out pin.

EMMERT FACE GRINDING MACHINE.

The accompanying illustration shows a machine designed and built by the Emmert Mfg. Co., Waynesboro, Pa., intended for the grinding of lathe and planer tools, for squaring up ends of work, and for miscellaneous grinding in the toolroom or machine shop. As will be noticed from the illustration, the machine embodies several features in which its design differs from the common design of this kind of machine. One of the novel features is the provision for the use of a diamond for truing up both the side and the periphery of the wheel. This was made because the builders of this machine realized the difficulty of obtaining a true side on an emery wheel by an ordinary emery wheel dresser. A straight edge or surface on tools and a straight face on the edges of work is easier and more accurately obtained by using the side of the wheel than the periphery, provided the side is straight. To permit both the side and the periphery of the wheel to be used for grinding, the work table is located in front of the side of the wheel, and extends in front of the periphery, as shown. The table is carried by a transversely swinging arm, and in the end of the arm is a longitudinally adjusted diamond holder. When the table is in use, it may be either clamped to prevent any transverse rocking movement or adjusted to allow a certain amount of such movement, which is often of advantage when grinding wide work. When truing up the wheel, an adjustable stop below the table is moved out, and the table swung backward away from the wheel. In this position, the diamond is swung across the face of the wheel for truing purposes.

Emmert Mfg. Co.'s Face Grinder.

The table is designed to slide longitudinally and is provided with a threaded hole to receive the diamond holder, which can be transferred to this hole when the edge of the wheel is to be trued. The table slide is mounted on a pivot

in the swiveling arm, and can thus be clamped at any angle, up to 45 degrees with the face of the wheel. Graduations are provided for proper setting. On the table is also provided an adjustable squaring device or protractor, which may be set from 45 to 90 degrees with the surface of the wheel. The wheel spindle of the machine is hardened, and runs in adjustable bronze boxes. A water tank of ample capacity is provided for cooling the work. The wheels used are 12 inches in diameter by $1\frac{1}{2}$ inch thick, and are recessed in the center as shown.

UNIVERSAL BORING, MILLING AND DRILLING MACHINE.

The machine shown herewith is built by the Universal Boring Machine Co. of Hudson, Mass. As may be seen from Fig. 1, it is of the type in which the work table is provided with longitudinal and cross movements on a stationary bed, and in which the spindle is mounted on a saddle in such a way as to give it longitudinal movement in its bearings and a vertical movement, provided by the adjustment of the saddle on a stationary column. While the machine thus conforms to a type, the details of the design have been worked out in a very original and ingenious fashion. Some of these details are illustrated in Figs. 2, 3 and 4.

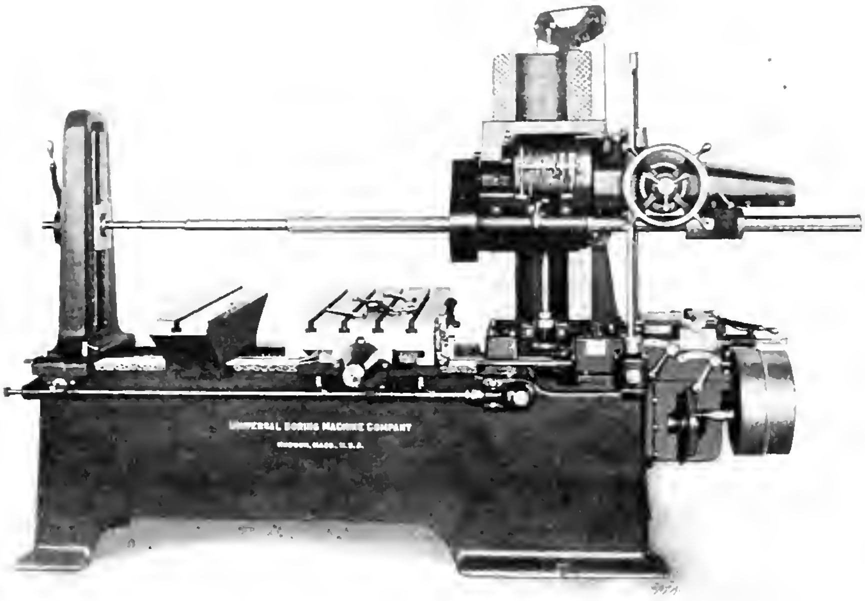

Fig. 1. The Universal Boring Machine Co.'s Universal Boring, Milling, and Drilling Machine.

In the first place, it will be noticed that the head is set at the right-hand end of the bed, contrary to previous practice in some other machines of this type. This arrangement permits running the spindle in the same direction for milling as for boring and drilling, and is convenient as well for the operator, who has the various controlling levers within easy reach of his right hand when closely examining the work. The base is of solid construction, and furnishes a suitable support for aligning the parts with sufficient accuracy to perform the high grade work for which the machine is intended. The column has guiding surfaces for the head so arranged that the latter is squared up by a comparatively long and narrow guiding surface, and at the same time it is provided with a wide area over which to distribute the wear. This guiding bearing has a length six times its width. In addition to this point, it should be noticed that the gibbing on one edge of the column is arranged with a square lock gib on the side nearest the work. One of the bearing surfaces on which the head moves is provided with a scale, which is graduated and marked in inches. The zero point indicates the position in which the center of the spindle is in a line with the top of the table.

An outboard support for boring-bars is provided, as shown, which is adjustable along the bed. The outboard bearing, which is gibbed to the internal guiding surface of this support, is raised and lowered by a screw connected by a spiral gearing and splined shafts to the elevating screw of the spindle head, so that the two move together simultaneously. A rapid raising and lowering movement is provided for the head. This may very profitably be used in connection with the vertical graduated scale just mentioned, making it possible to stop the rapid movement within $\frac{1}{8}$ inch of the desired setting of the spindle. From this point the hand adjustment is used to bring the dial on the elevating screw to a position to read the proper dimension in thousandths of an inch.

The boring-bar is driven from tight and loose pulleys operated by a belt running at constant speed. The loose pulley is provided with a method of self-oiling which does not require attention oftener than once a year or thereabouts. The design of the lubricating device is very simple, it consisting only of a hollow receptacle cast in the hub of the pulley, and filled with cotton waste which is saturated with oil, the latter being led to the bearing by a strip of wicking. Sixteen positive geared spindle speeds are provided, eight of them being obtained by a geared quick change mechanism, and this number being doubled by back gearing mounted in the head close to the spindle.

The construction of the speed box is shown in Figs. 2 and 3. To the driving shaft is keyed a cone of 4 gears *L*, fastened together, and capable of being shifted endwise by arms pinned to a rock-shaft *M*, which passes out through the front of the case. Here it has fastened to it a lever *A*, with a lock pin engaging four holes in the front of the casing, each of which corresponds to a position of the cone of four gears. On a shaft parallel to this driving shaft is mounted the tumbler gear arrangement shown in Fig. 2 and in detail in Fig. 3. This consists of a double rocker arm *N* mounted loosely on the shaft (though confined axially) and provided with pivots on each side of the shaft. On one of these pivots is mounted an idler gear *O* meshing with a small gear keyed to the shaft. On the other is mounted an idler meshing with a larger gear keyed to the shaft and pinned to a gear *P* having a position corresponding to the idler on the oppcsite pin of the rocker arm. This rocker arm has teeth cut in a segment of its periphery which mesh with a pinion operated by a crank *B* from the outside of the gear casing. This crank is provided with a pin which enters suitable holes in the casing, and thus determines the angular position of the rocker arm and the idler gears mounted on it.

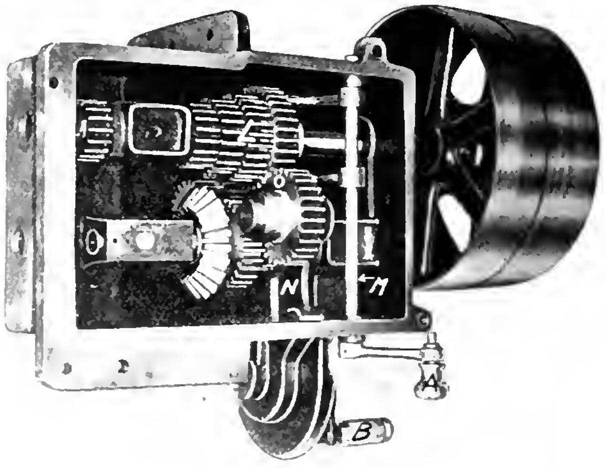

Fig. 2. The Change-gear Box which gives Eight Speeds.

The shifting of the cone of four gears and the rocking of the segment to which these idlers are pivoted, provides means for furnishing the changes of speed. In the position

shown in Fig. 2, the cone of gears is shifted so as to bring the largest one of the four in line with the pivoted idlers. In changing from one speed to another, these idlers are set in the neutral position, which allows the cone gears to be shifted freely without hitting them. When shifted to any given position, the holder carrying the idlers can be rocked to bring either the upper or the lower one into mesh with the gear presented for engagement, the position being located by the holes in which the lock pin on lever *A* is seated. The engaging of the upper or lower idler for each gear gives two speeds. This in combination with the four gears, gives eight changes of speed at this place, as previously mentioned. The bevel gear shown on the idler shaft in Figs. 2 and 3, transmits the movement through a vertical splined shaft to the head. From here (through a set of back gears operated by the handle seen at the front of the head) connection is made with a pinion driving a face-plate gear at the front end of the spindle. The sixteen speeds thus obtained range from 15 to 200 revolutions per minute, with a speed of 230 revolutions per minute given to the constant-speed driving shaft.

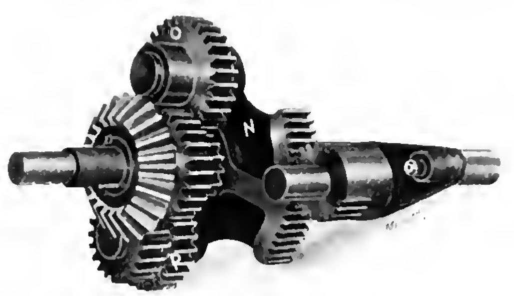

Fig. 3. Detail of the Tumbler Gear, seen in Fig. 2, which Doubles the Number of Speeds.

The spindle being thus driven by a geared face-plate on the side nearest the work, the capacity of the machine for doing heavy milling is greatly increased. Provision is made in the face of the spindle for bolting or otherwise fastening cutters, such as used in heavy milling work. The boring-bar feeds 27 inches, and can be arrested by a clamp bearing so that 55 inches of feed can be provided. A hand-wheel is set close to the work at a point convenient for operating and setting boring-bars. It allows the workman to be within easy reach of the cutting tool and of the hand-wheel and feed friction at the same time.

The machine has power feeds in all directions; that is, for the cross and longitudinal movements of the carriage, for the vertical movement of the head on the column, and for the longitudinal feed of the boring-bar. Nine feeds are provided, ranging from ¾ to 5½ inch feed per minute, taken from the constant-speed shaft. In connection with the spindle speed changes, this gives 144 different feeds in inches per revolution, ranging from 0.006 to 0.340. Of course all of these feeds per revolution cannot be obtained for each spindle speed.

The feed box is mounted above the speed change gear box at the right of the machine. It is controlled by levers *H* and *H*, each of which has three positions, permitting nine different combinations for the nine feeds with which the machine is provided. This mechanism controls all the feeds. It may be connected with the bar or table feed, as desired, by the manipulation of lever *C*. Connection with the feed elevating screw for vertical traverse in milling is made by operating lever *D*. This same lever shifted in the opposite direction gives a rapid movement of the slide on the column. These feeds, as well as all the other feeds and power traverse movements of the machine, are reversed by the operation of lever *E*. The power cross feed of the table is provided with an automatic stop operated by dogs seen at the right-hand side of the table in Fig. 1. The longitudinal feed of the carriage is obtained by connecting the splined feed shaft (transmitting the power to the table cross-feed screw) with the screw for the longitudinal feed of the carriage on the bed. This provision for power longitudinal feed of the carriage is an unusual one in boring machines, but it was so easily made that it was thought best to incorporate it in the design, as there may be cases in which it would prove useful.

All these adjustments can be operated for fine setting by hand as well, and it is interesting to note the way in which the adjustments and manipulating handles have been concentrated at the working end of the machine to make the operation as simple as possible. At *F* is shown the back gear controlling lever, the movement of which gives either a fast or slow speed to the spindle. This is located close to the spindle driving gear so that excessive torsion of long shafts is avoided. The hand-wheel for the rapid hand adjustment of the boring-bar is shown at *J*, with the feed friction mounted in its hub. The fine feed of the boring-bar, as well as the fine hand elevating adjustment, is effected by a crank on the end of squared shaft *K*. The carriage hand feed (which is out of the range of this engraving on the left) is controlled by another squared shaft. The belt shifter is seen at *Q*. A further point of convenience in the design of the tool is the segregation of the feed and speed mechanism in easily removable casings. The machine is to this extent constructed on the unit system. It is only necessary to remove six screws and pull out the feed and speed driving shafts, to permit the removal of the respective feed and speed box from the machine.

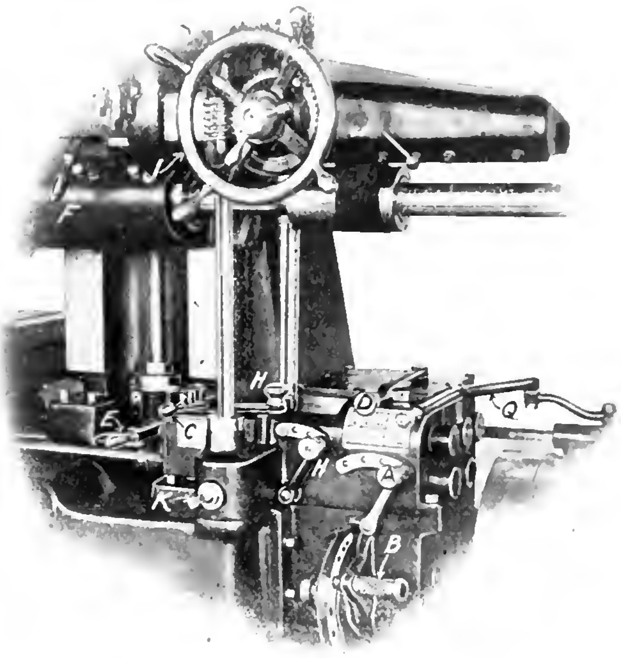

Fig. 4. View showing the Arrangement of the Controlling Handles in Locations convenient to the Operator.

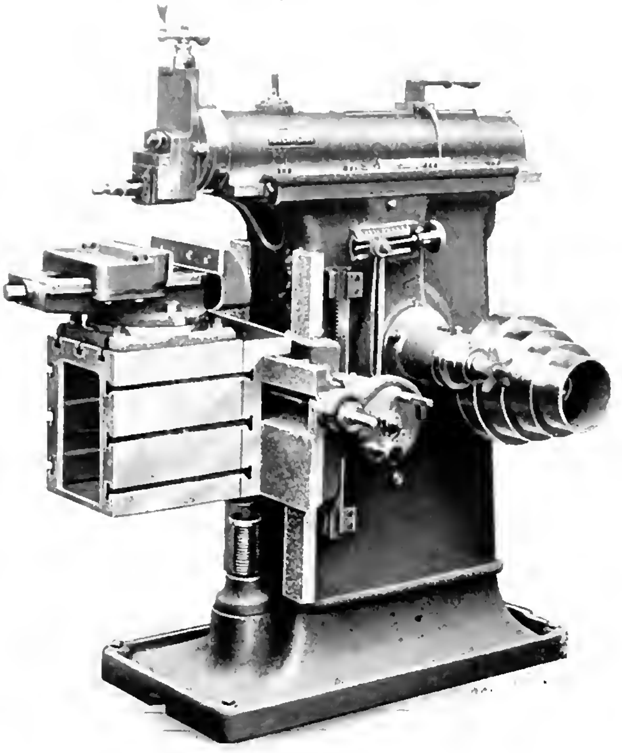
The machine is built to accurate dimensions throughout, so that the various parts are assembled without fitting in the principal dimensions. This means that a high grade of workmanship is employed, as is necessary on a machine to be used for the work for which it is designed. The weight and stiffness of the machine is also a great factor in producing accurate work. All the revolving parts such as shafts and studs are made of crucible steel and ground to size, while all bearings which have shafts running at any considerable speed are bushed with suitable bearing metal. In general, the builders have planned to make it a first-class tool in every respect, to meet the requirements for jig and fixture making, and for doing interchangeable work, as well, without the use of jigs and fixtures.

AMERICAN 15-INCH CRANK SHAPER.

Some time ago we published in MACHINERY a communication from one of our readers on the tool-room *versus* the machine-shop shaper. In this article many of the characteristic features required in each of these two classes of shapers were referred to. The distinction between a tool-room and a machine-shop shaper is becoming more and more apparent with the introduction of new machine shop methods, and it has been recognized by manufacturers of this class of tool that the ordinary shaper of the past is entirely inadequate to meet the demands of the present time. The shaper,

which in the past has often been regarded merely as a tool-room machine, has been made a manufacturing machine. In order to meet these changed conditions, the American Tool Works Co., 300-350 Culvert St., Cincinnati, Ohio, has brought out a new line of extra heavy and powerful shapers intended especially for heavy duty and designed with a view of permitting not only a high rate of production, but at the same time insuring accuracy of alignments and durability.

In order to secure the desired end, the column of the new shaper has been made wider and deeper than usual, and is strongly braced internally, thereby offering proper reinforcement along the lines of the heaviest strain. The column projects both at the front and the back in order to give a long bearing for the ram, and the base is made large, so as to give proper support to the machine. The ram is thoroughly braced by internal ribs, its bearing in the column is wide, and it is provided with a continuous taper gib, having end screw adjustment for taking up the wear. The stroke of the ram is positive, and there are four rates of speed, ranging from 20 to 65 strokes per minute. The length of the stroke can be changed without stopping the machine. A pointer on the ram, traveling along an index, as shown in the illustration, shows the length of stroke at any setting. The tool-carrying head can be set at any angle within an arc of 100 degrees, and is provided with an efficient locking device. The down-slide in the head is also fitted with a continuous taper gib, having an end-screw adjustment for taking up the wear. The feed-screw is provided with a graduated dial, reading to 0.001 inch. The tool-post is made large so as to permit using holders for inserted cutters.



Shaper of Heavy Design brought out by the American Tool Works Co.

The table is provided with three T-slots, both on the top and on the sides, and is made of a heavy box section, ribbed on the inside to insure strength. The apron has also three T-slots on its face to permit the clamping of work when the table is removed. The cross-rail is longer than usual, thereby giving the table a long horizontal range of travel. A telescopic elevating screw of large diameter is provided with ball bearings for making the elevation of the cross-rail easy. The cross-feed is of the builder's new patented design. It is variable and automatic, having a range from 0.008 inch to 0.200 inch, and can be changed while the machine is running. It is operated by the knob and screw shown on the side of the machine, by which a lever with an attached pointer is moved. The pointer indexes on a scale having 25 graduations, each graduation representing 0.008 inch feed. The construction is such that there is no necessity of change in adjustment of the feeding mechanism due to the change of position of the cross-rail. The feed gears are properly covered to prevent accidents.

The rocker arm is forked at the top, and this, together with a large opening through the column, permits a shaft of 2½ inches diameter to be passed under the ram for key-seating. Larger shafts may be key-seated by setting over the table so that the shaft passes outside of the column, the head then being set at an angle.

Throughout the design of this machine special attention has been paid to the lubrication of working parts. The ram slides are provided with felt wipers at both the front and center of the column. An oil pocket is cast integral with the column at the rear, for collecting waste oil. A large quantity of oil is stored in a pocket cast integral with the arm, and provided with suitable means of distribution for the thorough lubrication of the crank-pin and sliding block in the rocker arm. The counter-shaft has tight and loose pulleys 12 inches in diameter by 3¼ inches face, running at 180 R.P.M.

Some interesting tests have been carried out by the builders to ascertain the capacity of the machine. Cuts have been taken in cast iron ⅜ inch deep with 0.016 inch feed, 4 inches long, and ⅛ inch deep with 0.048 inch feed of the same length, with the belt on the second slow cone step. Another cut was taken in cast iron ¼ inch deep, 0.024 inch feed, 12 inches long, with the belt on the first slow cone step. In steel, a cut was taken ⅛ inch deep, 0.016 inch feed, 2½ inches long, with the belt on the second slow cone step, and the same cut 10 inches long, with the belt on the first slow step.

SCHELLENBACH 18-INCH CONE-DRIVEN LATHE.

The accompanying illustration, Fig. 1, shows an 18-inch by 8-foot cone-driven Schellenbach engine lathe, made by the John B. Morris Foundry Co., 933 Harriet St., Cincinnati, O. This machine is of the same general design as the company's geared head lathe, involving many original and ingenious features, which was illustrated in the June issue of MACHINERY. The difference between this machine and the one then described consists in the matter of the drive, the present machine being cone-driven instead of having a geared head.* It will, therefore, be necessary in this description only to call attention to the features involved in the design of the head, which is shown in section in Fig. 2. The driving cone is provided with three steps for a 3-inch double belt, the largest diameter of the cone being 12 inches. There are provisions for two sets of changes of speed through the back-gears, making in all nine changes of speed with a single speed counter-

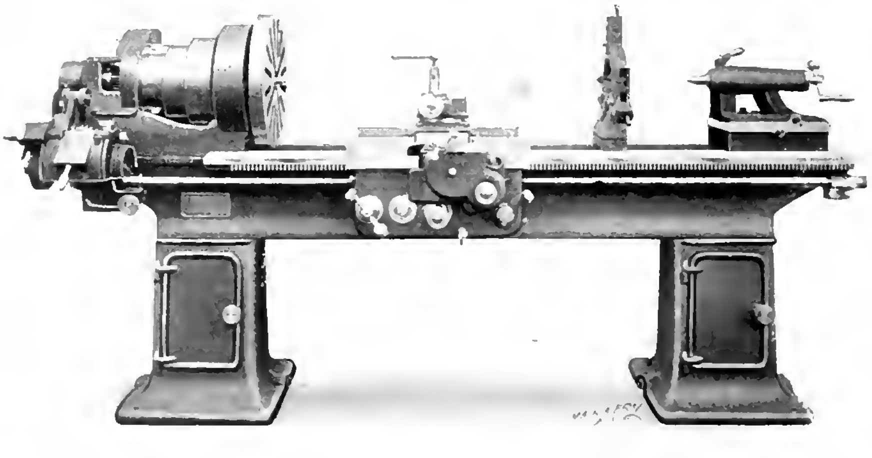


Fig. 1. Cone-driven Lathe built by John B. Morris Foundry Co.

shaft. However, the counter-shaft furnished with this machine is provided with double friction pulleys, and where a reverse motion is not required, it is possible to have a forward motion at two different speeds, thus giving 18 speed changes in all for the spindle of the machine. The back gears are operated in the usual manner. Special attention should be called to the very efficient manner in which the manufacturers have covered not only the back gears, but, in fact, all gearing on the machine. Not only has adequate covering been provided, but the covers have been made and attached to the machine in such a way as to present a very pleasing and harmonious appearance.

From the sectional view of the head, the arrangement of the drive can easily be studied. It will be seen that the spindle *A* has a flange at its right-hand end, where the gear *B* is doweled and screwed to it. This gear *B* is threaded internally in a recess, which receives the face-plates or the chuck. The chuck-plate *C* fits the counterbore of the chuck as indicated, is bored to fit on the end of the spindle, and is also threaded on the outside to screw into the gear *B*. It will be noticed that the flange of the spindle can thus be clamped tightly between the chuck-plate *C* and the gear *B*. This arrangement eliminates torsional strains within the spindle, when the drive is through the back gears. The overhang of the chuck from the face of the jaws to the front spindle bearing is not as great as with the ordinary type of lathe.

For the direct drive, the clutch teeth *D* formed upon the spindle engage with corresponding teeth in the clutch *E*, which is splined to a cone-pinion sleeve *G*. This clutch is operated at the back end of the head-stock by a spring-seated plunger, passing through the cone pulley. This plunger is provided with a knurled head having a pin to hold it out of engagement as shown.

The machine is provided with the quick change device described in connection with the geared head lathe, referred to above, giving a range of threads from 2 to 112. If required, the machine will be provided with a plain system of change gears as well as with this quick change system. While referring back to the former description for complete details, it may be of interest to mention some of the special features of this lathe, such as the double plate apron, and an arrangement for rough-chasing threads by the ordinary rack feed, in place of the lead-screw, the object being to preserve the accuracy of the lead-screw and to use it only for thread cutting where a high degree of perfection is required. This lathe is provided with cabinet legs, having hinged doors, as indicated. Another interesting feature is that a single wrench operates every adjusting screw throughout the lathe, including the tightening of the tail-stock to the shears. This lathe is also made in 14- and 16-inch sizes.

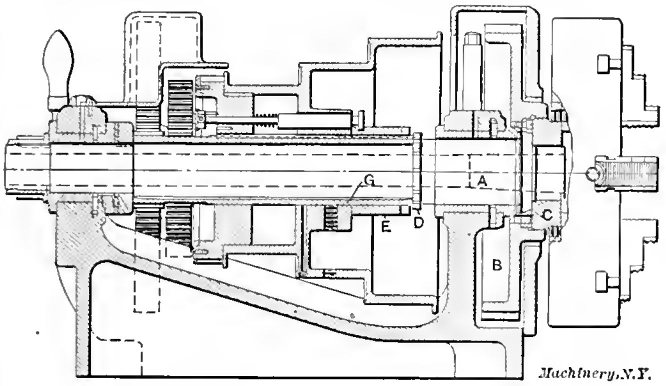

Fig. 2. Section through Head-stock of Lathe.

ACME HIGH-SPEED TWIST DRILL.

The drill and its socket illustrated herewith are manufactured by the Acme Drill Co., Sherman Ave. and Runyon St., Newark, N. J. The special feature of the combination is the strong drive obtained. As may be seen, the drill is made from a twisted bar of stock of special shape, milled accurately to dimensions. The shank is left straight and untwisted. The grooves in the sides of the shank are engaged by the rounded projections on the end of the collet, which effectively prevent the tool from rotating in its socket. The outside diameter of the shank is finished on a taper and fits a corresponding taper in the collet, being thus firmly supported and centered, as with the ordinary Morse taper drive. As may be seen, there is no tang to twist off. The drill is driven from its largest diameter, and no jaws, sleeve or wrench are necessary to tighten it. Owing to the method of manufacture, its cost is very low in comparison with other good high-speed drills.

A Twisted, Taper Shank Drill, with a Taper Drive.

The drill is made in standard sizes from ⅝ inch up to 2 inches, varying by 64ths. The collets and sockets correspond with the standard Morse taper sizes, and the collets have shanks fitting in Morse taper holes.

CINCINNATI FOUR-JAW INDEPENDENT CHUCK.

In Fig. 1 is shown an exterior view, and in Fig. 2, a cross-section of an improved independent chuck manufactured by the Cincinnati Chuck Co., Spring Grove Ave. and Sassafras St., Cincinnati, O. It might seem that there would be little possibility of improvement in an appliance so nearly standardized as the independent four-jawed chuck, but the makers have found that the tool is susceptible of improvement. In the ordinary independent chuck, the screws are mounted in semi-circular bearings, and receive the thrust on semi-circular shoulders formed in the cast-iron shell of the chuck. When these shoulders become worn in use, it is impossible to take out the play. As shown in Fig. 2, in this design, hardened bushings are provided at each end of each screw. The bearing surface and thrust surface occupy a full circle

Fig. 1. An Improved Design of Independent Chuck.

in each case, so that, in connection with the hardened materials used, the surface should wear at least three times as long. When end play becomes noticeable, it can be taken up by a machinist in a very short time, making the chuck as good as new in this respect. These bushings hold the screws absolutely in line with the jaw, preventing any tilting of the screws and consequent cutting of the thread. The screws are of the highest grade of spindle steel and have their bearings carefully ground. The shell is made from the best quality of gray iron, and the jaws are reversible.

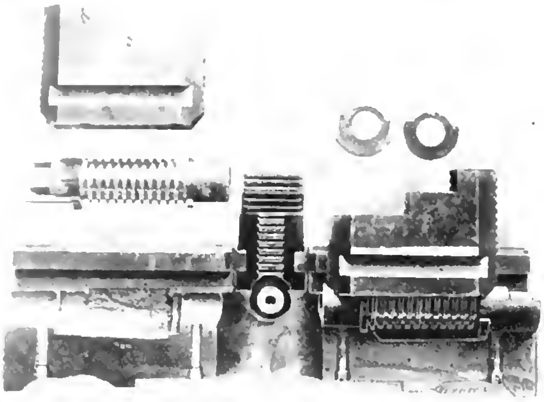

Fig. 2. Section of Cincinnati Chuck, showing Hardened Bushings for Screws.

THE VEEDER SPEED INDICATOR.

The Veeder Mfg. Co., of Hartford, Conn., has recently adapted the counting mechanism used in their well-known cyclometer and odometer to the work of the speed indicator. The device rearranged for this purpose is shown in Fig. 1, and in section in Fig. 2. As shown, it consists simply in mounting the regular registering or counting mechanism in the end of a drawn metal case, and in providing a ball bearing registering spindle and a suitable clutch for connecting it with the counter.

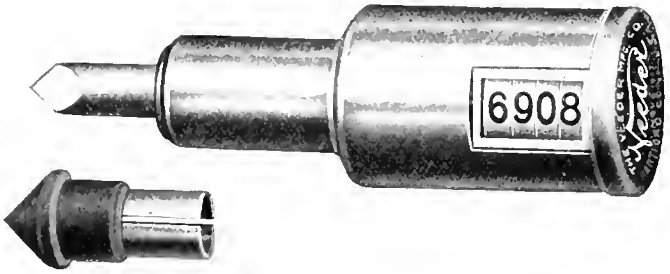

Fig. 1. The Veeder Speed Indicator or Revolution Counter.

The point of the spindle *E* is placed against the end of the shaft whose speed it is desired to measure. This spindle, which is provided with ball thrust bearings and is seated in bushing *F*, carries on its inner end the clutch member *C*. Under normal conditions, spring *D* presses bushing *F* outward so that the clutch member *C* is separated from the corresponding member *B*, attached to the spindle of the recording device. When, however, *E* is placed against the shaft whose speed it is desired to measure, spring *D* is compressed, the two clutch members come in contact, and the recording mechanism is driven from the shaft. When the reading is completed, the removal of the instrument allows the spring to expand, separating *E* and *C* and stopping the revolution of the counter.

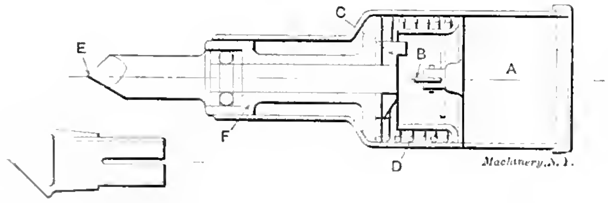

Fig. 3. Section through Indicator, showing Clutch and Ball Bearing

A feature of the device is the large number of revolutions provided for. The instrument registers up to 9,999 and repeats itself without requiring adjustment. This fact, and the ease with which the operation is automatically started and stopped, makes it possible to take readings without the use of the stop watch. Since readings may be taken for a long period of time even on high-speed shafts, it obviates the necessity for extreme accuracy in the timing of the interval. It is only necessary to watch the dial of the time-piece, the indicator itself requiring no attention. The difference between the readings of the counter at the beginning and end of the interval is the number of revolutions of the shaft in that time. It is essential to jot down the readings of the counter before beginning to count, because no arrangement is provided for setting it back to zero. Such a device would complicate the instrument, and it will be found much easier to take down the readings than to set back the counter. No matter in what direction the shaft runs, the difference between the readings will be the number of revolutions required.

The indicator is not affected by a magnetic field. This, in connection with the fact that the separate insulating tip shown is furnished with the instrument, makes it well adapted for use on generators and motors. It has frequently been used at as high as 5,000 revolutions per minute. It operates equally well in either direction, adding when running one way and subtracting when reversing.

Charles Stecher Co., 19 S. Jefferson St., Chicago, Ill. A high-speed bench drill which is built in miniature along the lines of the standard drill press, furnishing all the conveniences of the latter, including a slotted base for attaching large work. The base is cast in one piece with the countershaft frame. The drill is 10 inches swing and has a capacity for drills up to ½ inch in diameter.

Joseph Demarki, 194 Griffith St., Jersey City, N. J. Self-centering arbor which may be adjusted through a considerable range. This device is made in two sizes, one to hold from 4 to 10 inches, and the other from 10 to 20 inches. The work is gripped by a three-point bearing on each end, furnished by the sides of arms, spread outwardly by the pressure of a screw and nut.

Landis Machine Co., Waynesboro, Pa. All-steel cutter head of improved construction for holding and controlling the milled chasers used in this firm's bolt and pipe thread cutters. These chasers are made entirely of steel with the important wearing parts hardened. The head, when in closed position, is locked entirely within itself so that none of the thrust of the cutting action is taken between rubbing surfaces. Any set of chasers is adjustable for any diameter within the range of the head.

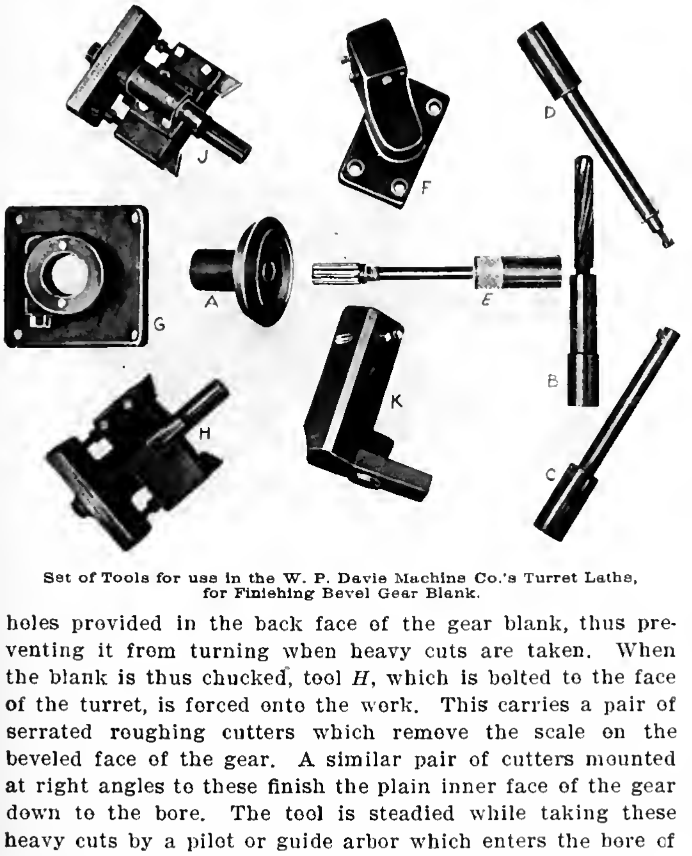
Bridgeford Machine Tool Works, Rochester, N. Y. A gap lathe intended primarily for refinishing car axle journals without removing the wheels, and for this purpose made with a very wide gap sufficient to clear car wheels of standard gage. It may also be used as a single end axle lathe. To make this possible, the head-stock is arranged so as to slide on the bed by a rack and pinion movement, to bring the wheel within the range of the carriage. It may also be equipped for refinishing engine truck axle journals, in which case an extra carriage is arranged between the wheels, leaving a short gap on each side.

Cincinnati Milling Machine Co., Cincinnati, Ohio. A new line of high-power milling machines, designed entirely from original data as to speeds, feeds, pressure of cut, etc., obtained from experiment. These machines are built on the unit system, and are so arranged that, by the interchange of various units, the machine may be arranged for constant speed or cone pulley drive (in either case with the shaft at right angles or parallel to the spindle), variable speed or a constant speed motor drive, and with the feed in inches per minute or in fractions of an inch per revolution. The same design throughout, with the exception of the spindle mechanism and the upper part of the column, is also used for the vertical spindle machine.

FINISHING BEVEL GEAR BLANKS IN THE DAVIS TURRET LATHE.

We show in the engraving a set of tools designed by the W. P. Davis Machine Co., Rochester, N. Y., for use on its turret lathe for finishing bevel gear blanks such as shown at *A*. This gear is clamped in the chuck with the hub projecting outward. The first operation consists in running the three-lipped drill *B* through the work. This roughs out the cored hole in the hub. This hole is next trued with the boring tool shown at *C*. The double-ended boring cutter at *D* is then passed through the hole, sizing it ready for the reaming. The reamer shown at *E* is mounted in a floating holder and finishes the hole to accurate size. The knee tool *F* is now brought into position and the outside of the hub is rough turned, after which it is finish turned with a similar tool *K*. All of these tools, of course, are carried by the turret. The back of the gear and the end of the hub are next faced with cross-slide tools, completing the machining of this side of the gear.

In the second operation, the turned shank of the bevel gear is held in the special chuck shown at *G*. This consists of a simple casting, bolted to the face-plate of the lathe, and having a bored hub provided with a clamp similar to that in common use for holding tool shanks in the turret of the screw machine. It is provided also, as shown, with two pins projecting from the face of the boss, which fit into corresponding holes provided in the back face of the gear blank, thus preventing it from turning when heavy cuts are taken. When the blank is thus chucked, tool *H*, which is bolted to the face of the turret, is forced onto the work. This carries a pair of serrated roughing cutters which remove the scale on the beveled face of the gear. A similar pair of cutters mounted at right angles to these finish the plain inner face of the gear down to the bore. The tool is steadied while taking these heavy cuts by a pilot or guide arbor which enters the bore of the work. The tool shown at *J*, which is very similar in construction, is next brought into operation to finish these same surfaces. The finishing of the back bevel in the blank is effected by forming tools carried in the front and back cross slides, one of them being used in the roughing operation for removing the scale, while the other finishes the surface to size.



Set of Tools for use in the W. P. Davie Machine Co.'s Turret Lathe, for Finishing Bevel Gear Blank.

This series of two complete operations requires 15 minutes for each gear, from the rough casting to the finished blank complete. The dimensions of the finished work are: diameter of hub, 2 5/16 inches; outside diameter, 6 5/32 inches; length over all, 5 inches. The builders of this outfit make a specialty of providing their turret lathes with suitable sets of tools for rapid and accurate work on cast iron parts of varied shapes and sizes.

Remember that the world does not owe you a living, but it does owe you an opportunity to earn a living.

AN AMERICAN MECHANIC IN EUROPE—7.

A SERIES OF LETTERS FROM OSKAR KYLIN ON THE EDITORIAL STAFF OF MACHINERY.

Copenhagen, Denmark, September 14, 1908.

The business conditions in the Scandinavian countries have, although slowly, continued to improve during the month of August. Judging from the reports in the trade journals and from the opinions of a few machinery dealers who have direct connections with the large trade centers in Germany and England, the conditions in these countries have improved even in a greater degree, and hopes are expressed that the crisis of the year will soon have passed entirely. The labor troubles in Sweden, which were referred to in my letter in the September issue, have been satisfactorily settled, and a return made to normal conditions in this respect.

General Conclusions regarding the European Machine Tool Trade.

The present letter will conclude the series which the writer has contributed to Machinery regarding European trade conditions. It may, therefore, be appropriate to here summarize some of the general conclusions reached, and emphasize the points which appear to be of the greatest importance.

If a comparison is made between the general state of development of the machine tool industry in America and the different countries which the writer has visited during the past spring and summer, it must be said that America is still holding its own, and is leading in this industry. This is true both in regard to the design of machine tools and in regard to the methods of manufacture. Without underestimating the importance of design, the methods of manufacture are, however, in the opinion of the writer, of greater importance. When meeting the competition of foreign manufacturers on foreign ground, the American makers face the disadvantage of higher per capita wages, and in order to lower the cost of manufacture per machine, systematic methods must be employed. Germany, however, has not failed to see the importance of this. The advantage of the systematic methods which can be employed in specialized manufacture are being more and more recognized. It is true that in Germany there still exist many concerns which work along in the old rut, and which have not as yet specialized in any particular line; but these firms are forced to recognize the success achieved by such manufacturers as have devoted themselves to a single line, and in order to be able to compete, the former firms must finally follow the trend of the times.

England must be considered as a close third in regard to modern machine tool manufacture. Some English makers appear to be somewhat more conservative than the German, and seem to believe in the superiority of their own methods, but this is not true of all English firms, and there are many concerns which can be favorably compared with average American firms in regard to equipment and product. With the exception of France, where the machine tool industry has not reached any large proportions, the remaining European countries are small as compared with the ones mentioned; and shut out from one another by tariff walls, they find it, as a consequence, difficult to keep step with the larger nations. Forced to largely depend upon the home market, the firms of these smaller nations cannot turn out their product in very large quantities, and are consequently, in a measure, prevented from specializing to the same extent as is possible in a large country with a large home market. These smaller nations too, however, are learning the industrial watch-word of the times, "specialization."

What has been said above with reference to the situation of the machine tool industry in the different countries is, of course, true only in a general way. It must be understood that there are to be found concerns of the very highest standard in any country, no matter what its size is. These concerns have, so to speak, broken away from the peculiarities that belong to the different nations, and have become more or less international in the manner in which they are managed.

It must be considered an undeniable proof of the superiority of the design of American machine tools that they are so frequently copied abroad, sometimes even by firms having a

reputation of their own. Germany appears to be the hot-bed of this copying, but it is by no means confined to that country. The writer found evidences of such copying in a large number of places, all the way from Italy to Sweden. It should be understood, however, that it is not only American machines that are subject to imitation, but all good designs, of whatever origin, are imitated in a degree corresponding to the quality of the design and the usefulness of the machine. This same system of imitation, of course, also takes place in America, one manufacturer imitating the successful design of another. This imitation in a sense, is deplorable, because it very often prevents a concern which has expended a great deal of capital and energy in the development of a machine of high standard from reaping its due profit, and it is difficult to find a remedy outside of the protection afforded by patent laws.

In my previous letters I have pointed out, from time to time, that many American machine tools are, in some respects, too weak for European conditions and material, and opinions to this effect expressed by European machine tool users have been quoted. Although it is true that, generally speaking, the American design is weaker than the European one, it seems, however, as if some of the persons interviewed had exaggerated the matter. Although it cannot be denied that when used on very heavy work and hard material, as used in Europe, American machine tools are often too weak to stand the strain, it may sometimes be that the machines have been put to uses for which they were not intended. No matter to what extent the criticism is unjustified, however, the American manufacturer should not permit it to pass by unnoticed, because many European users believe that the American machine tools are too weak, and even if their ideas are erroneous, whatever can be done to prevent such an opinion from working an injury to American export trade ought to be done.

It should once more be emphasized in connection with this that American manufacturers who really want any European market should not neglect to thoroughly study the conditions of the machine industry over here. Many conditions here influence the American machine tool trade which appear to be comparatively unknown in America; the European industries are making rapid progress, and the situation of a dozen years ago is changing by leaps and bounds, and it is surely necessary for American machine exporters to keep posted in order to know how to handle the trade properly.

It has been pointed out to the writer by a few machine tool users that there is a tendency of the modern machine tool designer to make the machines too complicated. It has been claimed that there are features on the machines which are but very rarely used, and when the time required for placing the attachments in proper position on the machine is considered, it often eliminates any saving in time from their use. There may, of course, be several reasons for this claim. Sometimes the user himself may be at fault because of having bought the wrong machine for his needs; sometimes the operator may be inexperienced in the use of an attachment which is but seldom required, and spend an unnecessarily long time in its adjustment. At any rate, there is apparently some truth at the bottom of a matter so often pointed out. The criticism seems to particularly refer to the universal machines in which the designer attempts to have the machine accomplish almost anything, thereby making it too complicated, and consequently too expensive. When buying such a machine, the user often has to pay for some feature which he will never need.

In an open market, Europe, of course, has, if it employs modern manufacturing methods, still an advantage in the somewhat lower wages that are paid here, but the general tendency in the European countries is for a decided increase in wages, and it may be that, before many years, about the same level in wages will be reached in Europe as prevails in America. This will eliminate one of the arguments used by the advocates of a protective tariff, and might perhaps lead to a reduction in tariff duties between the various industrial countries of the world. This would mean a larger market for the manufacturers of machine tools, and leave room for a still greater degree of specialization than that of the present day, thereby making possible a better utilization of human labor, natural resources, and capital.

OBITUARY.

Lyman M. Starrett, one of the builders of the *Monitor*, and the oldest printing press pattern-maker in America, died at his home in Brooklyn Manor, Long Island, September 15, aged seventy-five years. For sixty years he had been an employe of R. H. Hoe & Co., New York. He was the inventor of the first street sweeper drawn by horses, and of a number of other valuable devices.

Gardner D. Hiscox, the author of several well-known books on technical subjects, died at his home in East Orange, N. J., September 13, aged eighty-six years. Mr. Hiscox was the author and compiler of "Mechanical Movements, Powers and Devices," "Compressed Air: Its Production, Use and Applications"; "Horseless Vehicles, Automobiles and Motor Cycles"; "Modern Steam Engineering"; "Hydraulic Engineering," etc. Although a prolific writer and a man of considerable repute as authority on mechanical subjects, Mr. Hiscox was not a college graduate, having had a common school education only. His wife, three sons and a daughter survive him.

Dr. Theodor Peters, President Verein deutscher Ingenieure (Society of German Engineers) died in Berlin, September 2, 1908. Dr. Peters had devoted all his time and energy to the interests of the society for more than 25 years, and the important position which the society to-day occupies among the leading engineering associations of the world was largely due to his untiring efforts. He was particularly interested in the publication of the *Technolexikon*. At the present time it seems as if this stupendous undertaking would be carried to a successful completion, although it was not permitted one of its ablest and most enthusiastic supporters to see the work finished.

Edward B. Pike, president of the Pike Mfg. Co., Pike, N. H., died at his home, August 24, following an operation for appendicitis, aged sixty-three years. He was salesman for the Enterprise Mfg. Co., Philadelphia, beginning in its employ some time in the early 70's, and finally becoming head salesman. His health becoming impaired, he associated with his brother, A. F. Pike, in the scythe-stone and oil-stone business in 1878, and in 1884 the A. F. Pike Mfg. Co. was organized with A. F. Pike president and E. B. Pike vice-president. The brother died in 1891 and E. B. Pike became president. The business was rapidly developed under Mr. Pike's management, and is one of the best known in the sharpening stone trade.

* * *

PERSONAL.

H. M. Lucas, president of the Lucas Machine Tool Co., Cleveland, Ohio, sailed for Europe, September 5, for a business trip in the interest of his company.

Henry C. Karlson has opened an office at 39 Cortlandt St., New York, where he will act as solicitor of patents and as designer of automatic and special machinery.

H. L. Mills, formerly of the sales department of the Whiting Foundry Equipment Co., has resigned to become president of the American Specialty Co., 1440 Monadnock Blk., Chicago, Ill. This company is marketing the "Use-Em-Up" drill socket.

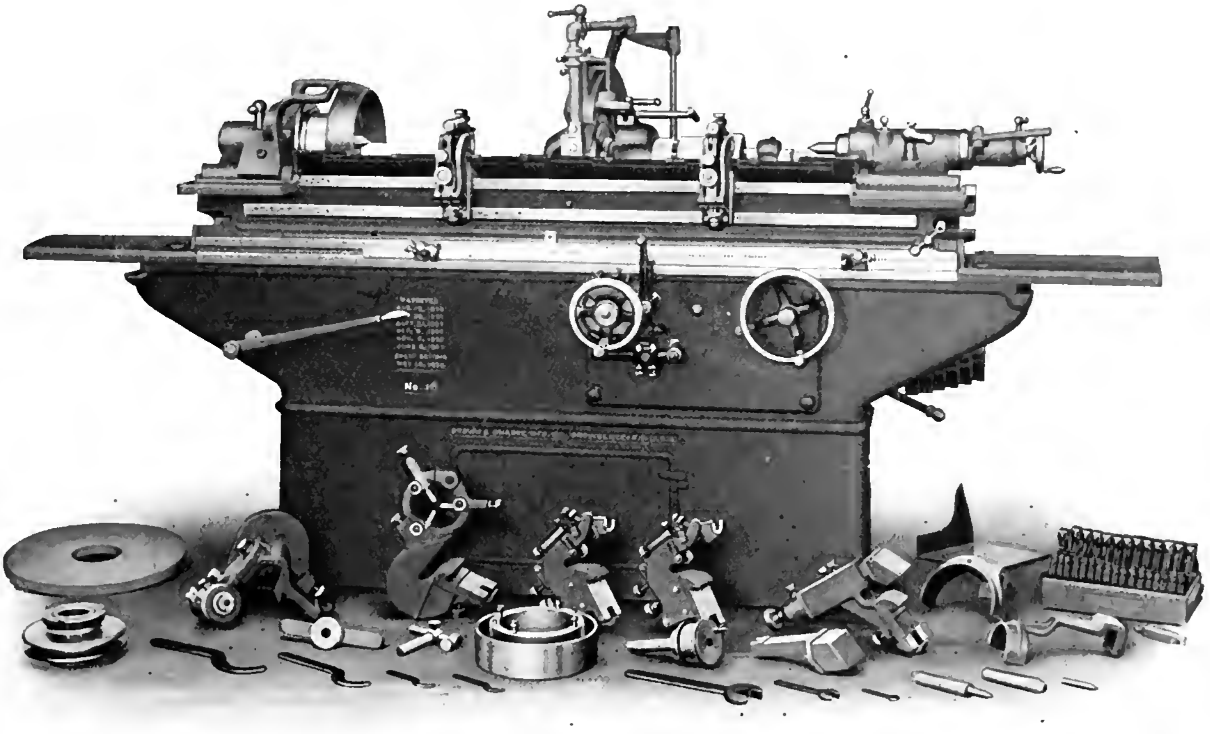
W. B. Gardiner, for the past ten years employed in the model department of the Winchester Repeating Arms Co., New Haven, Conn., has been appointed superintendent of the manufacture of the Smith one-lock adjustable reamers, made by the Wm. J. Smith Co., New Haven.

Richard Froboese, recently mechanical engineer of the Imperial Gas Engine Co., San Francisco, Cal., has engaged in business for himself as consulting engineer in all matters pertaining to gas power. Mr. Froboese, who is a graduate of Braunschweig, Germany, will have an office at 507 Mission St., San Francisco. His experience in the past eight years was with the Power & Mining Machinery Co., Milwaukee, and the Union Gas Engine Co., and the Hercules Gas Engine Co., of San Francisco. He designed the present types of engines now

Brown & Sharpe Mfg. Company

PROVIDENCE, RHODE ISLAND, U. S. A.

Not only is a B. & S. Grinding Machine Accurate when you start it but its Accuracy is Durable.



The importance of this point cannot be overestimated in that the Grinding Machine you want is the one that will wear well.

And nothing contributes so much toward the attainment of lasting accuracy as emphasis on Quality of Workmanship.

Sufficient weight that vibration may be eliminated as far as possible, each part in right relation to the whole, and correct alignments insisted upon, are all factors that establish accuracy as a permanent feature in B. & S. Grinding Machines.

A CIRCULAR OF ANY OF THE B. & S. GRINDING MACHINES SENT TO ANY ADDRESS.

being built by the latter company, and it is his intention to specialize along this line as consulting engineer.

C. L. de Muralt has been reappointed professor of electrical engineering at the University of Michigan for the coming year. Prof. Muralt will devote his attention during the winter semester to the consideration of the general aspects of applied electricity. The course of lectures will include discussion of the characteristics and application of electricity and continuous current motors; the design, construction and operation of electric plants; the principles and methods of transmitting, distributing and controlling alternating currents; the calculation and operation of electric railways; and the commercial management of electric properties and interests.

* * *

COMING EVENTS.

October 12-16. American Street and Interurban Railway Engineering Association convention at Atlantic City. Office of the Secretary-Treasurer, Engineering Societies Building, 29 West 39th St., New York.

October 13.—The season of professional meetings of the American Society of Mechanical Engineers will be opened in October by a meeting of the Gas Power Section, in the Engineering Societies Building at 29 West 39th St., New York. Mr. H. L. Doherty, chairman of the Meetings Committee of the section, will present a report for discussion, outlining plans for future work, and there will also be a discussion of standards to be used in gas power work. Two papers will be read, one by E. A. Harvey on gas-producer plants, with data upon costs, performance, etc.; and one by N. T. Harrington giving the results of tests to determine the loss of fuel weight in a freshly charged producer, due to increase of ash contents in the fuel bed. The first paper will be illustrated by lantern slides, showing actual plants and plans for the arrangement of apparatus.

October 13-15.—Annual meeting of the Railway Signal Association at Washington, D. C. C. C. Rosenberg, 12 North Linden St., Bethlehem, Pa., secretary.

October 13-15.—Annual meeting of Federation of Trade Press Associations, at Chicago, Ill. Morton Hiscox, secretary, 1431 Monadnock Block, Chicago, Ill.

October 20-21.—Annual convention of the National Machine Tool Builders' Association at the Hotel Imperial, corner of Broadway and 32d St., New York P. E. Montanus, Springfield Machine Tool Co., Springfield, Ohio, secretary.

October 22.—Machinery's annual outing.

November 19-21.—Annual meeting of the National Society for the Promotion of Industrial Education, Atlanta, Ga. James P. Haney, 546 Fifth Ave., New York, secretary.

December 1-4.—Annual convention of the American Society of Mechanical Engineers, Engineering Societies Building, 29 West 39th St., New York City. C. W. Rice, 29 W. 39th St., New York, secretary.

December 31-January 7.—Ninth annual show of the American Motor Car Manufacturers' Association at Grand Central Palace, New York City.

January 16-23.—Ninth annual show of the Association of Licensed Automobile Manufacturers at Madison Square Garden, New York.

NEW BOOKS AND PAMPHLETS.

Wireless Telegraphy and Telephony. By Walter W. Massie and Charles R. Underhill. 76 pages, 4¾ x 7¼ inches. 28 illustrations. Published by D. Van Nostrand Co., 23 Murray St., New York. Price $1.00.

This work describes in simple manner the nature of ether waves and the apparatus used in wireless telegraphy and telephony. It is explained that the ether waves employed in wireless telephony differ from light waves, principally in the length of the wave. Light waves range from 1/64,000 inch for extreme violet to 1/33,000 inch for extreme red, while the waves employed in wireless telegraphy vary in length from 650 feet to nearly 2 miles. The work will be found valuable by those who desire a non-technical description of the art.

A Proper Distribution of Expense Burden. By A. Hamilton Church. 116 pages, 5 x 7½ inches. Published by the *Engineering Magazine*, New York. Price $1.00.

The book is made up of a series of articles originally published in the *Engineering Magazine*. The author has given much attention to the correct distribution of the expense burden, which, as everyone knows, is one of the difficult problems in accurate cost accounting. It treats of interlocking general charges with piece costs; distributing expense to individual jobs; the scientific machine rate and the supplementary rate; classification and dissection of shop charges; mass production and new machine rate; and the apportionment of office and selling expenses.

Manual for Engineers. Compiled by Charles E. Ferris. 162 pages, 2¾ x 5½ inches. Published by the University Press, Knoxville, Tenn. Price 50 cents.

This popular compilation of tables and other data has passed into the eleventh edition. The last edition contains new and valuable matter, including a carefully arranged four-place logarithm table. A four-place logarithm table answers for many arithmetical problems in engineering work, as well as the more cumbersome tables of five, six, or more places. The work was originally compiled to bring before the minds of business men and manufacturers, the strongest possible argument in favor of technical education, giving, as it were, an object lesson of the vast fund of technical data available to those interested in mechanical work.

Internal Combustion Engines. By Rolla C. Carpenter and H. Diederichs. 597 pages, 6 x 9 inches. Illustrated. Published by the D. Van Nostrand Co., 23 Murray St., New York. Price $5.00.

The aim of the author in the preparation of this work was to present in as simple terms as possible the fundamental and theoretical principles, relating to internal combustion engines, and to describe the various methods of applying these principles to the practical construction. The contents of the work by chapters are as follows: Introduction, Definitions and Classification, Indicated and Brake Horse Power; Thermodynamics of the Gas Engine; Theoretical Comparison of Various Types of Internal Combustion Engines; The Various Events of the Constant-Volume and Constant-Pressure Cycle as Modified by Practical Conditions; The Temperature Entropy Diagram Applied to the Gas Engine; Combustion; Gas-Engine Fuels—the Solid Fuels, Gas Producers; The Gas-Engine Fuels—Carbureters and Vaporizers; Gas-Engine Fuels The Fuel Mixture, Explosibility, Pressure and Temperature; The History of the Gas Engine; Modern Types of Internal Combustion Engines; Gas-Engine Auxiliaries, Ignition, Mufflers and Starting Apparatus; Regulation of Internal Combustion Engines; The Estimation of Power of Gas Engines; Methods of Testing Internal Combustion Engines; The Performance of Gas Engines and Gas Producers; Cost of Installation and of Operation.

CATALOGUES AND CIRCULARS.

Morse, Williams & Co., Philadelphia, Pa. Catalogue No. 4 on Hindley worm gears and Hindley spirals. The catalogue is illustrated with examples of Hindley gearing used in pump drives, windlasses, turret turning apparatus, etc.

Rockwell Furnace Co., 26 Cortlandt St., New York. Catalogue of portable heaters and melting furnace for melting all metals, tinning, galvanizing, tool hardening and all operations requiring molten metal or other heated baths.

C. H. A. Dissenger & Bro., Wrightsville, Pa. Catalogue A of Capital gas and gasoline engines, made in sizes from 2½ to 200 horse-power; also catalogue B of Capital gasoline traction engines, built in sizes from 16 horse-power to 80 horse-power.

Thompson Grinder Co., Springfield, Ohio. Catalogue of Thompson universal grinding machine, showing the grinder converted into a plain grinder, a surface grinder, a die grinder, a knife grinder, an internal grinder, a cutter grinder, a high-speed grinder, etc.

Lufkin Rule Co., Saginaw, Mich. Catalogue No. 48 on measuring tapes and rules of every description. The list includes steel tapes, bronze tapes, surveyors' chain tapes, pocket steel tapes, pocket linen tapes, metallic warp tapes, steel rules, steel shrink rules, tinners and circumference rules, etc.

Lumen Bearing Co., Buffalo, N. Y. Booklet advertising Lumen bronze die castings, which are made with such accuracy that no machining is required. They are particularly adapted to the construction of typewriters, adding machines, telephone parts, and all small interchangeable machinery parts made in large quantities.

General Electric Co., Schenectady, N. Y. Pamphlet entitled "Transformer Steel," giving a brief account of the material used in transformer construction, and calling attention to the company's improved type H transformer in which the described steel is used. In writing for this pamphlet, designate it as No. 3687.

Gem Mfg. Co., 3253 Spruce St., Pittsburg, Pa. Catalogue of brass and steel oilers showing the old line of oilers manufactured by the company, and a new line just put on the market. The catalogue includes specialties such as foundry chaplets, inspectors' and locomotive torches, brass alcohol lamps, flexible shafts, portable drilling and grinding attachments, breast drills, universal joints, scratch brushes, etc.

Dayton Machine and Tool Works, Dayton, Ohio. Catalogue No. 2 for grinding machines designed for tool grinding and manufacturing. These grinders are manufactured in three sizes, and are designated as plain cutter and reamer guide grinder, universal cutter and tool grinder No. 1, universal cutter and tool grinder No. 2, which latter can be converted into a shaft and internal grinder or a surface grinder.

Winkley Co., 866 Warren Ave., W., Detroit, Mich. Catalogue of oiling devices. The Winkley Co. brought out the first oil hole covers as a substitute for open oil-holes, loose plugs, screws, etc., in 1892. The catalogue illustrates a variety of styles that have been developed, suitable for all classes of machinery. These include the self-closing and the hand-closing types. A line of grease cups has been added and specialties such as brass dowel pins for patterna and special brass work to order.

Taimont Mfg. Co., 55 to 71 Amory St., Roxbury, Mass. Catalogue of "Trimo" tools, which include the "Trimo" pipe wrench, the "Trimo" chain wrench, "Trimo" pipe cutter, "Trimo monkey-wrench," "Trimo" giant chain pipe wrench, "Trimo" special narrow jaw wrench, "Trimo" basin wrench for plumbers, etc. The company has issued a new edition of "Facts are Stubborn Things," being an account of mechanical tests made with the United States testing machine at Watertown Arsenal, Mass., to determine the strength of various makes of monkey-wrenches.

Hendey Machine Co., Torrington, Conn. Catalogue of engine lathes. The construction of the 20- and 24-inch geared-head lathe is illustrated. The geared-head lathes are built in 12-, 14-, 16-, 18-, 20- and 24-inch sizes, and this type of lathe is illustrated with both motor and belt drive. The line of cone pulley lathes with reinforcing tie-bar between the spindle bearings is illustrated in detail. Lathe attachments are illustrated for relieving cutters, turning tapers, turning balls, tool-room equipment, etc. The catalogue is one of the most interesting issued by any machine tool builder.

Rahn-Carpenter Co., 2935-2941 Spring Grove Ave., Cincinnati, Ohio. Catalogue No. 7 of engine, turret and gap lathes, built in 16 inches to 32 inches swing. The catalogue is beautifully illustrated, and besides showing the various sizes of lathes, attachments, and accessories, it illustrates the method of crating lathes for domestic and foreign shipment. The latter consideration is very important, as many American tools have received a "black eye" because of the careless and unsafe crating and protection given to the finished parts. The method of crating illustrated insures a machine being received in good condition if subjected to the ordinary rough handling that goods receive in ocean transport.

Hammacher, Schlemmer & Co., 4th Ave. and 13th St., New York. Catalogue No. 355 of tools for all trades, and supplies. The catalogue contains 1,200 pages 5¼ x 7¼ inches, of which 28 pages are devoted to the index alone. This fact gives an idea of the great number of tools and supplies listed. The catalogue lists tools for the machinist, carpenter, cabinet maker, piano tuner, die-sinker, toolmaker, mill-wright, electrician, lumberman, engineer, draftsman, upholsterer, tailor, painter, paper-hanger, molder, brick-layer, cement-layer, etc., and general supplies for manufacturers. It is one of the most complete catalogues of tools and supplies for manufacturers ever issued by any company of dealers, and is a credit to the concern represented. On account of the high cost per copy, the catalogue cannot be distributed free, except to purchasing agents, and those in position to influence the purchases of manufacturing concerns. Others desiring a copy can obtain same for $1, which sum will be credited on the first order amounting to $10.

MANUFACTURERS NOTES.

W. J. Smith Co., New Haven, Conn., has appointed Fred Ward & Son, Inc., First and Howard Sts., San Francisco, Cal., the Pacific Coast agents for the sale of Smith one-lock adjustable reamers.

B. P. Fortin Tool Co., Woonsocket, R. I., recently sold, through its agency, the Prentiss Supply Co. of Boston, a No. 2 and a No. 8 universal jig to the United States Government Torpedo Station, at Newport, R. I.

Crocker-Wheeler Co. has opened a new office in the Gumbel Building, Kansas City, Mo., for the sale of the Crocker-Wheeler motors, dynamos, transformers, switch-boards, etc. The office is in charge of Mr. A. W. Paine.

Lyon Metallic Mfg. Co., Aurora, Ill., has just completed a large addition to its factory, and is now operating with double the old number of employes. The concern manufactures a complete line of factory equipment, making a specialty of unit shop racks, tote boxes, barrels, office and shop lockers, gear boxes, etc.

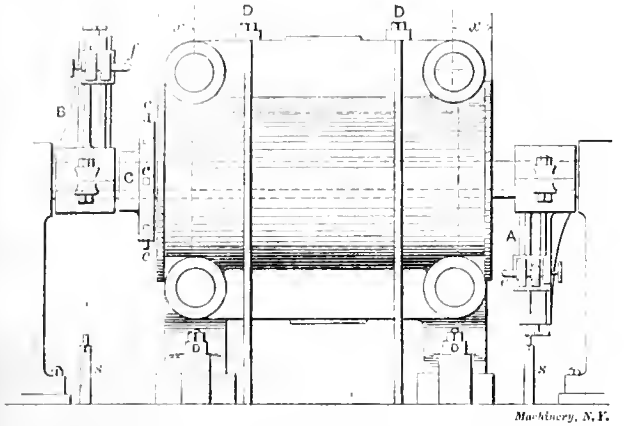
National Battery Co., Buffalo, N. Y., announces that the receivership under which it has been operating since last February was terminated August 19, and that all claims against it have been settled. Full control of the reorganized company has been secured by the Cutler-Hammer Mfg. Co., Milwaukee, Wis., but the plant of the

Supplement to MACHINERY, November, 1908.

Operations for the Article in this number entitled "Machine Shop Practice—Boring and Planing Corliss Engine Cylinders."

SHOP OPERATION SHEET NO. 79.

M. B. Stauffer. MACHINERY, November, 1908.



To Bore a Corliss Engine Cylinder.

NOTE.—The machine best adapted for this operation is the regular Corliss cylinder boring machine, and we shall assume that such a machine is available.

1. Adjust the main boring-bar and the bars for boring the valve ports so that they will clear the work; then place the casting on the machine table.

2. Move the tail-stock along the bed until there is room enough between the facing arms *A* and *B* and the ends of the cylinder, for the tool-head *C* to clear.

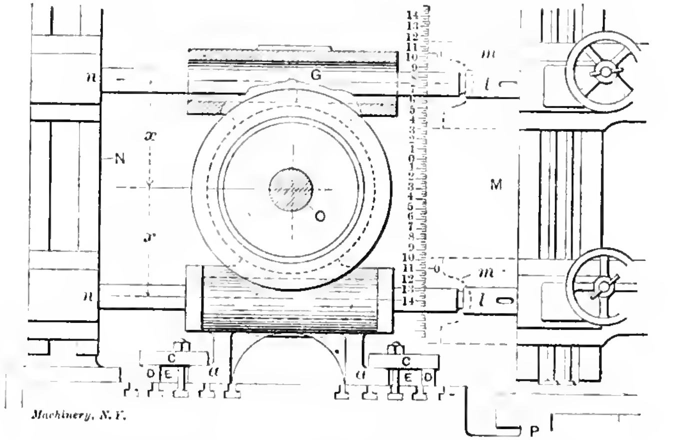
3. Set the cylinder vertically (by placing parallel pieces beneath the feet) and horizontally until the boring-bar is central, preferably, with the outside cylindrical surface of the cylinder. When set in this way, the cylinder, when bored, will have walls of a uniform thickness. With a surface gage, test the valve ports on both sides of the cylinder to see if they are parallel with the machine table, and, if necessary, adjust the casting by inserting thin steel wedges beneath its feet. Clamp the casting securely to the table by clamps *D*.

4. Fasten the roughing cutters *c* in the tool-head, and set them to bore within about 1/32 inch of the finish diameter; also insert tools *e* and *f* in the facing arms *A* and *B*. Fasten stops *s* to the platen to operate the star feed of the facing arms. Start the machine and proceed to rough bore the cylinder and face the ends, simultaneously. When facing the ends, the amount of metal to be removed should be determined by the distances *x*, as well as the dimension over all, so that the ports, when bored, will be central with the outside of the boss. When taking the roughing cut, examine the bore frequently to see that there are no imperfections in the casting which would render it useless.

5. Finish facing the ends of the cylinder, making it the required length. Take a finishing cut through the bore and counterbore both ends. The counterbore is to prevent a shoulder being formed in the cylinder, and it should extend in far enough so that the piston ring will over-lap it slightly when the piston is at the end of its travel.

SHOP OPERATION SHEET NO. 80.

M. B. Stauffer. MACHINERY, November, 1908.



To Bore the Ports of a Corliss Engine Cylinder.

NOTE.—This operation is performed with the cylinder in the same position as when being bored, and it may be done simultaneously with that operation.

1. The dimensions *x* from the center of the cylinder to the center of the ports, and also the distance from the face of the cylinder to the centers of the ports, should first be ascertained from the drawing. The next step will then be to set the port boring spindles *l* the required distance above and below the center of the cylinder, and from the ends.

2. On the side of the spindle column *M* are graduations, as shown by the dotted lines representing an end view of the column. When the zero mark on either of the spindle heads *m* coincide with the zero mark on the scale, the axis of the boring spindle is in the same plane as that of the main boring-bar *O*; therefore, the two spindles can be set vertically by this scale to the required dimensions.

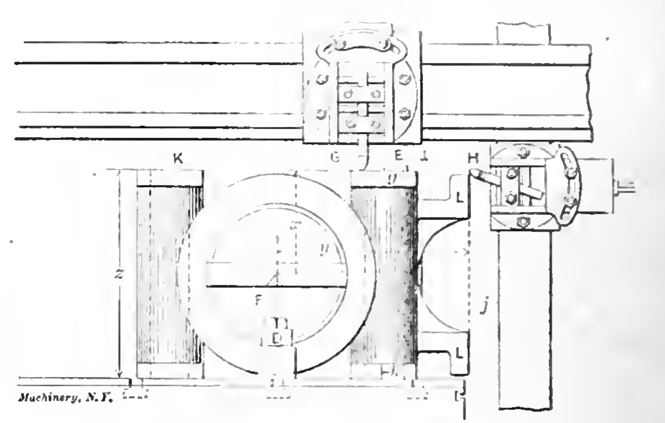
3. Place two boring-bars through the ports, and then shift the column *M* along the platen *P* until the centers of the spindles are the required distance from the face of one end of the cylinder. The outboard bearings *n* on column *N* are next set in line with the spindles *l*. On the platens at the base of each column, are graduations which are used when aligning the outboard bearings. The distance that the column *M* has moved along its bed, is noted, and then the column *N* is set to the same reading.

4. Insert the boring-bars in the spindles *l*, and take roughing cuts, making the holes within 1/64 inch of the finish diameter. Examine the ports to see that all steam edges are trued and free from imperfections. The roughing tools should do all the cutting on the front edges, that is, the cutting edge should not be beveled as this will tend to deflect the bar. Next bore the ports to the finish diameter, using tools honed to a keen edge so as to obtain a smooth finish.

5. When one set of ports is bored, the main and outboard columns are shifted a distance equal to the distance between the port centers, and the remaining ports bored.

SHOP OPERATION SHEET NO. 81.

M. B. Stauffer. MACHINERY, November, 1908.



To Plane a Corliss Engine Cylinder.

1. Set the cylinder in an upright position on the platen, resting it on the feet *L*, and insert centering pieces in both ends of either the steam or exhaust ports, and locate the centers. Set the edge of a long straight-edge *E* to coincide with the two centers on one side of the cylinder and scribe a line *g*. Repeat this operation on the other side, locating a line *h*.

2. Place the casting in the position shown in the engraving, insert centering pieces in both ends of the bore, and locate centers *F*. With a surface gage, test the centers *F* at both ends of the cylinder, and adjust the casting until they are the same height. Move the planer table until one end of the cylinder is opposite the finished edge *j* of the housing, and measure the distance from this edge to the center *F*. Move the table a distance equal to the length of the cylinder, and again measure from the center to the housing. The casting should be shifted until these measurements are equal.

3. With a long square, test the two lines *g* and *h*, and adjust the casting until they are perpendicular with the surface of the platen. The position of the casting may be changed by inserting thin steel wedges or liners beneath it.

4. Clamps *D* should be placed at each end of the bore, and stops against the outer end of the casting for taking the thrust of the cut. When the clamps are tightened, all points should be tested again, and, if necessary, readjustments made.

5. Clamp a roughing tool *G* in the tool-holder, and set it to 1/32 inch over dimension *x*. In the side head, clamp roughing tool *H* and set it to 1/32 inch over dimension *y*. Take roughing cuts over the surfaces *J* and *K* and the feet *L*, simultaneously. Rough plane the exhaust flange; replace roughing tools with finishing tools, and finish surfaces to the required dimensions. Invert the casting, resting it on the finished surfaces *J* and *K*, set the finished foot parallel with the edge of the table, and plane the opposite side of the cylinder to the dimension *z*, and the steam flange.

Supplement to MACHIN

Tables for the Articles in this number entitled "Computation Table fcr Reg

I.—FORMULAS AND FACTORS FOR SOLVING REGULAR POLYGONS.

Z = angle subtended at center by side

P = perimeter of polygon

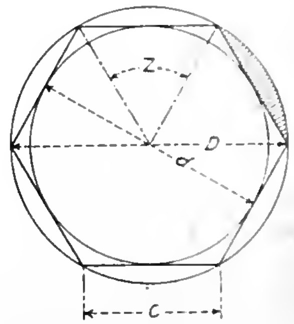
C = length of one side

A = area of polygon

N = number of sides.

d = diameter of inscribed circle

D = diameter of circumscribed circle



In the formulas below, the trigonometrical expressions necessary to use for solving regular polygons are replaced by the letters B, F, H, K and M, the numerical values of which for the most common number of sides in polygons are given in table II. The expressions these letters signify are:

$$B = \frac{1}{N} \operatorname{cosec} \frac{180^\circ}{N} \qquad F = N \tan \frac{180^\circ}{N} \qquad H = \frac{N}{8} \sin \frac{360^\circ}{N} \qquad K = \frac{N}{4} \cot \frac{180^\circ}{N}$$

$$M = 2N \sin \frac{180^\circ}{N}$$

Quantities to be found.	Quantities Known.				
	P	A	C	D	d
P		$P = 2\sqrt{FA}$	$P = CN$	$P = \frac{MD}{2}$	$P = Fd$
A	$A = \frac{KP^2}{N^2}$		$A = KC^2$	$A = HD^2$	$A = \frac{Fd^2}{4}$
C	$C = \frac{P}{N}$	$C = \frac{2\sqrt{FA}}{N}$		$C = \frac{MD}{2N}$	$C = \frac{Fd}{N}$
D	$D = BP$	$D = 2B\sqrt{FA}$	$D = NBC$		$D = BFd$
d	$d = \frac{4KP}{N^2}$	$d = \frac{4\sqrt{AK}}{N}$	$d = \frac{4KC}{N}$	$d = \frac{2MKD}{N^2}$

Example: A lathe spindle requires 18 speed changes, from 6 to 250 R.P.M. Find the speeds in geometrical progression.

$\frac{1000}{250} = 4$ (ratio between highest R.P.M. in table and highest R.P.M. in example); $4 \times 6 = 24$. Follow the horizontal line from figure 18 in the left-hand column to the figure nearest to 24 in this line. This figure is 22.5, in the 20 percent column. The speeds required are the values given in this column opposite figures 1 to 18, divided by 4. Thus 250, 200, 160, 128, etc., are the speeds wanted.

SETTING-ANGLES FOR MILLING ANGULAR CUTTERS AND TAPER REAMERS.*

W. A. KNIGHT.†

W. A. Knight.‡

In the calculation of setting-angles for angular cutters, end mills, taper reamers, and the like, the number of angles involved usually makes the calculations difficult and uncertain, and, as a general thing, the settings can be obtained by the cut-and-try method in less time than it takes to compute them. It is a great satisfaction, however, to be able to give a workman a blank for angular cutters with full data as to angles of elevation, set-over, or other adjustments required. In some cases, especially where the calculations can be carried out in the drafting-room, time can be saved, all guesswork eliminated, and data for the settings put on the drawing the same as other dimensions. In the case of an angular cutter the problem may be stated as follows:

Given a milling cutter blank of any angle β, to have any number of teeth n to be cut with a single angle cutter of any angle ϕ, to find the angle of elevation of index-head, so that when teeth are cut, the lands shall be of equal width throughout their length.

Fig. 1 represents a side and end view of the blank, and Fig. 2 the index head adjusted to the proper angle for the blank under consideration.

Let r = radius of blank,

n = the number of teeth,

β = the angle of blank,

ϕ = angle of cutter,

θ = tooth angle $= \dfrac{360}{n}$,

γ and δ angles, as shown in Fig. 1.

In Fig. 1, the line OA is the axis of a cone which would result from prolonging the blank down to a point. The line OC is the intersection of the two planes which form the sides of the tooth space, and hence the cutter must run parallel to this line while cutting a space. The head must then be elevated so that the line OC is parallel with the table, and in doing so we will have turned it through an angle equal to AOC, or α. Line EF is drawn perpendicular to OC. From the figure then,

$$\tan\alpha = \frac{AD}{AO}.$$

But $AD = AB - BD$, and $BD = BC \sec\alpha$.

Therefore $AD = AB - BC \sec\alpha$.

But $AB = r\cos\theta$; $BC = r\sin\theta\cot\phi$; and $AO = r\tan\beta$.

$$\text{Therefore } \tan\alpha = \frac{r\cos\theta - r\sin\theta\cot\phi\sec\alpha}{r\tan\beta} \qquad (1)$$

For convenience of calculation let $\tan\beta = x$; $\cos\theta = y$; $\sin\theta\cot\phi = z$. Cancelling out the r's and making these substitutions transforms equation (1) to

$$\tan\alpha = \frac{y - z\sec\alpha}{x}$$

$$\text{or } x\tan\alpha = y - z\sec\alpha$$

Substituting the sine and cosine for the tangent and secant, we have:

$$\frac{x\sin\alpha}{\cos\alpha} = y - \frac{z}{\cos\alpha}$$

$$\text{Squaring this gives: } \frac{x^2\sin^2\alpha}{\cos^2\alpha} = y^2 - \frac{2yz}{\cos\alpha} + \frac{z^2}{\cos^2\alpha}.$$

$$x^2\sin^2\alpha = y^2\cos^2\alpha - 2yz\cos\alpha + z^2.$$

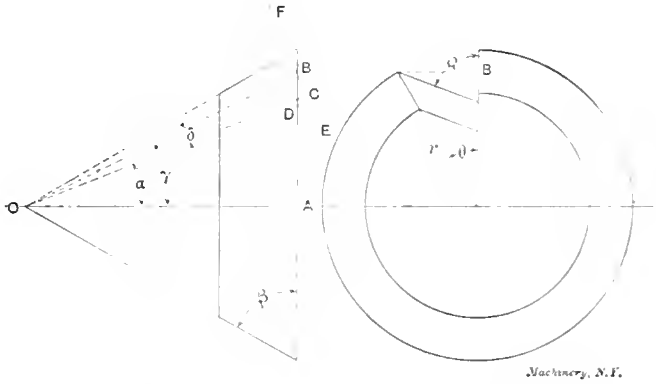

Fig. 1. Diagram for Calculating Setting-angle for Angular Cutters.

Substituting in terms of cosine gives $x^2 - x^2\cos^2\alpha = y^2\cos^2\alpha - 2yz\cos\alpha + z^2$, or $(x^2 + y^2)\cos^2\alpha - 2yz\cos\alpha + z^2 - x^2 = 0$, from which

$$\cos\alpha = \frac{yz}{x^2 + y^2} \pm \sqrt{\frac{y^2z^2}{(x^2 + y^2)^2} - \frac{z^2 - x^2}{x^2 + y^2}}$$

or, finally,

$$\cos\alpha = \frac{yz \pm x\sqrt{x^2 + y^2 - z^2}}{x^2 + y^2}$$

where $x = \tan\beta$; $y = \cos\theta$; and $z = \sin\theta\cot\phi$.

It will be observed that this is a very unwieldy and difficult equation to handle and we can arrive at a much easier solution by introducing the auxiliary angles γ and δ, the difference of which is the angle desired. In other words, by dividing the problem into two parts, we can obtain comparatively simple expressions for γ and δ, and a simple subtraction then gives α. The angle AOB or γ, Fig. 1, would be the angle of elevation if we were cutting the blank with a 90-degree cutter. In this case δ would disappear and $\gamma = \alpha$. From the figure,

$$\tan\gamma = \frac{AB}{AO}; \text{ but } AB = r\cos\theta; \text{ and } AO = r\tan\beta.$$

$$\text{Therefore } \tan\gamma = \frac{\cos\theta}{\tan\beta} \qquad (2)$$

$$\text{Also } \sin\delta = \frac{BC}{OB}; \text{ but } BC = r\sin\theta\cot\phi; \text{ and } OB = \frac{r\cos\theta}{\sin\gamma}.$$

---

* For previous articles on this and related subjects see: "To Calculate the Setting of the Dividing Head when Cutting the Teeth of End Mills," by George G. Porter, April, 1904, and "Formulas for Milling End Mills and Clutches," by Irving Banwell, February, 1908.

† Address: 206 W. Lane Ave., Columbus, Ohio.

‡ W. A. Knight was born in Delaware County, Ohio, 1864, and received a grammar school education. In 1880 he entered the employ of the Novelty Iron Works, and after serving three years in that shop went to the A. R. Rarig Co., general founders and machinists. Later he was with Royce & Pulling Steam Pump Co., erecting pipe work and shafting, overhauling engines and doing general repair work. In 1885 he was made stationary engineer for the Union Passenger Station, Columbus, Ohio, and continued in that capacity until 1887. During the three years he filled this position he became greatly interested in physics and general science and acquired a strong desire for a technical education. Leaving the position, he associated with H. P. Minot (who had worked for twenty years in the shop of the Putnam Machine Co., Fitchburg, Mass.), overhauling engines, taking indicator diagrams, etc. A 20-light dynamo was built for lighting the shop, this being one of the early lighting machines constructed. The building of this machine led to the organization of the Minot Electric and Machine Co., of which Mr. Knight was foreman and electrician. Upon the dissolution of the company in 1892 following the death of Mr. Minot, Mr. Knight obtained employment with the Jeffrey Mfg. Co., and in 1893 obtained a position at the Ohio State University as assistant in industrial arts and foreman of the machine shop. Later he became an instructor in machine work and graduated from the institution in 1900 with a degree of mechanical engineer.

$$\text{Therefore } \sin\delta = \frac{\frac{r \sin\theta \cot\phi}{r\cos\theta}}{\sin\gamma}$$

$$\text{or } \sin\delta = \tan\theta \cot\phi \sin\gamma. \qquad (3)$$

With equations (2) and (3) we can find the value of γ and δ, and their difference is the angle of elevation.

For $\beta = 0$ (case of an end mill, teeth on the end) equation (2) becomes $\tan\gamma = \frac{\cos\theta}{0}$, or $\tan\gamma$ is infinite, from which $\gamma = 90°$. Substituting sin 90 for $\sin\gamma$ in (3) gives $\sin\delta = \tan\theta \cot\phi$. But $a = \gamma - \delta = 90 - \delta$, or $\cos a = \cos(90-\delta) = \sin\delta$, and since $\sin\delta = \tan\theta\cot\phi$ we have, finally, for the end mill.

$$\cos a = \tan\theta \cot\phi \qquad (4)$$

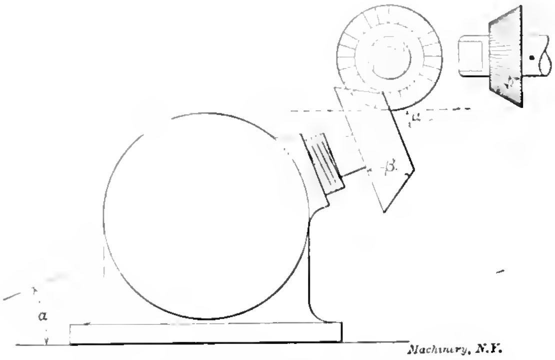

Fig. 2. Diagram of Head, Blank, and Cutter for Milling Teeth.

This is the same equation given in MACHINERY, April, 1904, by Mr. George G. Porter, and is a special case of the more general equation.

In this solution, and in the final equations, the width of land does not appear. The teeth of the cutter are considered as being cut to a sharp point; that is, without lands. This is done to simplify the mathematical work, and in no wise affects the results. It can be shown mathematically that the angle of elevation, when teeth are cut with a single angle cutter, is independent of both the width of land and radius of blank. The solution is therefore of general application. With the proper angle of elevation we can make the width of lands anything we choose, and they will be of equal width *after being backed off for clearance.*

Example: A 70-degree milling cutter blank is to have 18 teeth, and to be cut with a 65-degree single angle cutter. What will be the angle of elevation of the index head?

Fig 3 Diagram for Calculating Setting Angle for Taper Reamer.

In this example $n = 18$; $\beta = 70$ degrees; $\phi = 65$ degrees; $\theta = \frac{360}{18} = 20$ degrees.

The work would be carried out thus:

log cos 20 deg. $= \bar{1}.97299$
log tan 70 deg. $= 0.43893$

log tan γ $= \bar{1}.53406$

from which γ = 18 degrees 53 minutes.

log tan 20 deg. $= \bar{1}.56107$
log cot 65 deg. $= \bar{1}.66867$
log sin 18 deg. 53 min. $= \bar{1}.51007$

log sin δ $= \bar{2}.73981$

from which δ = 3 degrees 9 minutes.

$a = \gamma - \delta =$ 18 deg. 53 min. — 3 deg. 9 min. = 15 deg. 44 min.

The angle of elevation is therefore 15 degrees 44 minutes.

Taper Reamer Held on Centers.

In the case of a taper reamer held on centers, we wish to know how much the tail center should be elevated above the live center so that the cut shall be of correct depth at each end of the reamer. The taper per foot could be converted into degrees, and the formulas in the preceding part of this article used to determine the angle of elevation from which the elevation could readily be found; but it is more convenient to work with the taper per foot, and, proceeding as follows, we can find an expression for the elevation in terms of this taper.

[Attention should, however, be called to the fact that the formula deduced below is only approximately correct, although the error involved is so small that for all ordinary tapers, say up to one inch per foot, the difference is not of any account for practical purposes. As will be seen, the elevation of the tail center is assumed to be $OA - O_1A_1$ (see Fig. 3). The true elevation, however, is $(OA - O_1A_1) \cos v$, if v be the angle between the axis of the work and the bottom of the reamer flute. The cosine for small angles is so near unity that the difference becomes of no account. For a reamer with ¾-inch taper per foot, for instance, cos v would become 0.9995. On account of the small angle between the plane in which angle θ and angle ϕ are measured, they have been considered to be in the same plane, in order to give a more convenient formula for calculation. It should be remembered, however, that to do so is permissible only in the case of reamers with a comparatively slignt taper, and that the formulas below should not be used for reamers of abnormally large tapers. For such reamers the formula for angular milling cutters should be employed, which formula is mathematically correct.—EDITOR.]

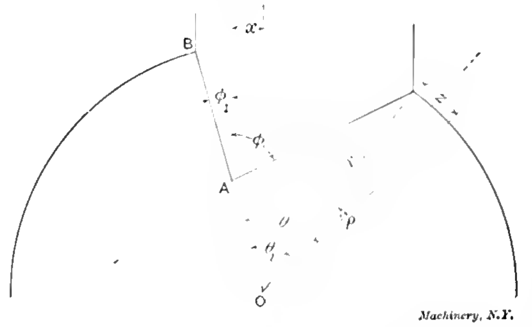

Fig. 4. Double-angle Cutter for Milling Straight Reamer Flutes.

As before, let

n = number of teeth,
ϕ = angle of cutter,
θ = teeth angle $= \frac{360}{n}$,
T = taper per foot,
l = total length of reamer, or distance between centers, in inches,
E = elevation of tail center.

From Fig. 3, $E = OA - O_1A_1$

$$OA = r\cos\theta - r\sin\theta\cot\phi;$$
$$O_1A_1 = r_1\cos\theta - r_1\sin\theta\cot\phi, \text{ and}$$
$$E = (r - r_1)(\cos\theta - \sin\theta\cot\phi),$$

$$\text{But } (r - r_1) = \frac{Tl}{12 \times 2};$$

$$\text{Therefore } E = \frac{Tl}{12 \times 2}(\cos\theta - \sin\theta\cot\phi). \qquad (5)$$

Example: A taper reamer is to have 6 teeth, a taper of ¾ inch per foot, is 8 inches long and is to be cut with an 80-degree cutter. How much should tail center be elevated?

In this case $\theta = \frac{360}{6}$, or 60 degrees, and $\phi = 80$ degrees.

Then $E = \frac{0.75 \times 8}{12 \times 2}(0.5 - 0.866 \times 0.176) = 0.087$, or elevation = 0.087 inch.

Case of the Double-angle Cutter.

The use of a double angle cutter for grooving a taper reamer or angular mill adds several complications to the setting of the machine, not met with when using single angle

cutters. In the first place the center must be offset a certain distance so that when the cutter is sunk into the blank the proper depth, the faces of teeth will be radial. Secondly, the reamer or mill must be turned through a horizontal angle as well as a vertical one in order that the plane of the face of the teeth shall pass through the center or axis of the cone. Stated differently, the cutting edge should be an element of the cone, and since the offset distance is different for the large and small ends of the reamer, to adjust for this, the tail-center must be set over a distance equal to the difference of these values. Thirdly, the radius and width of land must be taken into account. And fourthly, the expressions for the angle of elevation are altogether more complicated, so much so in fact as to be of little practical value.

Since, however, the angles of a taper reamer are small, we can, by neglecting some of the factors which affect the result but slightly, arrive at something like workable expressions for the different settings.

Consider, first, the offset for a cylindrical piece, or say a straight hand reamer. Fig. 4 represents the end with one space cut. The cutter with which the space is cut has angles ϕ and ϕ_1 either side of the center so that the angle cut in the reamer is $(\phi + \phi_1)$.

Let z = width of land; ρ half the angle subtended from the center by z; and x the offset.

We have, first, $\theta_1 = \theta - 2\rho$ and $\sin \rho = \dfrac{z}{2r}$. (6)

$$x = OA \sin \phi_1.$$

From well-known trigonometrical relations,

$$\frac{r}{\sin\,[180-(\phi+\phi_1)]}=\frac{OA}{\sin\,[180-(180-(\phi+\phi_1)\;-\theta_1)]}$$

from which $$OA=\frac{r\,\sin\,[(\phi+\phi_1)-\theta_1]}{\sin\,(\phi+\phi_1)}.$$

Therefore $$x=\frac{r\,\sin\,\phi_1\,\sin\,(\phi+\phi_1-\theta_1)}{\sin\,(\phi+\phi_1)}. \qquad (7)$$

Example: What would be the offset for a 1 1/8-inch reamer, 8 teeth, lands 1/16 inch wide, to be cut with a double angle cutter having angles of 15 and 65 degrees?

$$\theta = \frac{360}{8} = 45 \text{ deg., } \sin \rho = \frac{0.0625}{1.125} = 0.0555, \text{ or } \rho = 3 \text{ deg. } 11 \text{ min.}$$

$$\theta_1 = 45 \text{ deg.} - 6 \text{ deg. } 22 \text{ min.} = 38 \text{ deg. } 38 \text{ min.}$$

$$\phi + \phi_1 = 80 \text{ degrees.}$$

$$\phi + \phi_1 - \theta_1 = 80 \text{ deg.} - 38 \text{ deg. } 38 \text{ min.} = 41 \text{ deg. } 22 \text{ min.}$$

$$\text{Then } x = \frac{0.562 \sin 15 \text{ deg.} \times \sin 41 \text{ deg. } 22 \text{ min.}}{\sin 80 \text{ deg.}} =$$

$$\frac{0.562 \times 0.2588 \times 0.6608}{0.9848} = 0.098.$$

Reamers are usually cut with 90-degree cutters, the Brown & Sharpe standard tap and reamer cutter having angles of 30 and 60 degrees. If we were using one of these instead of the one considered, the work of calculation would be much simplified, for with $\phi + \phi = 90$, equation (7) becomes

$$x = r \sin \phi_1 \cos \theta_1 \qquad (8)$$

Equation (7) is strictly true for a straight tap or reamer, but only approximately so for a taper tap or reamer. The reason for this is that in deducing the expression for set-over, our angles lie in a plane perpendicular to the axis of cylinder. As soon as this axis is changed by elevating the tail center as in the case with a taper, we shift this plane by an angle equal to the angle of elevation. Projecting the angles back then onto the original plane modifies them to some extent, and hence the error. For a taper reamer with a taper not exceeding 1 inch per foot, the error can be neglected, being within the limits of accuracy of the setting of the machine. We may, therefore, use equations (7) and (8) for taper reamers with tapers not exceeding 1 inch per foot, the same as equation (5) previously referred to.

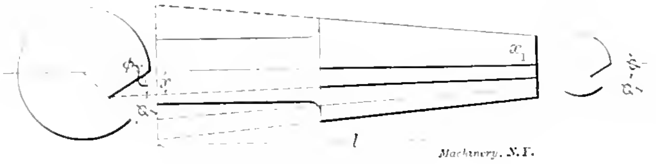

Fig. 5. Case of a Taper Reamer milled by a Double-angle Cutter.

It should be borne in mind that there are two kinds of set over, one which may be called the *table set over* in which the table, centers and all are moved over a certain distance, and another, the *center set over* in which one or the other of the centers is set over. To make this a little more apparent suppose we have a reamer ½ inch diameter at the small end and 1 inch at the large end. By equation (7) we find the set over for the large end to be 0.17 inch, while for the small end, it is 0.12 inch. If we move the table off center 0.17 inch for the large end, it will be over too far for the small end, while if it is adjusted right for the small end, the large end will not be over far enough. Swinging the table through a horizontal angle will not compensate for this difference, for the line of travel of the table will still be in the line of centers. It is therefore necessary to shift one or the other of the centers by an amount equal to the difference between the table set-over for the large and small ends of the reamer. See Fig. 5.

It follows from what has been said that unless provision has been made to adjust the tail center of a milling machine sidewise, it is impossible to cut a taper reamer with a double angle cutter without having the cutting edges of the teeth twisted with relation to the center line. If the work be held on the index head independently of the tail center, the head must be turned through a horizontal angle to escape the same consequences.

There is still one more thing to be considered. The vertical adjustment or elevation of the tail center as given by equation (5) is for a single angle cutter. For a double angle cutter this should be multiplied by the cosine of the angle of the double angle cutter which cuts the radial face of the tooth, or if we call this new elevation E_1,

$$\text{then } E_1 = E \cos \phi_1, \qquad (9)$$

Collecting these equations together, we have:

Single angle cutter

$$\text{Angle of elevation, } \alpha, \text{ for angular cutters} = \gamma - \delta, \qquad (1)$$

$$\tan \gamma = \cos \theta \cot \beta, \qquad (2)$$

$$\sin \delta = \tan \theta \cot \phi \sin \gamma, \qquad (3)$$

$$\text{For end mill } \cos \alpha = \tan \theta \cot \phi, \qquad (4)$$

In terms of taper per foot, elevation of tail center

$$E = \frac{Tl}{24} (\cos \theta - \sin \theta \cot \phi), \qquad (5)$$

Double cutter angle

$$\theta_1 = \theta - 2 \rho; \ \sin \rho = \frac{z}{2r}, \qquad (6)$$

$$\text{Table set over } x = \frac{r \sin \phi_1 \sin (\phi + \phi_1 - \theta_1)}{\sin (\phi + \phi_1)} \qquad (7)$$

$$\text{Table set over for 90-deg. cutter } x = r \sin \phi_1 \cos \theta_1 \qquad (8)$$

$$\text{Elevation of tail center } E_1 = E \cos \phi_1. \qquad (9)$$

The use of a double angle cutter has several advantages over the single. The pressure of cut comes more nearly over the center of the work, and there is no drag of the cutter teeth along the radial faces of teeth being cut, and hence a smoother cut is possible. A small angle to the side of a cutter makes it clear the work much the same as swinging the tool box of a planer causes the tool to clear on the return stroke when planing a vertical surface. We are enabled to use formed cutters which can be ground without changing their form. However, in view of the difficulties in making the adjustments, it is questionable whether the single angle cutter would not be the better.

* * *

The writer of a sensational story in the *Saturday Evening Post* which details the alleged experience of a convict in a States' prison, causes his chief figure in the drama to do certain stunts that rather take away a mechanic's breath. For example: "From the machine shop in the foundry (sic) he stole a big heavy file . . . At length he stole from the machine shop another file, a smaller one of diamond (sic) steel and with it he began to sharpen the big one of softer steel into a knife." This seems like a rather big and discouraging job, even for a convict with unlimited time at his command. Again: "He took ten needles and fitted them into the wooden stem of a brier pipe . . . close together like the teeth of a comb. They were hard; they made a diminutive saw; and they bit steel. With these needles he began to saw off his bars. He sawed for a year and had three bars nearly through," etc. A convict who can make a saw out of ten sewing needles that will cut through three steel bars ¾ inch in diameter ought to have a gold medal. He is a genius whose ability exceeds that of an Edison. Some file makers should get his name and address. The lucky one will make a revolution in file manufacture!

* * *

The construction and location of a machine shop tool room often is a somewhat difficult matter to decide upon. The location should be as central as the construction of the shop will permit, and its construction should be elastic to permit of growth with the growth of the shop, but any system of wooden drawers and shelves is objectionable, both because of lack of elasticity and the fire risk. Mr. Lucas, of the Lucas Machine Tool Co., Cleveland, O., proposes to make a new tool room in his enlarged shop of steel unit-drawn sections about four feet high, 12 to 14 inches wide, and 30 inches long, placed side by side, so as to enclose an area large enough for the tool room machines and attendants. All these steel units contain drawers for tools and supplies, but not all the units will have the drawers opening into the tool room. Part of them will be reversed so that the drawers will be accessible to the operators of machines in the immediate vicinity. This scheme has the merit of simplicity and extensibility. The only addition required to the steel units to form a tool room enclosure is a gate and a low wire net fence along the top. Such a construction does not interpose an obstruction to a general survey of the shop. It permits the tool room to be easily moved, extended or changed whenever the shop conditions require it, and is a construction durable and fireproof.

DESIGN AND CONSTRUCTION OF METAL-WORKING SHOPS—3.

W. P. SARGENT.*

In considering the building of a new and enlarged plant with the aim of attaining the lowest possible cost of product and the highest possible productive efficiency, the first question is naturally—"Where shall we build?" In answering this question, with the country at large as a field, one would probably choose a site in the vicinity of Pittsburg or Birmingham if the cost of material greatly exceeded the cost of labor in a given product. Chicago, St. Louis, or Cincinnati, would be the choice for superior shipping facilities, and the vicinity of Niagara Falls would be favored for low cost of power. The outskirts of large manufacturing cities would be the most favorable from the standpoint of adequate labor supply. Taking all things into consideration, the Middle West, in the light of its wonderful industrial advance during the past decade, furnishes a happy medium between the advantages of the other sections of the country. It will provide an adequate labor supply of all grades, cheap fuel (coal at $1.00 to $2.00 per ton), and an abundance of excellent factory sites at a reasonable cost for land.

Who has not, within a few minutes after leaving any of the large manufacturing cities of this section, looked from the car window, first, on flat tracts of land parcelled into lots with cement sidewalks and occasional houses, and with electric interurban cars probably in view, and a little later upon level farms, with possibly a water course in the foreground and a streamer of smoke in the distance indicating the existence of another railroad. There is a good site for a large works, as such land can be purchased for $250 to $500 per acre, and often in single tracts of 150 to 200 acres from one owner. Low spots somewhat removed from the natural building location should not be considered as detrimental, as they are needed for dumps for foundry dirt and ashes, which will amount to 5,000 cubic yards per year from a plant such as will be described.

Fig. 19. A Site for a Large Works, possessing Many Advantages.

A farm may not seem to be the best site for machine shops, perhaps because the intense activity of a large plant is in such contrast to the quietude of a farm that the superior advantages may not appeal strongly; and doubts may be entertained of the securing and retaining of men in competition with the glamor of residing in the crowded city districts. That adjacent land, however, will be parcelled out for building lots, and that there will be a colony of homes before a large new works is in operation, is almost a certainty; and that the more reliable class of workmen will be attracted, is equally certain.

If the site chosen is within the city limits, there will be but a single fare on street cars, and the new plant will secure the benefits of municipal fire, water, and sanitary service to supplement its own service. But the non-success of securing a desirable site within the city limits need not deter the building of the plant just outside the limits. Any railroad will be glad to run a special morning and evening service to accommodate the workmen living within the city. Fire insurance rates will, however, approximate 25 cents per $100 more, if the plant is outside the municipal fire service limits. The well known tendency of cities to grow in the direction of industries in the outskirts, will in time bring fire service, at least soon enough to provide reserve facilities when extension of the works is necessary. But, of course, works of large size should be sufficiently protected by their own appliances not to be dependent.

Fig. 19 shows one of a number of fine sites about three miles from the center of a manufacturing city of 35,000 inhabitants. The line of trees in the distance is on the bank of a stream that would furnish water for all purposes except for drinking. Wells can be driven almost anywhere in the vicinity, and an abundance of pure cold water obtained. Beyond and paralleling the stream is a street with an interurban electric line; and about half a mile south a steam road crosses the street and parallels the stream, thus giving to the site a road on either side. The space is sufficient to allow of a rectangular site being laid out about 1,500 feet east and west and 2,000 or 3,000 feet north and south.

Preliminary Estimate.

We will now get to work on a general estimate of the amount of land required, and of the approximate cost of the project, basing the space figures on those given in column 1 of Table VIII. We will tentatively plan the layout of a new and complete plant to employ 1,500 men on medium and heavy machine tools. How much land will be required and how much space under roof will be required to work 1,500 men in all departments, or, in other words, to increase the production to $3,000,000 per year at $2,000 per man? The number of square feet per man under roof is given as 368, which applies during crowded conditions and includes a number of shacks and a large percentage of pattern storage. It should be noted that the percentage of total space under roof to the total space for machining is 540 as compared with 341, the mean of the plants Nos. 5, 6, 7, 8 and 9, but as all the details will not be considered in this broad estimate, we will use the figure given, being on the safe side, and will consider that the corporation officials would make their own allowances on the sum total of the money to be spent, anyway.

Space Occupied by Buildings and Total Ground Space.

For the total floor space take 1,500 men at 368 square feet each, as requiring in round numbers 550,000 square feet. We will assume that 25 per cent of this space will be galleries, reducing the total 137,500 square feet, and making the total ground floor space under roof 412,500 square feet. We will adopt a rectangular layout similar to that of the West Allis Plant and will therefore multiply 412,500 by 2 and get 825,000 square feet as the total of the ground space within the building rectangle. Increasing this by 60 per cent, to provide for extensions to make the total number of men employed 2,500, adds 495,000 square feet, making 1,320,000 square feet, sufficient to cover all the building ground space ever required. The area for trackage may be taken as 50 per cent or 660,000, making the grand total that should be purchased 1,980,000 square feet or 45.5 acres, or 50 acres in round numbers.

---

* Address: 315 South First St., Rockford, Ill.

Approximate Cost Estimate of New Plant.

Taking a maximum of $500 per acre makes the investment in land $25,000	$ 25,000
We will aim to keep the cost of buildings of all classes within an average of $1.70 per square foot, and for 550,000 feet of floor space the total cost of buildings may be placed at $935,000	935,000
For power equipment we will assume one I. H. P. per man; 1,500 H. P. of boilers, including reserve battery stokers, piping, auxiliaries, engines, generators, switch-boards, and coal-handling and storage apparatus at $90 per H. P., totals	135,000
It is rather difficult to arrive at the cost of cranes using a unit figure, but if we assume that 400,000 square feet of space inside and outside will be served by cranes at 50 cents per square foot, the total cost will be about $200,000	200,000
Heating: Taking 412,500 square feet occupied by buildings and multiplying by an average height of 50 feet gives us 21,000,000 cubic feet as the approximate cubical contents; with a ratio of 150, this requires the equivalent of 140,000 feet of direct radiation, which at 60 cents per foot, and with some extra allowance, makes the cost for this item in the neighborhood of $90,000	90,000
The nominal horse-power of motors required for direct and group driving approximates 1 H. P. per man and 1,500H. P. of motors at $15 per H. P.	22,500
Trackage in the yards will approximate 6 miles at $9,000 per mile	54,000
Switch engine, locomotive crane, and rolling stock	12,000
The sprinkler equipment and inside piping will cost 7 cents per square foot for 550,000 square feet—$38,500—and 10 cents per square foot for yard piping, tanks, etc.—$55,000—totals	93,500
The machine tool equipment will cost about $600 per man or for 1,500 men $900,000 or about $8.00 per square foot of space used for machining. But if a new shop replaces an old one, the machine tool equipment would certainly be moved, and it is probable that the new tools needed at the beginning would be covered by the sum of $200,000, leaving the remaining tools to be purchased when needed	200,000

The above items indicate a gross expenditure of $1,767,000

Product.	Medium and Heavy Machine Tools.		Light and Medium Machine Tools.		Medium and Heavy Engines and Mining Machines.		Light and Medium Machine Tools.		No. 1 after Rebuilding Space Allotted		Heavy Engines, Expansion of No. 3.		Light, Medium, Heavy Pumps, Condensers.		Compressors, Rock Drills, Light, Medium, Heavy.		Corliss Engines, Turbines, Pumps.	

Plants Nos. 1, 2, 3, and 4 are unimproved. Plant No. 5 is rebuilt. Others are entirely new.

Taking a range both ways we will say that the plant can be built for $1,600,000 to $2,000,000, of which there could be charged off an amount equal to the market value of the old plant and of equipment not removed to the new plant.

It is a difficult thing to find a customer for old shoes which the owner has outgrown and worn out, especially of such a size, and it is hardly probable that a corporation will release to the ravages of time and man, a property which for $500,000 could be enlarged and improved to employ 1,500 men even though the limit of expansion would be reached. Only a corporation so happily situated as to have built and grown in the heart of a metropolis, with the value of its real estate enhanced to the extent that the proceeds of the sale of its ground would partly build the new plant, would consider a proposition of this size. Possibly also a concern having absolutely reached its limits of expansion would decide upon eventually having a plant that would be right, and would plan as a whole, and build in part, as their needs necessitated and their resources would permit.

A new plant, however, is what all overgrown concerns would like to see, and the writer will proceed on the assumption that the means would be forthcoming, especially as the designing of a new plant of this size will cover most of the problems that arise in planning the extension of old plants.

The General Layout.

Referring to Table VIII, the reader will notice that the percentages are based on the space used for machining (sepa-

rated from the tool-making and supply departments, which are included in the figures given for the machine shop total), but should be considered as approximate for the plants that are not given in detail. Table IX takes into account the number of men, and the modifications necessary to form unit figures that can be used as the basis for laying out the new plant.

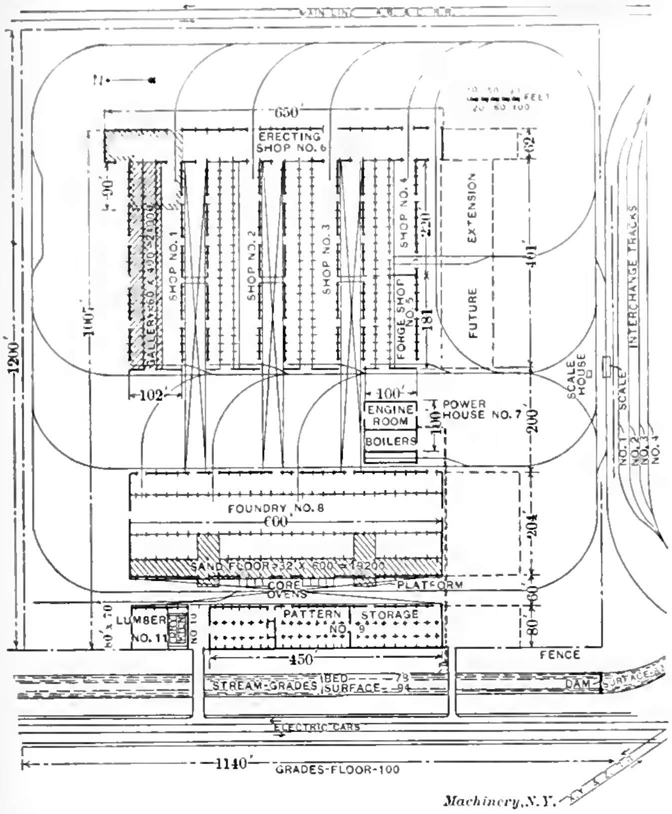

Fig. 20. Block Plan of Model Plant.

As the relative number of men in the different departments is constantly changing, and the departments are not all at their highest efficiency at the same period, it is necessary to analyze each department separately, and the composite figures obtained will probably differ from the data obtained for any definite date. For instance, the number of men given in Table IX is not the number employed at the time that the foundry complement was compiled, but figures are taken that balance better.

In the works from which these figures were obtained the space is badly broken up. The main erecting bay—50 feet wide—is not wide enough to erect a double line of the heavy machines at one time and utilize the space to the best advantage. Work that should be placed adjacent to the tools ready for machining is sandwiched in between machines undergoing erection, thus making the erecting space, to a great extent, merely storage space for work in progress. In a building intended for erecting only, the amount of this waste space should be transferred to the machining space, and it should be noted that the figures for square foot per man are modified, and 300 square feet per man is taken as a unit for both erecting and machining space. The foundry space is crowded, so the unit per man is made 250 square feet. The total number of men is reduced to a unit of 357 or approximately 1/3, allowance being made in the foundry for expected superior arrangement, and in the pattern shop for the employment of a greater proportion of men to expedite work from the drawing-room to the foundry. It should be noted that the modified space ratios correspond better with those of the new plants in Table VIII.

The unit figures are multiplied by 4 to provide for an increase in force to 1,500 men, or approximately 33 per cent more. If later extensions are needed, the addition of another unit will provide an increase of 25 per cent; and if we lay out our buildings right, the extensions can be made without interfering with the production in the least. We can now block out roughly the size of the main buildings, basing our conclusions on the data from Table X.

Erecting Shop.

The heavy erecting space in bays 2 and 6 in Table X is 27,500 square feet, and the medium erecting in bays 1, 3, 4, 5, and 9, occupies 30,500 square feet. The widths of the bays vary from 35 to 50 feet, and as the widest are not wide enough to erect a double line of machines, and the narrow ones do not economize room, we will consider that a width of 60 feet will not be excessive or detrimental to the effective use of the cranes. It should be remembered that the bridge traverse of cranes is more rapid than the trolley traverse; traverse of cranes is more rapid than the trolley traverse, can be increased proportionately; or, what amounts to the same thing, the trolley will have a chance to accelerate to the highest speed and even get a short run at the high speed, on a crane speeded as they ordinarily are.

From the erecting space (67,200 square feet) in Table IX, the amount required for fitting (17,200 square feet) is deducted, leaving 50,000 square feet as the space that should be considered for the main erecting space. Dividing by 62 feet (the crane span plus 2 feet) we get 806 feet as the approximate length of the erecting shop. This is merely a tentative figure, as we may want to modify the dimensions on account of considerations of space distribution.

For the machining, we have plenty of latitude in the arrangement of space, as the percentage of the total machine space that requires cranes of 15-ton capacity is about 11

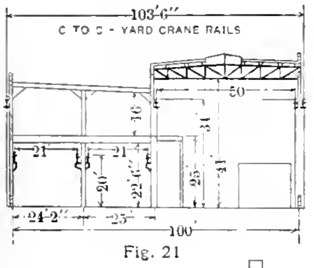

Fig. 21

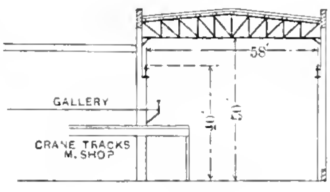

Fig. 22

per cent. This percentage of the 172,800 square feet required for machining is 19,000 square feet, and a bay 52 feet wide and 400 feet long will be ample, leaving 152,000 square feet to be taken care of by galleries and smaller crane bays. Before settling on a cross-section for the machine shops, the percentages of the space under cranes, and that used for the heavy and medium work should be determined from Table X, and the amount of space for a complete unit (from Table IX) apportioned accordingly.

We have the following figures from the preceding discussion. 1. A width of about 60 feet for the erecting shop. 2. A main bay in one machine shop about 50 feet wide and 400 feet long. Summing up the machining space in Table X that is not served by cranes, we get 48,000 square feet and this equals 54 per cent of the total of 88,000 square feet in the old shops. Taking 54 per cent of the desired 172,800 square feet, we get 93,000 square feet of space that can be on galleries or under galleries. The planers occupy about 29 per cent, and this calls for 50,000 square feet in the new shops.

To secure low cost and quick delivery of construction material, it is self-evident that the buildings should be as nearly alike as possible in dimensions and details, following the methods of all successful manufacturing, in providing for duplicate parts in large lots. As the space will not permit of the discussion of all the steps leading up to a tentative plan, the block plan Fig. 20 is presented together with a brief explanation of the reasons for the arrangement and proportions, wherever the conclusion has not been reached in the preceding paragraphs.

It should be noticed that 180 feet in length of Unit No. 4 has been modified for use as smith shop. As we have been generous in the space allowed per man in this department, this shop (by night work, if

necessary, which is profitable for heavy forge working) should be ample to take care of a 25 per cent increase in the rest of the plant.

A width of 100 feet inside is taken as basis for the wing shops. A gallery 50 feet wide, adjacent to the 50-foot main bay, and 25 feet from the floor, affords good light and ventilation under the gallery. A gallery 10 feet wide projecting into the main bay does not interfere with the placing or operation of the heavy tools and provides a central location for stairways, elevators, wash-rooms, shop offices, tool-rooms, storage, etc., without encroaching on the main gallery floor. With this cross-section, the floor area per unit is 40,000 square feet on the first floor and 24,000 square feet on the gallery, totaling 64,000 square feet, or more than is called for in Table IX for both machining and erecting. Therefore three shops 90 feet in length are assigned to erecting and assembling, which shortens the main erecting shop to about the length of the foundry. A portion of the space in shop No. 4 is assigned to storage and shipping, and also a portion at the south end of the main erecting shop. A width of 204 feet is adopted for the foundry.

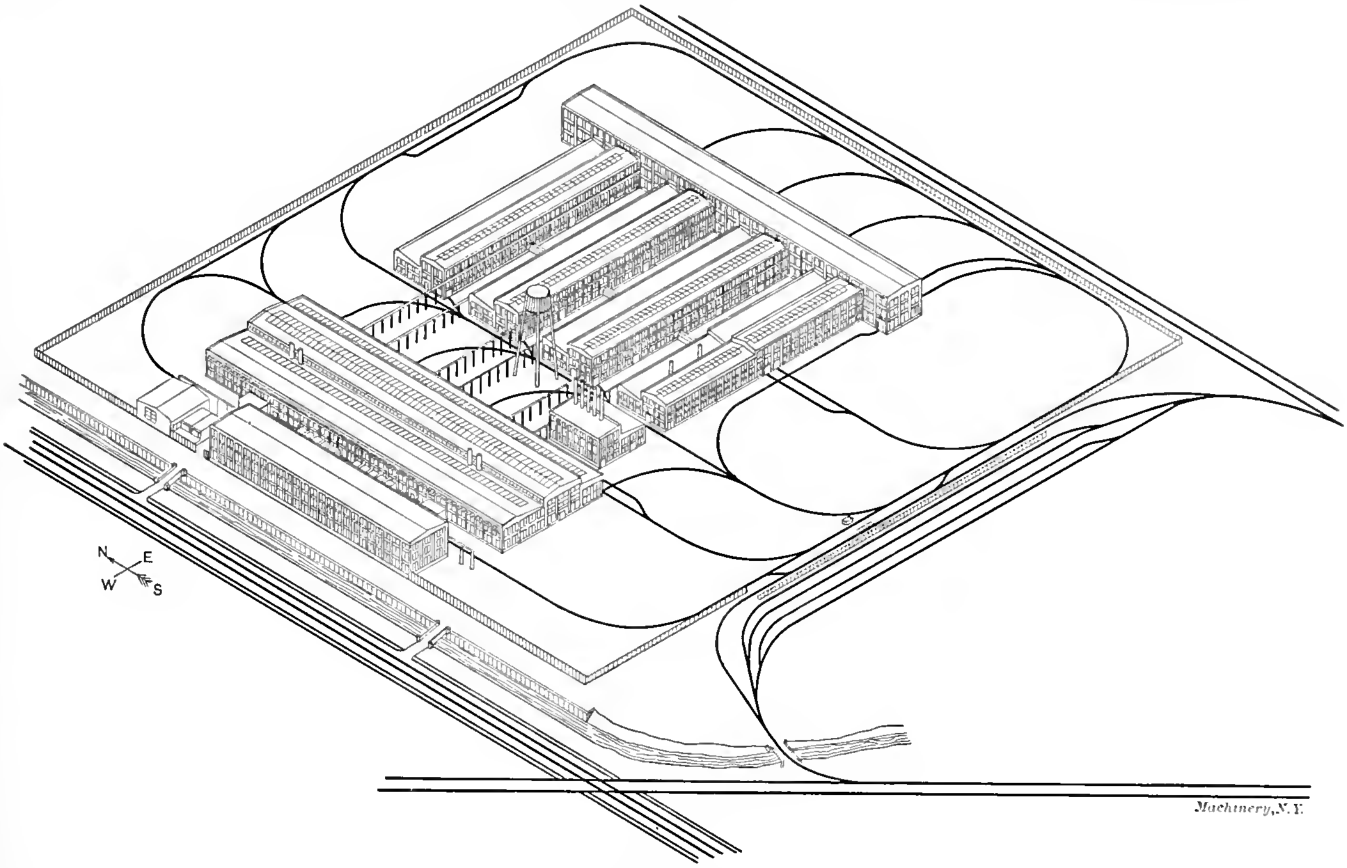

Fig. 27. Perspective of Model Plant

Assuming that 10,000 square feet each would be required by the drafting department and office (from Table VIII), and taking 22,000 square feet for the pattern shop (from Table IX), and 63,000 square feet for the pattern storage (slightly more than given in Table VIII for Plant No. 1), the total of 105,000 square feet is deemed sufficient for these departments. Making one building 80 feet wide and 3 stories high, the length is kept to about 450 feet.

This arrangement provides for the drawing room on the top floor, the offices on the second floor and the pattern shop on the ground floor. These departments will therefore get light from all sides but the south. Lumber storage is provided near the pattern shop and this corner of the works will be relatively free from the smoke of switch-engines and the dirt from the foundry, as the prevailing winds are from the southwest. The direction of the prevailing winds in warm weather should be well considered, and the plant laid out to get the benefit of them, if no more important feature has to be sacrificed by so doing.

Cross-section of Buildings.

The distance from floor to roof truss in the various buildings is determined by the required height of crane rails (distance under the hook is approximately the same), and tho clearance required for the cranes themselves. The following table gives clearances sufficient to permit of installing the cranes built by the leading makers.

		Clearance	
Capacity.	Span	Rail to Truss	Rail to Column
5-ton (Trolley on lower flange of girder.)	33′	2′ 6″	7″
10-ton	50′	6′	8″
15-ton	60′	6′ 6″	10″
20-ton	60′	6′ 6″	10″
30-ton	70′	8′ 6″	12″
40-ton	70′	8′ 9″	12″

The forge shop, Fig. 23, is given plenty of head-room, with swinging windows close to the roof, to provide adequate natural ventilation. Ordinary circular ventilators seem to fail in clearing such a shop of smoke and gases, and monitor louvres, as commonly placed, are not a great deal better.

The velocity of the efflux of the smoke and foul air is governed by the difference in temperatures between the air inside and the air outside. The average temperature in a forge shop is seldom greater than 90 degrees; with the outside temperature at 55 degrees (a yearly average for the Central states), the difference in weight of the two columns of air is so little that the foul air escapes only in a small amount through ventilators in the roof. Even at zero-temperature outside, the velocity of efflux is but slightly greater, as the velocity increases as the square root of the differences in temperatures.

The writer advocates the use of windows near the roof. These windows, when open, allow any horizontal air currents to blow straight through, as even a gentle breeze will have a higher velocity than is obtained through roof ventilators. Heating radiation will of necessity be supplied to make up for the loss of heat from the building. This method of ventilating is provided for all the other buildings, and especially in the boiler room. The air in the shops will be renewed in winter time by the natural filtration of air through the walls, and by the opening of doors. Heating engineers often figure on three changes per hour in large shops on account of these losses.

Central skylights of ribbed glass, in the roofs of the high buildings, will diffuse the direct rays of the sun so that

the workmen will not be seriously bothered. An overhead skylight on a roof within 30 feet of the floor is almost an absurdity, as its effectiveness for lighting must be greatly nullified by painting in order to protect the men from the heat of the direct rays. This, of course, does not apply to saw-tooth skylights.

The headroom of the pattern shop building, Fig. 24, is 20 feet, or one-fourth of the width. This ratio is given by a number of authorities as necessary for good lighting. The rule works out in practice, as may be observed in many instances.

Arrangement of Space Model Plant.

The following figures are given for comparison with the Table V of the October issue, covering plants already built.

	Square Feet	Percentage.
Rectangular space bounding buildings, 650 by 1,007 feet, equalling	654,000	100
Covered by buildings............	389,000	59.4
Under yard cranes..............	93,600	14.3
Tracks and vacant space..........	172,400	26.3
Average haul of castings to shops..........		500 feet
Maximum distance of electric transmission..		700 feet

The layout shown in Fig. 20 permits of the allotment of space for the different departments in close accord with the desired figures of Table IX, as will be seen by comparing Table XI with Table IX.

Allowing space for erecting and assembling in the wing shops has many advantages. Scraping and fitting and group assembling can be done in under the gallery floor, served by light cranes. When the groups are ready for erecting, they can be carried out into the main space by the cranes on the runways projecting into the No. 6 building. This reserves the high shop strictly for its designed and most productive purpose. Then again the portion of the 50-foot bay of the wing shop reserved or allotted to erecting, forms a neutral ground between the machining and erecting departments, and is ready for instant use to accommodate an overflow from either branch of the work. In other words, this space can take care of the surges of forced production, and the common trouble attendant upon the placing of a new and very large tool in a space already overcrowded, is obviated.

Yard Cranes.

The cranes in the yard between the foundry and the pattern storage buildings will handle the charging trucks loaded with pig iron from the storage piles to the outside platforms, which form extensions to the charging floors. The cranes will also handle the heavy flasks and core-boxes between the points of storage and use.

Water Source.

A stream of water, even though the flow is small but steady, is worth a good deal to a large works, as a dam will form a reservoir of a far greater capacity than needed. And the water can flow through the condensers to the lower level of the stream with but little pumping, and also keep the fire-pump primed without a tank.

The block plan Fig. 20 and the isometric view Fig. 27 are self-explanatory, especially to one who has followed the previous papers of this series.

Unless the engineer-in-charge has a large force of tried men and plenty of time, it is much better, in fact, almost necessary, to use the service of an architect on a project of this size. The architect's estimate of cost will check that of the engineer.

The succeeding instalment will cover the data and instructions that would be required to start an architect on the definite plans for the buildings, and will give costs that will form a basis for estimating the many details of works construction.

* * *

An interesting substitute for the ordinary forms of wall paper has, according to the *English Mechanic and World of Science*, been introduced in India, in the form of a damp-proof wall covering made from copper. The material varies in thickness from 0.0012 to 0.006 inch. Apart from its wearing qualities this wall covering is insect-proof, as well as damp-proof, which makes it particularly desirable in India during the rainy season.

HOW TOM CROSSED THE RUBICON.[*]

A. P. PRESS.

I met Tom the other noon at lunch—that is, he was Tom when I knew him last. He is Mr. Smith now, and he is superintendent of the Laporte Machine Co.; but when we were foremen together at the E. G. Co., he was just plain Tom, and he ran the "West" shop. Tom left the E. G. Co. a long while ago, and I hadn't seen him for years till this week. Monday when I was out at lunch in came Tom, or Mr. Smith, I should have said; he took a seat at the same table with me, and we had a good old talk.

I never knew why he left the E. G. Co., and, as Tom said, he didn't know himself for a long while. As I told you at the start Tom was foreman of the "West" shop for years and he "made good"—so good, in fact, that other firms in the same lines of work wanted him, and they kept making him good offers, and that got him "on the run." Tom didn't seek the jobs, but the jobs came around looking for him. Finally one firm made him an offer of $1,800 a year, and as he was getting only $27 per, he couldn't say "no." He didn't close the deal, but he sent a note up to the "super" that he wanted to leave; "see me on this," was what he got back, and Saturday noon he went up and saw the "super."

"Well, have you crossed the Rubicon yet?" were the first words the "super" said to Tom as he came in the door.

Now, Tom was a good man; he could handle a lathe or a planer, and he could get a lot of good work out of a poor set of men, but he was not strong on Roman history, and though he had heard the name before, he wasn't sure whether it was a river in Asia or whether it was a part of the third degree of the lodge that he had been put through a week before. In fact, he rather thought it was the lodge, so he answered back promptly, "I suppose I have, sir."

"Well," said the "super," "I never like to change the personnel of the foremen, but if it's too late it can't be helped."

He went on and gave Tom a lot of good advice, but not a word did he say about more money; and after he was done Tom went out feeling kind of queer. As he told his wife when he got home, he didn't know whether he had a compliment or a "call down," but the "Old Man" had used him fine, but after he got through he didn't know where he was at.

He went with the Laporte Co. and made good all right, but, as Tom said, "It never came to me till I got hold of an old book on Roman history, what the 'Old Man' meant by 'crossing the Rubicon.'" But as things have turned out I guess it is just as well.

* * *

A dirty line-shaft is a reproach to a shop foreman, and also is a fire hazard, especially in shops where considerable quantities of dust and lint are flying about. Accumulations of fuzz and grease on line-shafts are said to have started fires, and insurance companies in some cases require that the line-shafts be kept clean. The simplest and perhaps most effective method of doing this is by means of straw-board "travelers," which are simply annular disks of straw-board cut with the hole slightly larger than the diameter of the shaft. These disks are cut through from the hole to the exterior on one side so that they may be sprung over the shaft. In the magnificent machine shops of the Western Electric Co., Hawthorne, Ill., the travelers are largely used on the line-shafts, and the sight is somewhat uncanny. Hundreds of them are traveling back and forth all day, doing their work most effectively. The line-shafts are kept bright and perfectly clean of all accumulations, and the general appearance of the shop greatly improved.

---

[*] In Roman history "crossing the Rubicon" is the act of Julius Cæsar returning to Italy at the head of his army contrary to the orders of the Roman senate. He was governor of Gaul, and the commanding-general of the Roman army required to keep the province subjugated. His campaign had been a brilliant success, and in its progress he neared the boundary of Italy, where the desire to return to Rome became too strong to be resisted. To return he had to cross the Rubicon, a small river separating ancient Gaul from Italy, and this he could not do as commander of the army without committing treason, but personal desire overcame his patriotic scruples. Cæsar's entrance into Italy at the head of his victorious army caused the downfall of Pompey and the Roman republic, and the rise of the empire, of which he was the first emperor. Hence, "crossing the Rubicon" is a saying applied to any move that may have important consequences to the one making it.

THE WINDSOR MACHINE CO.—EXAMPLES OF ITS SHOP PRACTICE.

As everyone familiar with the machine tool business knows, there is a remarkable trio of machine shops hidden in the narrow valleys of the out-of-the-way State of Vermont. All three of these shops (which are within a few miles of each other, two at Springfield and the other at Windsor) are remarkable for the originality of their methods and their products, and thus give evidence of originality in the men behind them, as well. The writer had the good fortune, on his last visit to that locality, to enjoy there a period of crisp, sunny autumn weather, and it left the inevitable impression on his mind that the brisk Vermont air, and the freedom from the countless distractions of the city, must have a tonic and clarifying effect on the minds of these resident mechanical geniuses.

All speculation aside, however, the methods and products of the three shops mentioned will repay the careful study of anyone concerned with the building or using of machine tools. Much has been written about the work of two of these firms—the Jones & Lamson Machine Co., and the Fellows Gear Shaper Co., of Springfield, Vt. Less has been said, however, about the Windsor Machine Co., the third member of this trinity. This is probably due to the fact that while in point of years it is the oldest of the three, it has only of late years been rejuvenated to the extent of becoming an active factor in the machine tool trade. The following pages, therefore, devoted to a brief description of selected operations taken from the work of their plant, treat of material hitherto unpublished.

The Town and the Shop

Windsor is situated on the Connecticut River, about 110 miles from Boston, and 260 miles from New York, with the latter of which cities it has through train service in the summer. It lies in a region which is one of the beauty spots of the globe, and the chosen home of celebrated artists and writers. The salient features of the region, as may be seen from the view of the town shown above, are the winding Connecticut River, with its fertile, tree-shaded valley, and "blue Ascutney looking down" over its foot-hills from the westward. The roomy, old-fashioned mansions and story-and-a-half cottages of the town are fairly hidden in the great elms for which this valley is famous, and would make little showing in the picture, had it not been taken in the spring before the trees leaved out.

The shop gives plain evidence of having grown by gradual accretion from almost infinitesimal beginnings. It stretches

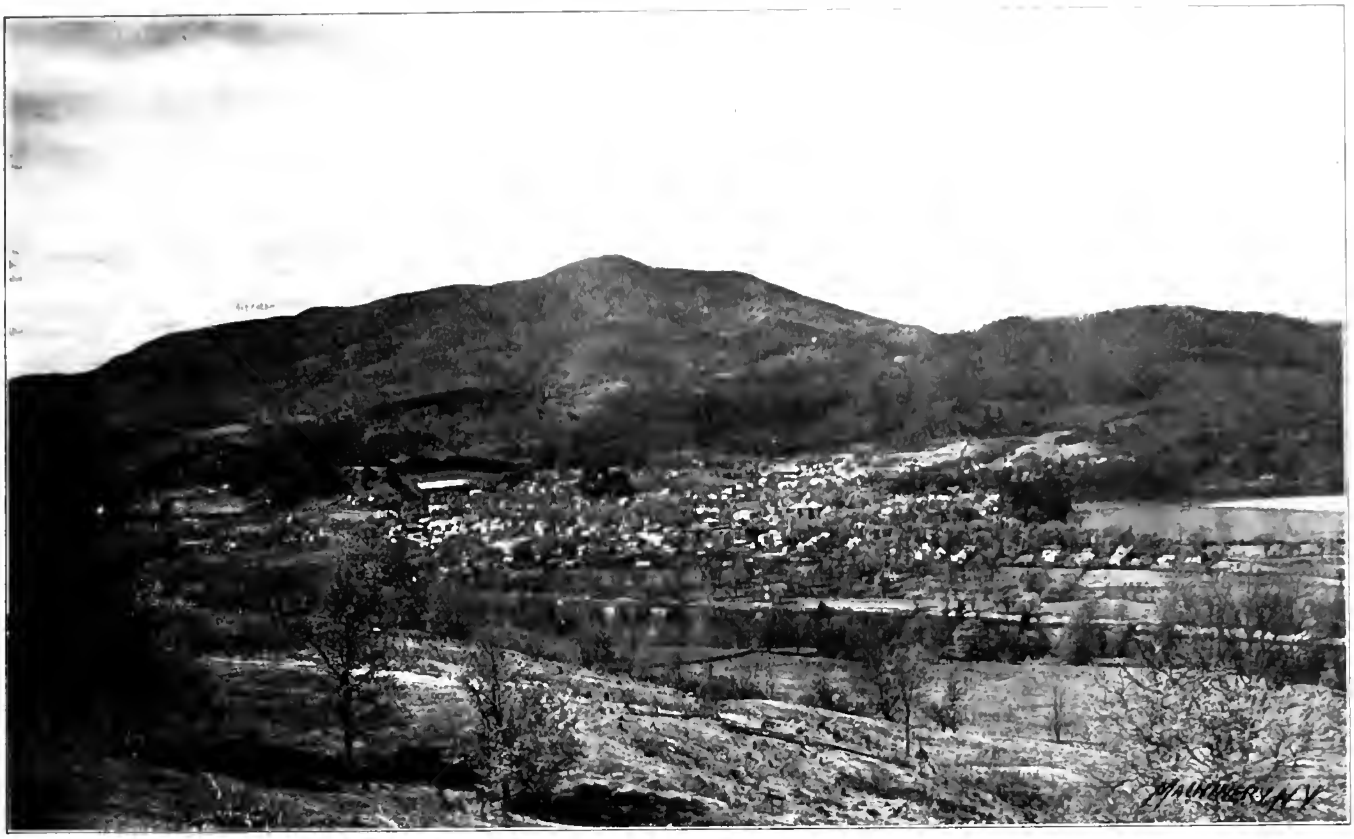

Fig. 1. The Home of the Gridley Turret Lathe; the Town of Windsor, the Connecticut River, and Mount Ascutney.

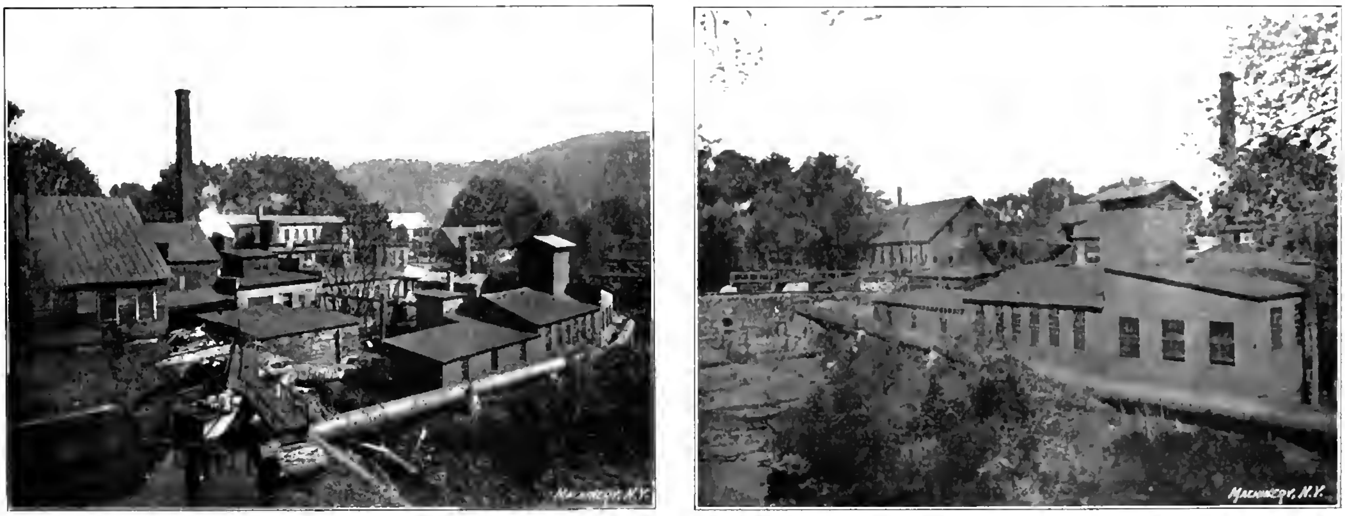

Figs. 2 and 3. Shops of the Windsor Machine Co. This Plant, like Topsy, was not born, but "just growed."

along the bank of Mill Brook, which comes tumbling down through the town from the hills in the rear (the reader must not judge of the "tumbling" from the picture, which was taken in a dry time), parting with its energy, as it goes, to the succession of water wheels with which the thrifty inhabitants have checked the precipitancy of its course. One of these turbines helps to drive the line shafting of the Windsor Machine Co., in times of normal rainfall. For the past few months, however, the work has fallen entirely on the Brown engine and the Sturtevant engine-dynamo set, which are needed even under normal conditions to help out the water power.

The Product of the Windsor Machine Co.

The Windsor Machine Co. makes the Gridley automatic turret lathes or screw machines. The single spindle form of this machine has been on the market for some years, and may be seen at work in almost any part of the screw-machine-using world. The four-spindle automatic design belongs to a more recent period, and was described for the first time in the department of "New Machinery and Tools" in the February, 1908, issue of MACHINERY, where the ingenious and original features of its construction were explained in detail and illustrated in a number of engravings. It will be remembered that the salient feature of the design of that machine was the construction of the spindle head, shown in Fig. 4. This has a bearing in the one-piece frame of the machine on the outside diameter of the spindle flanges, and on the journal formed on its shank, thus holding it firmly in alignment.

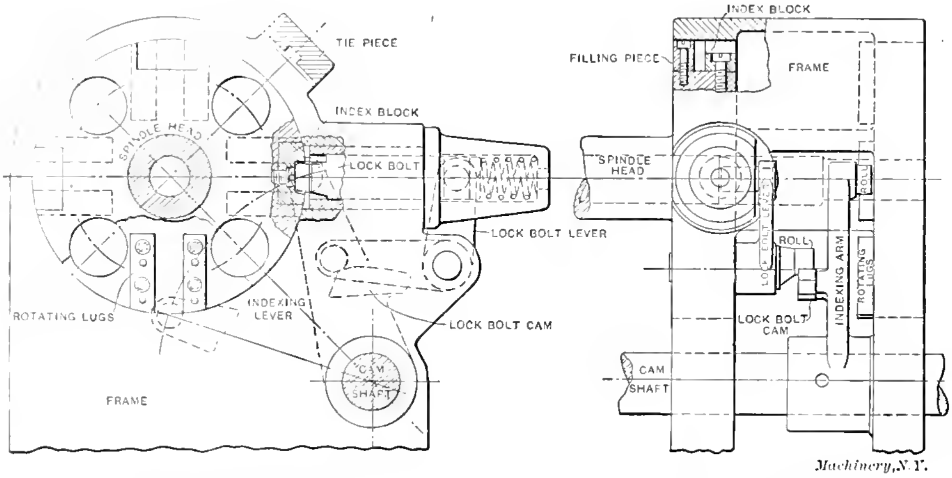

Fig. 4. Sketch showing the Spindle Head and the Indexing and Locking Mechanism.

Still more important than this item, in the vital task of preserving the alignment of the four spindles, is the mounting of the four-sided tool-holder on the solid shank of this revolving head, thus preserving the proper relations of the tools and the spindles even in the scarcely possible case of serious wear of the head in the frame. This feature, together with the locking of the head and the guiding of the sliding toolholder, at radial distances considerably greater than the radius of the circle in which the spindles revolve, gives a construction it is difficult to criticise, off hand.

In this, as in any other multiple spindle screw machine, the important point in the building of the machine, so far as accuracy is concerned, is the location of the spindle holes and of the indexing blocks in the revolving head. In a single spindle machine, if the index ring of the turret is not exactly divided, the machine may still be made to do its work accurately, as the holes in the turret may still be bored to line exactly with the spindle in each position. In a multiple spindle machine, however, if the spindle head is not exactly divided, there is no possibility of accurate work. The toolholder may be machined to line up with the spindle in one position, but when the head is indexed to the next position, this coincidence is lost beyond recovery. On account of this necessity for extreme accuracy, the machining of the spindle head will be described from start to finish, in the following paragraphs, being chosen as a representative piece of work, and one capable of testing the mettle of the most skilled mechanic.

Lathe Operations on the Spindle Head.

The first machine operation on the cast-iron spindle head, is that of boring and reaming the central hole. This is done in the lathe shown in Fig. 5. The operator of the lathe took the greatest pleasure imaginable in explaining each step of this operation to the writer. He hustled around and brought out one special tool after another, pausing after the explanation of each step only long enough to get a fresh breath, and, with a prefatory "now then," start off on the next lap. His enthusiasm is by no means unmatched among the machinists of these country towns, and is in marked and refreshing contrast with the time-serving spirit found among the workmen in large industrial centers. But perhaps these more sophisticated, city-trained workmen are not entirely to blame for their unsatisfactory attitude.

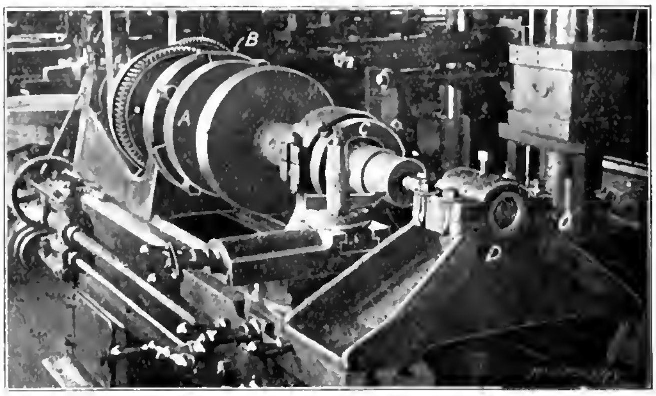

Fig. 5. Boring and Reaming the Central Bushing Hole in the Spindle Head.

The lathe carried a four jaw, independent chuck *B*, with a central bushing for supporting a boring-bar, as will be described later. The large end of the casting *A* is grasped and centered in this chuck, and the shank is rapped until it runs very nearly true. Then the revolving steady rest or "cat head" *C*, is pushed on over the shank, and the eight screws of the revolving bushing are set down gently on the work, after which a light chip is taken with an ordinary turning tool for an inch or so from the end of the shank. Then the screws in bushing *C* are released, and a test indicator is applied to the turned portion. If, as is almost invariably the case, the work runs out a trifle, the shank is rapped until the indicator shows a true running surface. Then the bushing screws are set down again, and the indicator is applied for a second time to see that the surface still runs true. All this is simply to make sure that the work is supported in an unstrained condition.

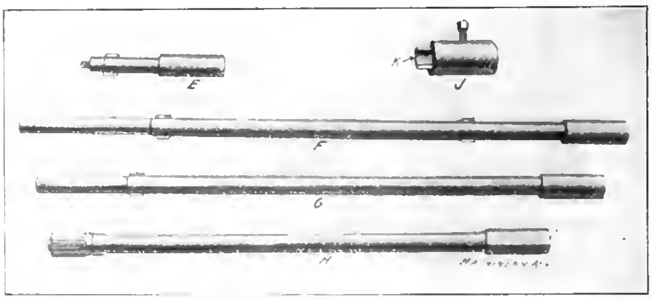

Fig. 6. Boring-bars, Reamers, etc , used in the Operation shown in Fig. 5.

To the wings of the carriage is bolted the heavy boring tool support *D*. In the first boring operation, this carries the short, stiff boring tool *E* (see Figs. 5 and 6). As may be seen in Fig. 4, the bore of the head is cored out to form an unfinished recess for the greater part of its length, leaving finished seats at either end for the "Lumen" bushings which

support the driving shaft. It is the work of this stiff boring tool *E* to rough bore the outer bushing seat at the shank end.

In the next operation, boring-bar *F* (see Fig. 6) is used. This has a pilot shank which fits in the hardened bushing in the chuck, and it carries two cutters—one for finish boring the outer or shank end of the hole, and the other for simultaneously rough boring the inner seat. The next bar *G* finish bores the inner seat, being steadied by the pilot which bears in the bushing in the chuck, as before.

The next operation is rough reaming. For the outer end, the shank of long reamer *H* is grasped at a point near the business end in the support *D*. For this purpose, bushing *J* is inserted in the support, along with half bushing *K*, down onto which the reduced stem of the reamer is held and seated by the set-screw. For rough reaming the further end, the half bushing is withdrawn, and the reamer is pulled out to its full length, so that its regular shank, seated in bushing *J*, is held in support *D*. At the conclusion of this operation, the work is removed from the machine, and the holes are finish reamed from either end by hand.

The head is now ready for the turning operations. Hardened plugs, ground so as to be very nearly absolutely true with their centers, are driven into the reamed holes from either end. The plug at the shank end has a notch cut in it which furnishes a seat for a bar, which, when hammered on the other end, serves to remove the plug. The plug at the head end is knocked out, in the obvious way, with a bar passing through the bore. Mounted on the centers in these plugs, the exterior of the head is finished all over in the lathe to accurate dimension, except on the outside diameters of the shank and of the two flanges. These are left large, to be finished by grinding. The threading at the end of the shank is also done at this time.

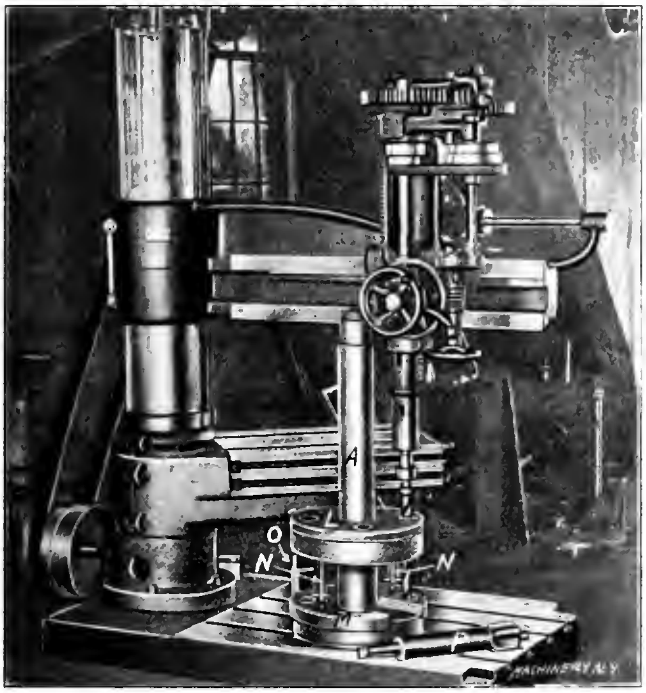

Fig. 7. Roughing Out the Spindle Holes in the Radial Drill by Drilling and Counterboring.

Boring the Spindle Holes.

The next, and the crucial operation, is the boring of the holes in the head for the spindle bushings. These holes are first rough bored under the radial drill. This operation is shown in Fig. 7. A jig is used which consists of two plates, *L* and *M*, the first fitting around the shank of the head, and dropped down over it to rest on the top of the upper flange, as shown, while the lower plate *M* is slotted through to the center to permit being slipped sidewise into position. Plate *M* is provided with a lip all around, which fits down over the periphery of the lower flange, and thus centers itself. It is clamped in position by two studs *N* with cross pin handles, which are screwed up against the bottom of the upper flange. A tongue *O*, screwed to *M*, enters a groove in *L*, and thus lines up the two members.

In this operation the long drill shown in place is first run down through the bushing in *L* and on through the upper flange, down into the bushing in *M*, and so through the lower flange, for each of the four holes. Then plates *L* and *M* are removed, and the drill is replaced with counterbore *P*, which clears the holes out to within 1/16 inch of their finished diameter.

After this, the heads are taken to the grinding machine, and finished very accurately on the outside diameters of the flanges and the shank, to insure accurate fitting in the subsequent jigs and in the final resting place in the frame of the machine. The reason for rough boring the holes before grinding is to prevent the possibility of bulging out, by the boring, the thin wall of metal between the holes and the finished edge of the flange.

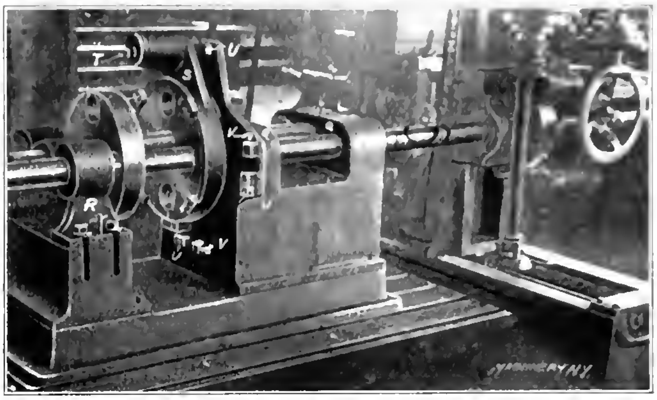

Fig. 8. Finish Boring the Spindle Holes in an Accurate Indexing Jig

After the grinding, the holes are accurately bored by the method shown in Fig. 8. The jig shown, mounted on the table of a Beaman & Smith boring machine, is provided with accurately sized journals at *Q* and *Q*, into which the shank of the head is slipped, bushing holder *R* being swung back out of the way for the purpose. On the inner flange of the head is clamped the dog *S*, in whose tail is seated at *T* a closely fitted, floating plunger, whose opposite sides are milled off flat on the projecting end. On the face of the jig are located four blocks, three of which are seen at *U*, *U*, and *U*, and four set-screws *V*. The flatted end of plunger *T* is pushed in between each of blocks *U* and set-screws *V*, in turn, and is clamped against the former by the latter. This is the means provided for indexing the work accurately to four positions.

Although the jig has bushings on both sides of the center line for boring-bars, as shown, only those on the front are used, the rough boring being done under the radial drill, as described. The boring bar is driven from the spindle of the machine through a universal joint, the bushings in *R* and *Q* being depended on entirely to control the alignment. Holder *R*, which swings back to permit changing the work, is located in its working position by an accurately-fitted dowel pin and suitable bolts.

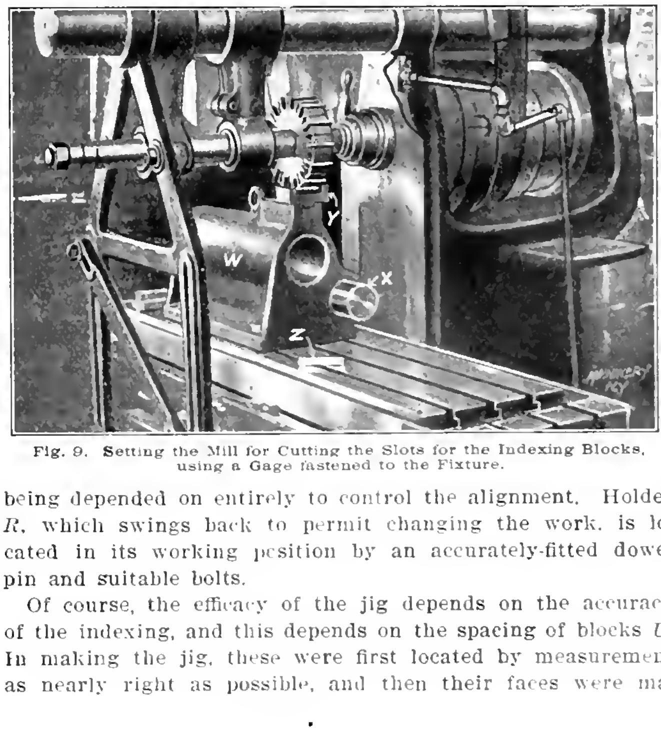

Fig. 9. Setting the Mill for Cutting the Slots for the Indexing Blocks, using a Gage fastened to the Fixture.

Of course, the efficacy of the jig depends on the accuracy of the indexing, and this depends on the spacing of blocks *U*. In making the jig, these were first located by measurement as nearly right as possible, and then their faces were ma-

chined and finally scraped to the proper dimension. This final fitting was done by actually boring a piece of work in the jig, and calipering the distance from one hole to the next, all around, until the scraping of the block brought the indexing to the required degree of accuracy.

Milling the Slots for tho Indexing Blocks.

The position of the spindles being thus located by the operation just described, it is next necessary to locate the indexing blocks for the spindle bushing holes. These blocks, as may be seen in Fig. 4, are fitted in slots milled in the periphery of the inner flange of the head. They are hardened and ground all over, and are provided with a milled groove having one straight and one taper face, fitting corresponding surfaces on the locking bolt. The straight face is the locating surface, the taper merely furnishing the means for forcing the straight face against the bolt. In making the blocks, the width and the straight side of the slot are carefully sized; this insures accurate indexing if the slots in the head are a good fit for the block, and if they are properly located with reference to the spindles. These requirements are attended to in the operation illustrated in Figs. 9 and 10.

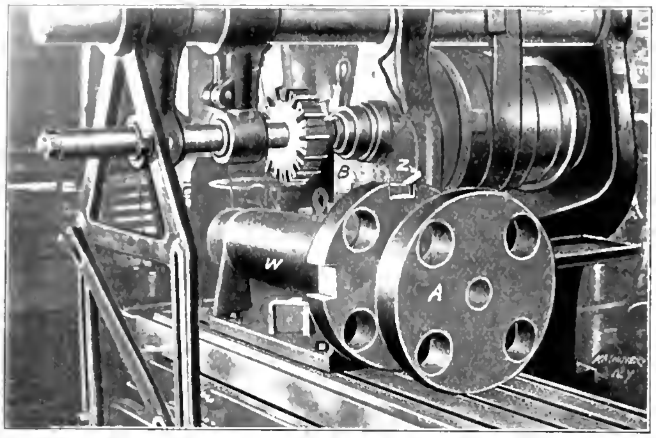

Fig. 10. Testing the Accuracy of the Slots in the Indexing Blocks, using a Test Block fastened to the Fixture.

On the table of the milling machine is clamped a fixture *W*, having a hole bored through it to accurately fit the ground shank of the work. At *X* is a plunger of the proper diameter and properly located, to closely fit the spindle bushing holes bored in the head. In a groove milled in the top of the fixture is located, by a closely fitting tongue, the setting gage *Y*. This gage has a groove of the exact depth desired for the groove in the work, but is wider on each side of the cutter by an amount equal to the thickness of the hardened "feeler" *Z* shown lying on the table. Two cuts are taken through the slots, the first with a cutter a few thousandths narrower than the required width and the second with a cutter of a thickness to exactly finish the slot to dimensions. The cutters are set for depth by raising the table until the revolving teeth just barely bite a tissue paper strip laid on the bottom of the groove in *Y*. The centering of the cutter is effected by the use of feeler *Z*, which must lie with equal freedom on each side, between the teeth of the roughing mill and the side of the slot in *Y*, and must just fit on each side, in the same position, for the finishing mill. The work is held in place by locating plunger *X*, and by a nut screwed into the threaded shank of the work, which brings the flange up against the face of the fixture.

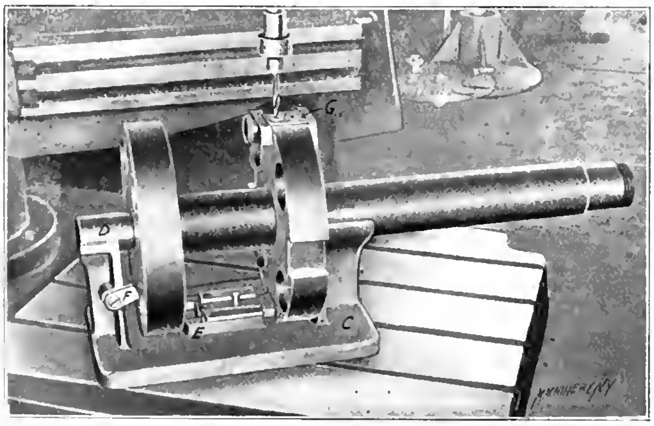

Fig. 11. Drilling the Screw Holes for Holding the Indexing Blocks and the Filling Pieces.

After each groove is cut through with the finishing mill, it is tested as shown in Fig. 10. The setting gage *Y* of the preceding illustration is replaced with a testing gage *B*, which fits in the same groove in the top of fixture *W*. It is provided with a projecting block, which enters the finished slot, and is of such width that the feeler *Z* (the same as shown in Fig. 9) should just fit on each side between the block and the sides of the milled groove. The advantage of using the feeler instead of having block *B* fill the slot, is obvious. Block *B*, under the former conditions, might be pushed along its groove until it entered the slot in the work, but if it met with a slight resistance so that it had to be jammed in, it might be quite difficult to tell on which side the interference occurred. With the feeler, this difficulty disappears.

Final Drilling Operations.

The head has next to be drilled for the screws and dowels which hold the indexing blocks in the slots. For this operation, as shown in Fig. 11, a plug *D* is driven into the flanged end of the work, which is laid in half round bearings in the fixture *C*, resting on this plug and on the ground shank. In the base of the fixture a block *E* is mounted, which slides into that one of the index slots which happens to be lowermost at the time; this locates the work. Latch *F* is swung around against the face of the flange and keeps the piece from shifting endwise.

Fig. 12. Drilling the Dowel and Screw Holes for the Rotating Lugs.

All of the fixture, as so far described, is used simply for holding the work, and presenting it properly to the drill. The jig proper is seen at *G*. As shown, it consists of a hardened block which fits closely into the slot in the work, and is clamped there by the strap and thumb-screw shown. The holes in this block guide the drill in locating the holes in the work. Besides the screw for the index block, a screw hole for the filling piece shown in Fig. 4 is provided for.

The final operation is that of drilling holes for the screws and dowels which hold the rotating strips seen in Fig. 4. As shown in the engraving, the head is indexed periodically by a roller on the end of a revolving indexing arm, which enters the space between two rotating strips at each revolution, and thus rotates the head after the manner of the well-known Geneva stop motion.

The arrangement for drilling the holes for these rotating strips is shown in Fig. 12. The shank of the head is set into the flanged base *H*, and is supported under the drilling

by the jackscrew arrangement seen at *J*. The jig proper is shown separately in Fig. 13. It consists of a plate *K*, carrying hardened bushings for the various holes to be drilled, and located by two plugs *L* and *M*, the first of which enters the central hole, while the other sets into one of the spindle holes. This plug *M* is provided with a pair of oppositely disposed radial plungers, one of which is seen at *O*. These are normally kept pressed in by a semi-circular spring snapped into the groove shown around the plug, but they may be forced out by a cone which presses against their inner ends, and is operated by the knurled knob *P* (see Fig. 12). When the jig has been set with plug *L* in the central hole and *M* in one of the spindle holes, and with plungers *O* pressed against the sides of the hole by the screwing up of nut *P*, the work is ready, as shown in Fig. 12, for the drilling.

While the strips are located on the inner face of the flanges, the drilling has, perforce, to be done from the outer side. This means that the holes must be put through very straight indeed. To accomplish this, the work is first spotted by a drill the full diameter of the bushing, and then a small drill is put clear through, followed by two successively larger ones, until finally the hole is cleaned out by a bit of the full diameter required. This gives holes so straight that the dowels fit accurately into the jig drilled holes in the strips of the opposite side. This operation completes the machining of this most important member of the Gridley four-spindle automatic screw machine.

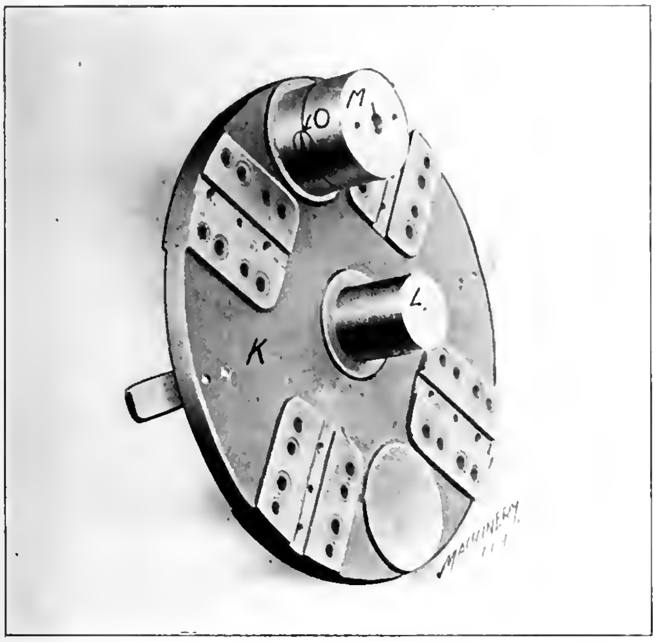

Fig. 13. Bushing Plate for the Drilling Operation shown in Fig. 12.

While the photographs from which the accompanying half-tones were made were not, in themselves, as may easily be seen, examples of the highest order of photographic art, the taking of them was no mean achievement. As was intimated in the beginning, the business of the Windsor Machine Co. has grown so gradually from such small beginnings, that the arrangement of the buildings leaves much to be desired. As a consequence, the place is crowded with machinery, so arranged that progress through the plant is slow and painful for a stranger. The difficulties of taking photographs may be imagined when it is stated that Figs. 9 and 10 were taken with the camera out in the yard, and pointed in through an open window. In other cases the camera tripod was precariously perched on planer tables or piles of castings, and at times it would have been convenient could the acrobatic local photographer have hung by his toes from the line shafting, like a bat.

It is probable that if Mr. ——— is elected president and business picks up, this firm will build new shops down by the railroad track, before many months. If these shops are built, and if as much ingenuity goes into their construction and operation, as into the doing of work in their present confined quarters, they will be well worth visiting and describing.

R. E. F.

JIGS AND FIXTURES—8.

EINAR MORIN *

DESIGN OF CLOSED JIGS.

In the sixth and seventh installments of this series, the subject of the design of open drill jigs has been dealt with. In the present installment it is proposed to outline the development of the design of closed or box jigs.

We will assume that the holes in the piece of work, as shown in Fig. 83, are to be drilled. Holes *A* are drilled straight through the work, while holes *B* and *C* are so-called "blind holes," drilled into the work from the opposite sides. As these holes must not be drilled through, it is evident that the work must be drilled from two sides, and the guiding bushings for the two blind holes must be put in opposite sides of the jig. The simplest form of jig for this work is shown in Fig. 84. The piece of work *D* is located between the two plates *E*, which form the jig, and which, if the jig be small, are made of machine steel and case-hardened. If the jig is large these plates are made of cast iron. The work *D* is simply located by the outlines of the plates, which are made to the same dimensions, as regards width, as the work itself. The plates are held in position in relation to each other by the guiding dowel pins *F*. These pins are driven into the lower plate and have a sliding fit in the upper one. In some cases, blocks or lugs on one plate would be used to fit into a slot in the other plate instead of pins. These minor changes, of course, depend upon the nature of the work, the principle involved being that some means must be provided to prevent the two plates from shifting in relation to each other while drilling. The whole device is finally held together by clamps of suitable form. The holes *A* may be drilled from either side of the jig, as they pass right through the work, and the guides for the drills for these holes may, therefore, be placed in either plate. Opposite the bushings in either plate a hole is drilled in the other plate for clearance for the drill when passing through, and for the escape of the chips.

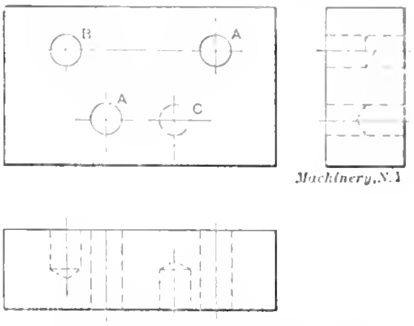

Fig. 83. Work to be Drilled.

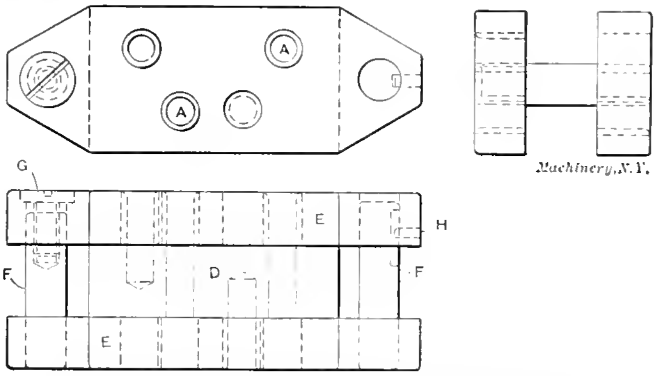

Fig. 84. Simplest Form of Closed Jig for Drilling Work in Fig. 83.

The two plates should be marked with necessary general information regarding the tools to be used, the position of the plates, etc., to prevent mistakes by the operator. It is also an advantage, not to say a necessity, to use some kind of connection between the plates in order to avoid mistakes, such, for instance, as the placing of the upper plate in a reversed position, the wrong pins entering into the dowel pin holes. This, of course, would locate the holes in a faulty position. Besides, if the upper plate be entirely loose from the lower, it may drop off when the jig is stored, and get mixed up with other tools. Some means of holding the two parts together, even when not in use, or when not clamped

---

* Address: 833 West Sixth St., Plainfield, N. J.

down on the work, should therefore be provided. Such a means is employed in Fig. 84, where the screw *G* enters into the guiding dowel pin at the left, and holds the upper plate in place. A pin *H*, fitting into an elongated slot in the dowel pin as shown at the left, could also be used instead of the screw. The design shown presents the very simplest form of box jig, consisting, as it does, of only two plates for holding the necessary guiding arrangements, and two pins or other means for locating the plates in relation to each other.

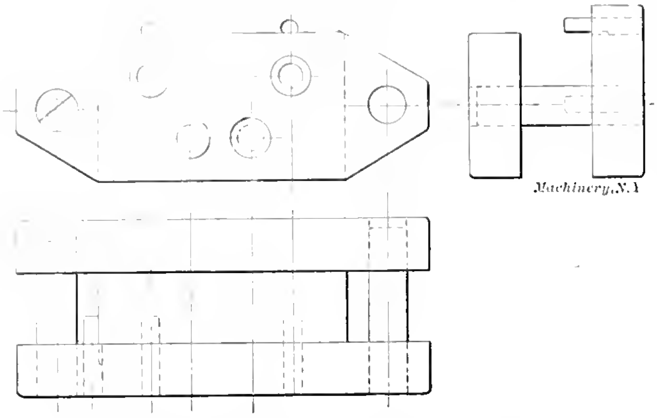

Fig. 85. Jig in Fig 84 Improved by adding Locating Pins.

In manufacturing where a great number of duplicate parts would be encountered, a jig designed in the simple manner shown in Fig. 84 would, however, be wholly inadequate. The simplest form of a jig that may be used in such a case would be one where some kind of locating means are employed, as indicated in Fig. 85, where three pins are provided, two along the side of the work and one for the end of the work, against which the work may be pushed up, prior to the clamping together of the two jig plates. In this figure the jig bushings are not shown in the elevation and end view, in order to avoid confusion of lines. The next improvement to which this jig would be subject would be the adding of walls at the end of the jig and the screwing together of the upper and lower plate, the result being a jig as shown in Fig. 86. This design presents a more advanced style of closed jig, and one of a type which could be recommended for manufacturing purposes. While the same fundamental principles are still in evidence, we have here a jig embodying most of the requirements necessary for rapid work. This design provides for integral clamping means within the jig itself, this being provided in this case by the screws *J*. The upper plate *K* is fastened to the walls of the lower plate *L* by four or more screws *M*, and two dowel pins *N*. The cover *K* could also be put on, as shown in Fig. 87, by making the two parts a good fit at *O*, one piece being tongued into the other. This gives greater rigidity to the jig. In this jig, also, solid locating lugs *F* are used instead of pins.

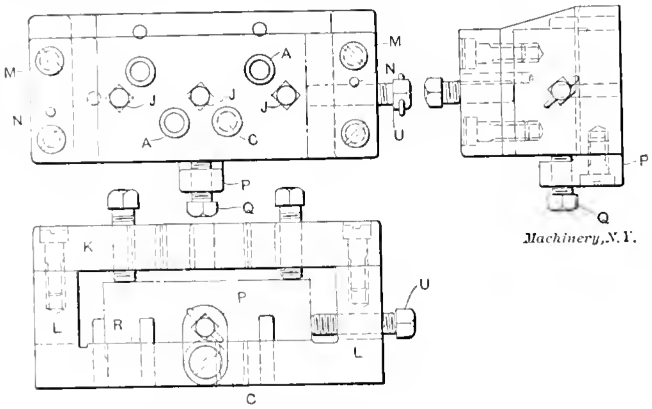

Fig. 86. Further Improvements in Jig, suiting it to Manufacturing Purposes.

Referring again to Fig. 86, by having a swinging arm *P* with a set-screw *Q* provided, the work can be taken out and can be inserted from the side of the jig, which will save making any provisions for taking off or putting on the top cover for every piece being drilled. If there is enough clearance between the top cover and the piece being drilled, the screw *Q* could, of course, be mounted in a solid lug, but it would not be advantageous to have so large a space between the top plate and the work, as the drill would have to extend unguided for some distance before it would reach the work. The set-screws *Q* and *U* hold the work against the locating points, and the set-screws *J* on the top of the jig, previously referred to, hold the work down on the finished pad *R* on the bottom plate. These screws also take the thrust when the hole *C* is drilled from the bottom side. It is rather immaterial on which side the bushings for guiding the drills for the two holes *A* are placed, but by placing them in the cover rather than in the bottom plate, three out of the four bushings will be located in the top part, and when using a multiple spindle drill, the face *R* will take the larger thrust, which is better than to place the thrust on the binding screws *J*. In the designs in Figs. 86 and 87 the whole top and bottom face of the jig must be finished, or a strip marked *f* in Fig. 88, at both ends of the top and bottom surfaces, must be provided, so that it can be finished, and the jig placed on parallels *D* as illustrated.

While the jig itself, developed so far, possesses most of the necessary points for rapid production and accurate work, the use of parallels, as indicated in Fig. 88, for supporting the jig when turned over so that the screw heads of the clamping screws point downward, is rather unhandy. Therefore, by adding feet to the jig, as shown in Fig. 89, the handling of the jig will be a great deal more convenient. The adding of the protruding handle *S* will still further increase the convenience of using the jig. The design in Fig. 89 also presents an improvement over that in Fig. 86 in that besides the adding of feet and handle, the leaf or strap *E* is used for holding screw *Q* instead of the arm *P*. This latter is more apt to bend if not very heavy, and would then bring the set-screw in an angle upwards, which would have a tendency to tilt the work. The strap can be more safely relied upon to clamp the work squarely. Two set-screws *J* are shown for holding the work in place. The number of these set-screws, of course, depends entirely upon the size of the work and the size of the holes to be drilled. Sometimes one set-screw is quite sufficient, which, in this case, would be placed in the center, as indicated by the dotted lines in Fig. 86.

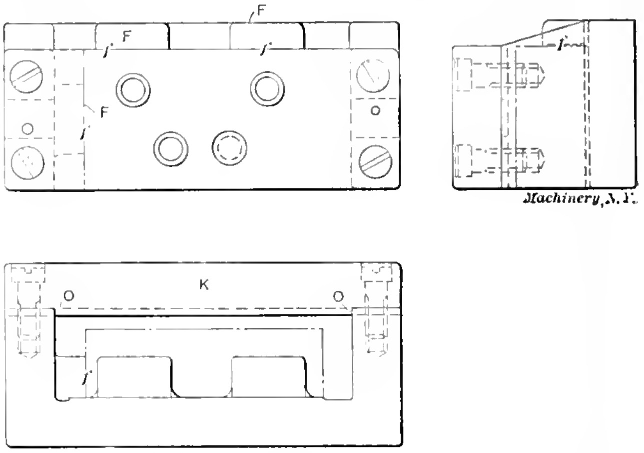

Fig. 87. Alternative Design of Jig shown in Fig. 86.

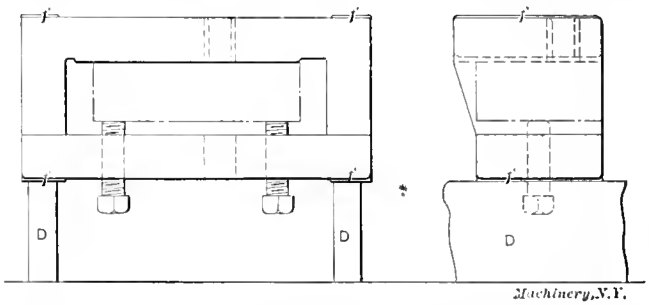

Fig. 88. Showing use of Jig in Fig. 86 in Combination with Two Parallels.

The type of jig shown in Fig. 89 now possesses all the features generally required for a good jig, and presents a

type which is largely used in manufacturing plants, particularly for fairly heavy work. The jig shown in Fig. 90, however, represents another type, somewhat different from the jig in Fig. 89. The jig in Fig. 89 is composed of two large separate pieces, which, for large jigs, means two separate castings, involving some extra expense in the pattern-shop and foundry. The reason for making the jig in two parts, instead of casting it in one, is because it makes it more convenient when machining the jig. The locating points, however, are somewhat hidden from view when the piece is inserted. The jig shown in Fig. 90 consists of only one casting *L*, provided with feet, and resembles an open drill jig. The work is located in a manner similar to that already described, and the leaf *D*, wide enough to take in all the bushings except the one for the hole that must be drilled from the opposite side, is fitted across the jig and given a good bearing between the lugs in the jig wall. It swings around the pin *E*, and is held down by the eye-bolt *F* with a nut and washer. Sometimes a wing-nut is handier than a hexagon nut. Care should be taken that the feet reach below the top of the nut and screw. The set-screw *G* holds the work down, and takes the thrust when the hole from the bottom side is drilled. The three holes *AA* and *B* are drilled from the top so that the thrust of the drilling of these three holes will be taken by the bottom of the jig body *L*. If one set-screw *G* is not sufficient for holding the work in place, the leaf may be made wider so as to accommodate more binding screws.

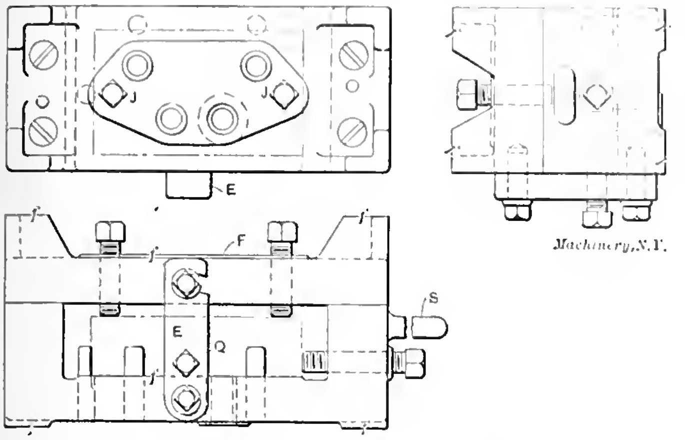

Fig. 89. Jig Improved by adding Feet Opposite Faces containing Drill Bushings.

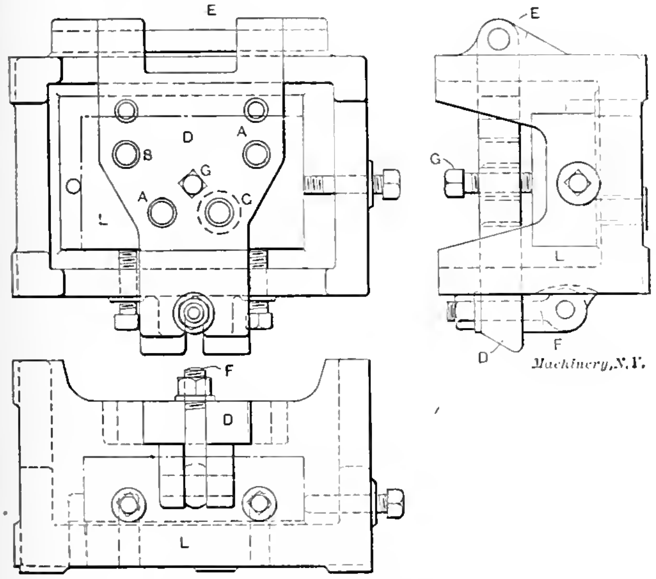

Fig. 90. Alternative Design of Jig in Fig. 89.

It should be mentioned here, however, that it is an objectionable feature to place the clamping screws in the bushing plate. If the leaf has not a perfect fit in its seats and on the swiveling pin, the screws will tilt the leaf one way or another, and thus cause the bushings to stand at an angle with the work, producing faulty results. In order to avoid this objectionable feature, a further improvement on the jig, indicated in Fig. 91, is proposed. In the jig body, the locating points and the set-screws which hold the work against the locating pins are placed so that they will not interfere with two straps *G*, which are provided with elongated slots, and hold the work securely in place, also sustaining the thrust from the cutting tools. These straps should be heavily designed, in order to be able to take the thrust of the multiple spindle drill, because in this case all the bushings except the one for hole *B* are placed in the bottom of the jig body. The leaf is made narrower and is not as heavy as the one shown in Fig. 90, because it does not, in this case, take any thrust when drilling, and simply serves the purpose of holding the bushing for hole *B*. The leaves and loose bushing plates for jigs of this kind are generally made of machine steel, but for larger sized jigs they may be made of cast iron. The leaf in Fig. 91 is simply held down by the thumb screw *H* of a type as shown in Fig. 48 in the July installment of this series.

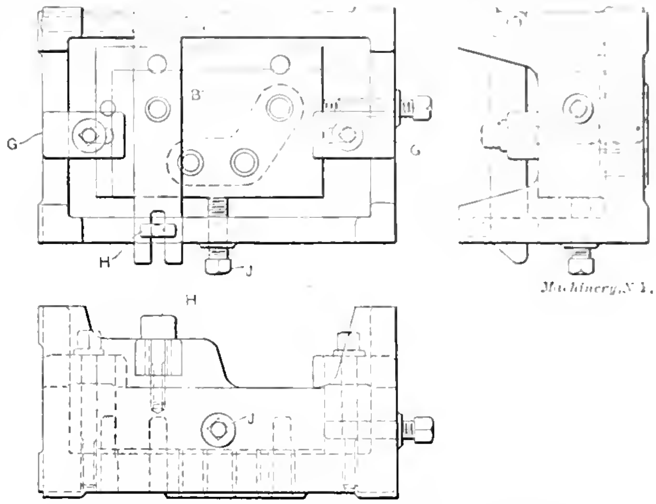

Fig. 91. Jig where Thrust of Drilling Operation is taken by Clamps.

If the hole *B* should be near to one wall of the jig, it may not be necessary to have a leaf, but the jig casting may be made with a projecting lug *D*, as shown in Fig. 92, the jig otherwise being of the same type as the one illustrated in Fig. 91. The projecting part *D*, Fig. 92, is strengthened, when necessary, by a rib *E*, as indicated. Care must be taken that there is sufficient clearance for the piece to be inserted and removed. Once in a while it happens, even with fairly good jig designers, that an otherwise well-designed jig with good locating, clamping, and guiding arrangements, is rendered useless for the simple reason that there is not enough clearance to allow the insertion of the work. The jig shown in Fig. 92 resembles, in reality, an open jig more than a closed jig.

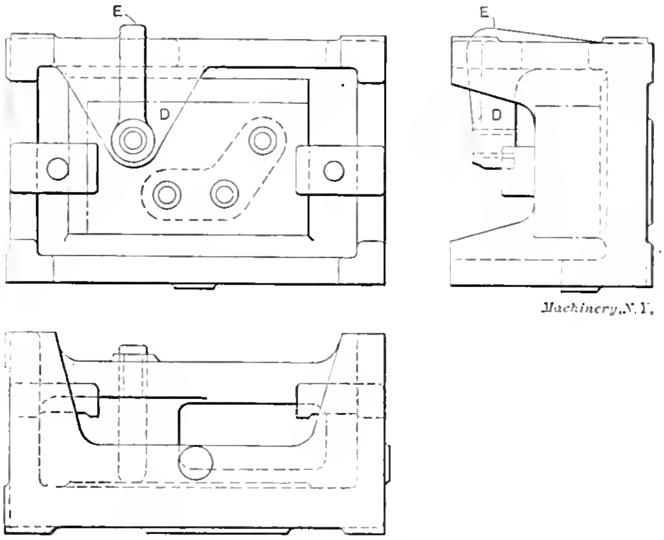

Fig. 92. Modification of Jig in Fig. 91, which practically brings it into the Class of Open Drill Jigs.

Fig. 93 shows the same jig as before, but with the additional feature of permitting a hole in the work to be drilled from the end and side as indicated, the bushings *E* and *F*

being added for this purpose. It will be noticed that the bushings in this case extend through the jig wall for some distance, in order to guide the drill closely to the work. Bosses may also be cast on the jig body, as indicated by the dotted lines, to give a longer bearing for the bushings.

Feet or lugs are cast and finished on the sides of the jig opposite to the bushings, so that the jig can be placed conveniently on the drill press table for drilling in any direction. It will be noticed that when drilling the holes from the bushings *E* and *F*, the thrust is taken by the stationary locating pins. It is objectionable to use set-screws to take the thrust, although in some cases it is necessary to do so. When designing a jig of this type, care must be taken that strapping arrangements and locating points are placed so that they, in no way, will interfere with the cutting tools or guiding means. In this case the strap *H* is moved over to one side in order to give room for the bushings *F* and the set-screw *K*. Strap *G* should then be moved also, because moving the two straps in opposite directions still gives them a balanced clamping action on the work. If the strap *G* had been left in place, with the strap *H* moved sideways, there would have been some tendency to tilt the work.

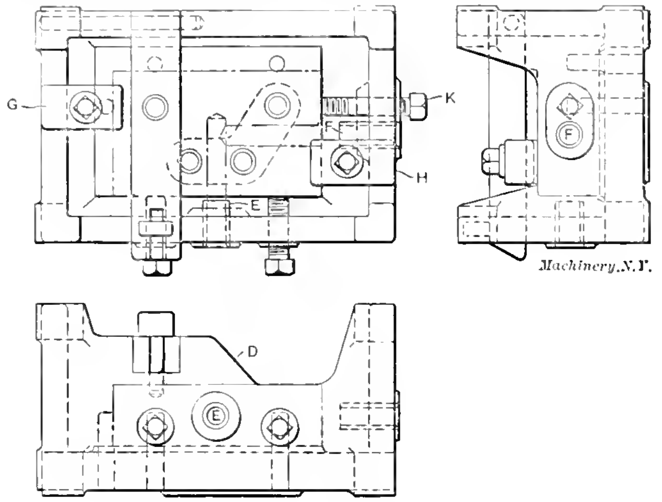

Fig. 93. Jig for Drilling Holes from Two Directions.

Sometimes one hole in the work comes at an agle with the faces of the work. In such a case the jig must be made along the lines indicated in Fig. 94, the feet on the sides opposite to where the drill bushings are placed being planed so that their faces will be perpendicular to the axis through the hole *A*. This will, in no way, interfere with the drilling of holes which are perpendicular to the faces of the work, as these can be drilled from the opposite side of the work, the jig then resting on the feet *B*. Should it, however, be necessary to drill one hole at an angle, and other holes perpendicular to the face of the work from the same side, an arrangement as shown in Fig. 95 would be used. The jig here is made in the same manner as the jig shown in Fig. 93, with the difference that the bushing *A* is placed at the required angle. It will be seen, however, that as the other holes drilled from the same side must be drilled perpendicular to the faces of the work, it would not be of advantage to plane the feet so that the hole *A* could be drilled in the manner previously shown in Fig. 94. Therefore the feet are left to suit the perpendicular holes, and the separate base bracket *B*, Fig. 95, is used to hold the jig in the desired inclined position when the hole *A* is drilled.

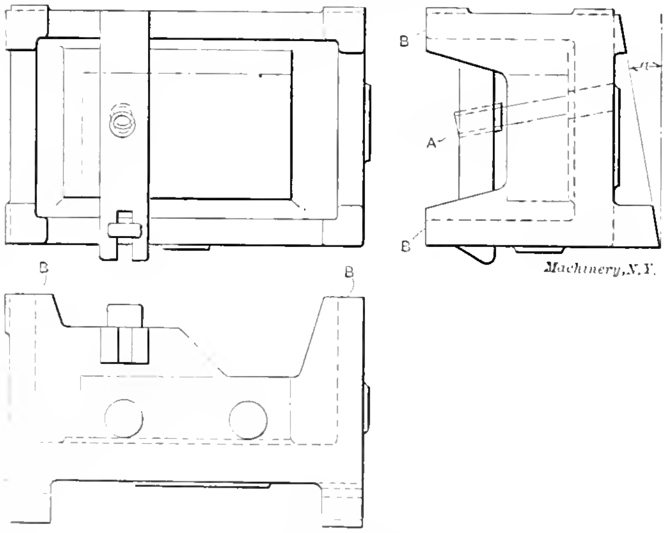

Fig. 94 Jig for Drilling Holes at an Angle.

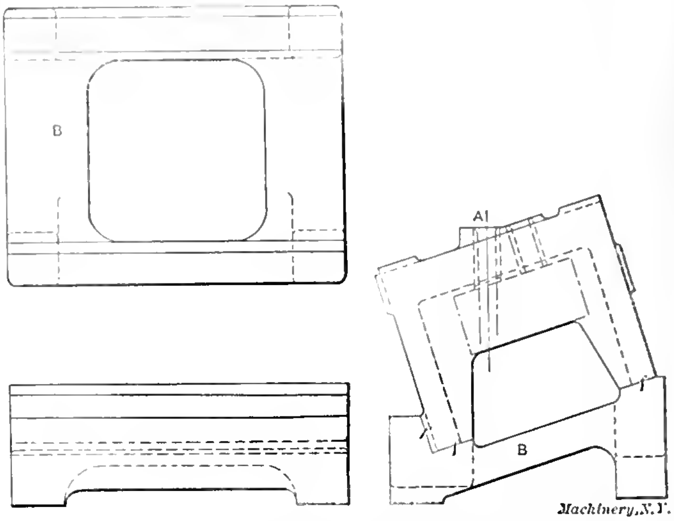

Fig 95. Jig and Stand for Drilling Holes at an Angle.

Stand *B* in Fig. 95 is very suitable for this special work. It will be noticed that it is made up as light as possible, it being cored at the center, so as to remove superfluous metal. These stands are sometimes provided with a clamping device for holding the jig to the stand. Special stands are not only used for drilling holes at angles with the remaining holes to be drilled, but sometimes special stands are made to suit the jig in cases where it would be inconvenient to provide the jig with feet, finished bosses or lugs, for resting directly on the drill press table.

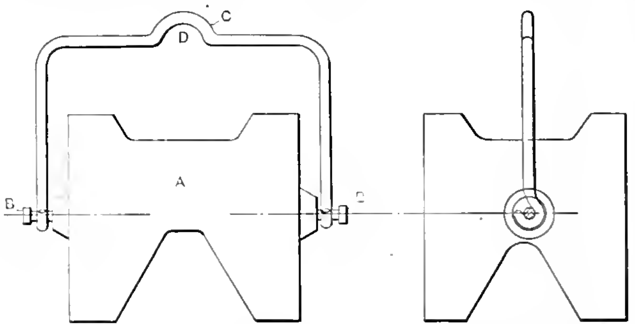

Fig. 96. Device for Turning over and Handling Heavy Jigs.

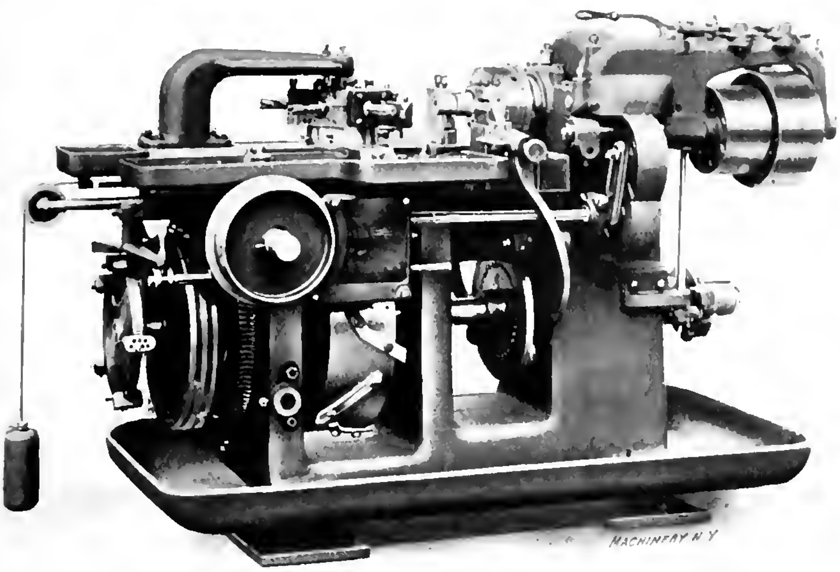
When a jig of large dimensions is to be turned over, either for the insertion or removal of the work, or for drilling holes from opposite sides, a helper will have to be called upon to assist the operator. The disadvantage of this is readily seen. In cases where the use of a crane or hoist can be obtained, it is very satisfactory to have a special device attached to the jig for turning it over. Fig. 96 shows such an arrangement. In this engraving, *A* represents the jig which is to be turned over. The two studs *B* are driven into the jig in convenient places, as near as possible in line with a gravity axis. These studs then rest in the yoke *C*, which is lifted by the crane hook placed at *D*. The jig, when lifted off the table, can then easily be swung around. The yoke is made simply out of round machine steel.

Comparing what has been said above with the outline of the development of open jigs in the September issue of MACHINERY, it will be seen that the principles involved are exactly the same, and that the development of jigs for various purposes is simply the application of these principles, with an appropriate amount of common sense, to the work in hand. The previous statements may be considered the A, B, C of jig making, and contain, of necessity, only the main principles on which the jig design is based.

HERBERT AUTOMATIC TURRET LATHE WITH SELF-SELECTING FEEDS.

On page 7 of the engineering edition of the September issue of MACHINERY was described, among other machine tools exhibited at the Franco-British Exhibition, an automatic turret lathe built by Alfred Herbert, Ltd., of Coventry, England. As described, the machine is intended for working on individual castings or forgings, or on blanks previously cut off. The work is chucked by hand, but all the operations performed on it are automatic, including the stopping of the machine at the completion of its cycle of operations. The head is gear-driven, and is provided with two sets of tight and loose pulleys, giving two speeds forward, or a forward and reverse motion, either of which may be shifted automatically, according to the requirements of the work. The machine in its general construction closely resembles the automatic screw machine built by the same firm, the modifications being, in general, only such as are required to fit it for finishing separate pieces as described, instead of making them complete from the bar.



An Automatic Turret Lathe for Castings, Forgings, and Cut Stock, in which Feeds may be varied for any Operation without Changing the Cams.

One of the most interesting features of the machine was not specifically mentioned in the description. This is the self-selecting feed mechanism, by means of which the rate of feed of the various tools in the turret may be varied independently of each other without changing the cams. The mechanism for this is most plainly seen in the rear view of the machine, shown herewith. In principle, the mechanism of the machine itself is identical with that of the original Spencer automatic screw machine. The feeding and controlling movements, such as the moving of the turret and cross-slides, the feeding of the stock, opening and closing of the chuck, reversing of the spindle, etc., are effected by cams and dogs carried on a long cam shaft, extending the length of the machine, beneath the bed. This is shown in the engraving. As in the original Spencer machine, this cam shaft may be given a rapid movement for the feeding and idle motions of the mechanism (such as returning the turret slide, etc.) or a slow movement for feeding the cutting tools, the change from one to the other being regulated automatically by dogs. The improvement consists in furnishing a number of rates of feed for the slow movement, making it possible to change the feed for any tool without changing the cams, as was formerly necessary. On this machine, in fact, the turret feed cams (which are mounted on the large drum seen directly beneath the turret) are all of the same shape, the feed mechanism being depended on entirely for the change in feed.

The self-selective arrangement is controlled by a disk keyed to the cam shaft at its extreme outer, or left-hand end, as seen in the engraving. This disk carries a series of dogs, as shown, each of which is provided with 7 holes, in any one of which a pin may be placed. As the cam shaft revolves this pin, just before the beginning of a new operation enters the V formed by the two projecting wings of the horizontal lever shown above the disk, thus shifting it to a position corresponding to the position of the pin in the dog. The long end of this lever (provided with a handle, as shown,) carries a roller confined between collars on the splined worm shaft which gives the slow movement to the cam driving mechanism. This splined shaft, which is thus adjusted from one position to another as occasion requires, is driven by a cone of 7 gears in the gear box at the back of the machine. This gear-box is shown in the engraving with the regular cover removed, and replaced with one having a glass window to show the mechanism. The shifting of the shaft by the pins and dogs shifts the position of the key in the cone of gears, thus connecting the proper one with the feed mechanism and giving the desired feed to the cutting tool.

It will be noticed that the shaft by which the cone of feed gears is driven, is connected by change gearing with the spindle driving shaft. This arrangement gives a certain definite feed in turns per inch or thickness of chip, for each one of the 7 sets of gears in the feed-box, no matter what changes may be made in the spindle speed. Provision is also made in the connecting mechanism for giving a forward movement to the feed whether the spindle is running forward or backward. The feeding movement is thus properly controlled at all times. The use of change gears permits raising or lowering the whole range of feeds to suit any material the machine may be required to work on. The fast movements of the cam-shaft are derived from the pulley shown just to the left of the feed-box, which runs at constant speed so that these movements always take place in the quickest practicable time, without reference to the rate of rotation of the spindle and the consequent rapidity of the feeding movement.

While the machine here shown is intended primarily, as described, for working on castings and stock held in the chuck, there would seem to be no reason why the same idea could not be applied in a modified form to the automatic screw machine working on bar stock, thus materially increasing its usefulness. It would probably be necessary in such a case to have the threading cam of steeper pitch than the others, and it might be necessary to make it adjustable. Except for this, the arrangement would seem to be easily applied in the form here shown. The greatest usefulness of the device would appear to be in the opportunity it affords to change the feed for a given tool without altering that of any of the others. It would also appear to simplify the matter of setting up, to a considerable degree.

* * *

Isinglass is a term commonly confused with mica, although it is a totally different substance. Mica is a silicate mineral mined from the earth, while isinglass is an animal product made from the air-bladders of certain fishes. The best isinglass, which is used in superior belt cements, is made from the air-bladders of the Russian sturgeon caught in the Baltic Sea. This fish is the same as the sturgeon caught in American waters, but some peculiarity of the water or food in the Baltic makes a great difference in the quality of the air-bladder. The bladders taken from the American sturgeon are thin and of poor quality, being valued at about $1.50 per pound wholesale, while those taken from the Russian sturgeon are three or four times as thick and of far better quality, being valued at about $3.50 per pound. The difference is important to manufacturers and machine shop proprietors, as belt cement made with the best isinglass as its basis is stronger than leather. A belt properly joined with the best cement will break at some other point rather than at the cemented joint.

TOOLS FOR INCREASING PRODUCTION IN BLACKSMITH SHOPS.*

JAMES CRAN †

The blacksmith has more difficulties to contend with in doing his work than any other class of mechanics. As a rule, he is heavily handicapped in not being provided with tools and appliances enabling him to do his work quickly and economically. To a certain extent he may be compared with the pattern-maker; he has to start his work, in the first place, with nothing to guide him except a blue-print or a sketch, often one-quarter or one-eighth size. This is all that is required if the work is plain and of regular shape; but if it happens to be bent, curved, or in the least complicated, it must be laid out full size, and a templet made before the actual work can be commenced. As compared with this, the machinist, and the majority of other mechanics, have their work shaped or partly shaped before it is turned over to them, which makes it comparatively easy. The pattern-maker can do most of his work at the bench; he can turn it around, and place it in any position to suit his convenience; he can stop at any time, and think over what his next move should be; he can cut, carve, glue, and build up, handling the work with his bare hands from the time he starts until it is completed. The blacksmith, however, is confined to the anvil or the steam hammer; his material must be heated before it can be worked to shape, and he must therefore handle it with tongs and lift and turn it with a crane if it is of large size; he has to make his plans and know exactly what his next move is to be while the material is heating, so that he will be able to do the greatest amount of work while the heat lasts. Unlike other mechanics he cannot, as a rule, cut his work to shape, but draws, upsets, and bends it until it is ready for the machine shop.

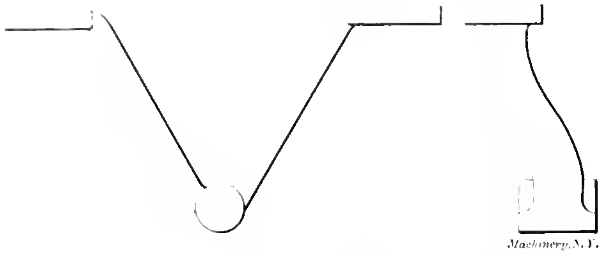


Fig. 1 Example of Forging Work which can be facilitated by using a Surface Plate.

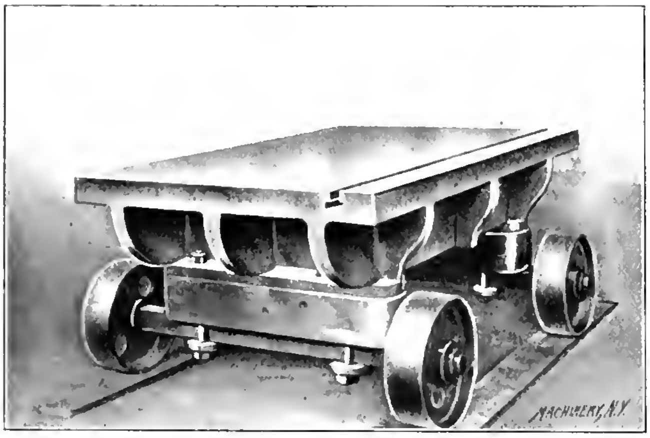

Fig. 2. Portable Surface Plate for Use in Blacksmith Shop.

To enable the blacksmith to do his work with convenience and accuracy, it would be well to supply him with some of the appliances that save time and reduce cost. In most blacksmith shops, forgings of odd and irregular shapes are, at times, made. Let us take the piece in Fig. 1, for example, which, while not complicated, would be a difficult piece to make with any degree of accuracy without a surface plate for trying the offset and the alignment of the different points. The surface plate shown in the half-tone, Fig. 2, is of a style best suited for machine blacksmithing. It was designed by a practical blacksmith and constructed so that it would meet, as far as possible, the requirements of the blacksmith shop. Being mounted on wheels, it can be moved around the shop to the place where it will be most convenient for the workman using it. The face is graduated in inches, which allows pieces being placed parallel with the plate and measured. Offsets and curves can also be gaged more accurately than would be possible if working from chalk lines. A T-slot, about four inches from one side, running the entire length, can be used for holding formers or similar tools to the surface of the plate. By using a square and a surface gage, the most complicated forgings can be made so nearly correct that there should be no trouble in machining the work.

A small surface plate of the same style should be provided for each forge. This plate need not necessarily be larger than eighteen or twenty-four inches square, with the face from 1¼ to 1½-inch thick. The plate is reinforced by ribs similar to those shown in Fig. 2. The wheels can be omitted, and a bench used to support the plate. A shelf may be placed between the plate and the base to accommodate clamps, bolts, etc., that may be used to hold work in position.

Benches with vises, attached to the walls of blacksmith shops, are not to be commended. There being no one constantly employed at the bench to keep things in shape, it is liable to be used as a place for dumping "any old thing." This not only gives the bench an untidy appearance, but makes it necessary to clear up the space every time the bench is used. With a portable vise and bench this difficulty would be overcome. Every man using the bench would be expected to clear off every tool and piece of material before returning the bench to its place in the shop. Vises attached to a porttable cast iron bench mounted on wheels can be moved around the shop to the place where they will be most convenient, saving time that would be wasted if a number of pieces had to be taken to the vise separately for some operation, especially if it happened to be located in some distant corner of the shop.

Fig.3

Fig.4

Figs. 3 and 4. Method employed for Forging Crank-shafts.

An emery wheel is a very essential piece of machinery for the blacksmith shop, as it is necessary to grind chisels and other tools quite often. If they have to be taken to another department for grinding, it means the waste of considerable time both for the blacksmith and his helper. No matter which one of them goes to do the grinding, the other generally takes a rest until the absent one comes back. Almost any type of grinder would answer the purpose, but the style known as the wet grinder is the most suitable, especially if arranged to supply the water automatically; otherwise it is liable to be used as a forging machine, which is bad practice for the blacksmith and poor usage for the wheel.

For cutting up stock and trimming the ends of forgings, such as shafts, spindles, or similar work, a power hack-saw can be used to good advantage. It requires but little attention, so little, in fact, that the blacksmith or his helper could attend to it between the heats without in the least interfering with their work at the forge. It cuts off the ends of forgings neater than is possible by hand, and the time it saves means increased production without increasing cost. It can also be used to advantage in the process of forging various pieces. Take small crank-shafts for example, as

---

* For additional information on kindred subjects, see the following articles previously published in MACHINERY: The Steam Hammer and Its Use, October, 1905; Tools for the Blacksmith Shop, September, 1908; System for the Blacksmith Shop, August, 1908.

† Address: 916 West Third St., Plainfield, N. J.

shown in Fig. 3, which are usually forged with the crank or throw solid. The stock between the webs must be removed either by drilling small holes around it, or by using a slotting machine. By using a hack-saw, the crank can be put in shape for the lathe before it leaves the blacksmith shop. The stock intended for a crank should be wide enough for the throw on one side, the journals should then be drawn out and rounded, after which the piece between them should be laid out as shown in Fig. 4, care being taken to keep the distance between all the webs short enough to allow for drawing in rounding the bearings. A small hole should be drilled at each corner for the hack-saw to run into. When the hack-saw has cut along the dotted lines, the crank can be heated, and the pieces removed with a chisel applied where solid lines are shown in Fig. 4. When the bearings are rounded, the crank-shaft can be heated and twisted so as to bring the throws on opposite sides of the forging. Any number of throws can be made in the same manner and could be set at any angle by using a surface plate.

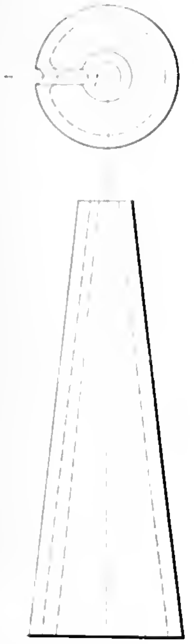

Fig. 5. Taper Cone for Forging Rings, Collars, etc.

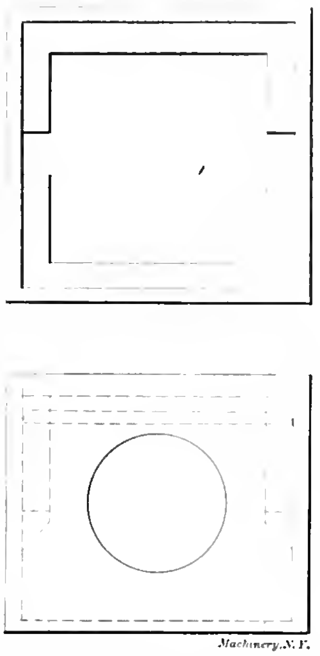

Fig. 6. Base for Swage Blocks.

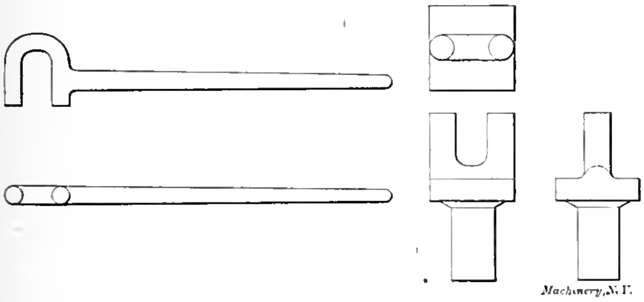
The majority of up-to-date concerns manufacturing heavy machinery have a number of portable motor driven machines which can be taken to the work when it is inconvenient to take the work to the machine. These machines are usually credited with being time and labor savers, and, as a rule, cost less to manipulate on certain kinds of work than would machinery installed in a permanent position. Portable motor-driven appliances for the blacksmith do not, however, seem to have received much thought or attention up to the present time. Yet, there is no mechanic who could use portable appliances to better advantage than the blacksmith. A portable forge with a motor-driven blower attached could, perhaps, be used for a greater number of purposes than any other portable appliances. Long pieces could be welded in the majority of cases with less trouble than with an ordinary forge. Such a forge could be used for heating braces or similar work in fitting them to castings or tanks. In short, any kind of work that is done at the ordinary forge could be done at any time or place where the appliance could be connected with electric power. If mounted on small wheels or casters and fitted with a handle of the style used for small trucks, this forge could be moved around anywhere with very little trouble, and work of larger dimensions could be handled than is possible with the portable hand forge commonly used for work done outside the blacksmith shop.



Figs. 7 and 8. Tools for Bending Work.

Some shops are provided with taper cones or mandrels for truing up rings or similar work. A set of taper cones, of which there are several styles on the market, is inexpensive, and well worth a place in the blacksmith shop equipment. The kind that is most convenient to use and gives the most satisfaction is shown in Fig. 5. This style of cone has a U-shaped groove its entire length, which permits tongs to be used to remove or place work upon it more conveniently than with the unslotted kind.

Swage blocks take the place of a large number of individual tools, particularly bottom swages and heading tools. There probably is a larger variety of shapes and sizes of swage blocks than of any other blacksmith tool on the market. The style that comes nearest meeting the requirements of machine blacksmithing is the square pattern with circular, hexagon, and V-shaped impressions around the outside edges, and square and round holes of different sizes in the center; one side of these holes should be countersunk. If mounted on a cast iron base or block, such as shown in Fig. 6, the swage block can be conveniently used either for swaging or heading forgings, by standing it on its edge in the recess in the center of the block, or laying it flat in the flanged section at the top.

In bending work to curves or sweeps, dogs of the style shown in Figs. 7 and 8 will answer the purpose better than any other tool. They can be used either on hot or cold work. The tool in Fig. 7 is intended to be used by hand in combination with that in Fig. 8, which latter should fit the square hole in the anvil. In making tools of this kind, it is important that the one to be used by hand be as shown, so that its bearing upon the work will be in line with the end of the handle; this prevents twisting of flat work or slipping on round work.

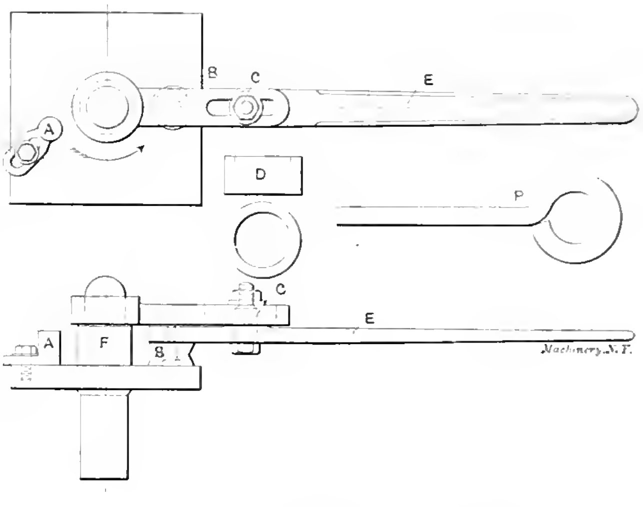


Fig. 9. Tool for Forging Open Eyebolts or Hooks

A tool for bending open eye-bolts or hooks is shown in Fig. 9. The shank of this tool is intended to fit the anvil. The part *A* is an adjustable guide for forming the first bend marked *P* on the eye-bolt shown. At *B* is shown a grooved roller which bends the eye to shape when turning the handle *E* from the left to the right as shown by the arrow. At *C* the lever is jointed, which allows adjustment for different sizes of material, and permits the roller to follow the shape of forming pin *F*, should its shape be other than round. The loose bushing shown at *D* is used to increase the size of forming pin *F* for making larger hooks or eyes. The bushings may be of any shape, but if other than round, they should be held in position by dowel pins. Tools of this kind should be fitted with an adjustable gage, so that the right amount of stock will be used for each piece. Hooks or eyes made on a tool of this type will not only be neater and more uni-

form in shape, but can be made in one-quarter of the time required if made by hand.

An appliance that would save time, trouble, and a large amount of unprintable language, is a small crane or hoist for each forge to be used only for work at the anvil. When too long or heavy for one man to handle, it is often necessary for the blacksmith to get another man to help him to handle heavy work. If trestles or "horses" are used, they must be moved or adjusted in height every time the piece is turned or moved, which often takes as much time as is used in doing the work itself. A small crane made of structural shape steel or steam pipe, properly trussed and braced, and fitted with a 1,000-pound chain hoist and snatch block, would overcome most of the difficulties. It could be easily adjusted to any height or position, would not come in the blacksmith's way, and would always be found in its place when wanted.

No blacksmith shop equipment is complete without platform scales for checking the weight of forgings and weighing stock before being used. It takes less time to weigh any kind of iron or steel than it does to figure out its cubic capacity and weight.

Machinery and tools help the blacksmith as much as any other mechanic; they make it possible for him to do more and better work, increase production and reduce cost, and thereby add to the efficiency of the blacksmith shop.

* * *

The use of denatured alcohol gas has not yet grown to the proportions confidently expected by the promoters of the industry. It was thought that when the United States government tax of $1.10 per gallon was removed, the use of denatured alcohol would soon rival that of gasoline for power purposes. The drawback to the extensive use of denatured alcohol is that so far it has not been feasible to manufacture it from vegetable products at a price that would successfully compete with gasoline. There is considerable interest now in the process of making alcohol from natural gas. Representatives of the Internal Revenue Department of the United States Government have visited Europe to study newly developed methods of manufacture of methylated or denatured alcohol from natural gas and crude petroleum. The Germans, with their characteristic enterprise for chemical research, have discovered a process which has unusual commercial possibilities. A company has been organized in the United States to promote the industry, which is being backed by Mr. Carl von Hartzfelt, Wheeling, W. Va., who also has discovered or invented a process. It is claimed that by the American process, 5,000 feet of natural gas will produce 50 gallons of alcohol, and that the cost of alcohol will be greatly reduced. Natural gas is sold to consumers in the gas fields of some localities as low as 10 cents per thousand cubic feet. At this rate the cost of gas per gallon of alcohol produced would be about one cent. Natural gas contains about 94 per cent methane, and the percentage of alcohol which may be obtained varies with the percentage of methane contained. The process is essentially as follows: The natural gas is subjected to heat in the presence of oxygen and steam which prevents complete combustion, inasmuch as the temperature is kept below the decomposing point of alcohol and destructive distillation or oxidation of the gas is induced. The action takes place in an electrically-heated German silver coil of closely woven fine wire gauze enclosed in a porcelain retainer or enamel retort. The product is a fluid containing alcohol, benzol, nitric acid and prussic acid.

* * *

It is interesting to note the low temperature obtained by Professor Onnes, when liquefying helium, to which reference was made in the September issue of MACHINERY. During his experiments, he kept helium at a temperature of 4.5 degrees K. for two hours, and finally evaporated the liquid under a pressure of about one centimeter of mercury, when the temperature is estimated to have been not far from 3 degrees K. The expression 3 degrees K. means 3 degrees centigrade above absolute zero, the expression being derived from the name of the late Lord Kelvin, who first defined the zero of the absolute temperature scale.

SYMBOLS IN MATHEMATICAL AND ENGINEERING FORMULAS.

The subject of making certain symbols, representing mathematical quantities in scientific publications, the same in all languages, has been considered for some time by the International Electrotechnical Commission, which has committees in different countries. These committees deal more especially with symbols for electrical quantities, but the system might, with advantage, be extended to embrace all important quantities in the field of engineering. The difficulties met with, are, in the first place, the difficulty of persuading a number of writers and publishers, who have become accustomed to a certain symbol for a certain quantity, to change it in favor of another, and, in the second place, that there are not enough letters in the alphabet at our disposal to give an absolutely distinct symbol to each quantity, without resorting to a combination of more than one letter to form a single symbol. There is also another objection to using letters to represent quantities in a system of universal notation, because, unless initial letters are used, there is no connection in the mind of the reader between the letter and the quantity, and the symbol is difficult to remember. We cannot always use initials, because the initial letters differ in different languages. For instance, in England R commonly stands for resistance, while in Germany the letter W is used, representing *Widerstand*; besides, the same initial occurs in a great number of different quantities. For instance, R might stand for resistance, reluctance, radius, etc.

The only way of avoiding both difficulties would be to use a number of new symbols, for which type could be made like ordinary letters, and which would represent distinct quantities in engineering formulas. In choosing a symbol a simple picture would be selected that would remind one of the quantity in question. For instance, ɭ might represent temperature. If we were told that this simple outline of a thermometer represents temperature, there would be no difficulty in remembering it. Similarly, / might represent force, and various other symbols might be derived from it. For instance, ϟ, electro-motive force (conventional representation of lightning); and ∩ magneto-motive force. Any formula expressed in symbols which have a definite meaning, would be completely self-contained, and would be an exact statement of a mathematical or physical fact. Perhaps some slight addition to the symbol, or even to the whole formula, could be used to indicate that the standard system of units is employed, and without such an addition the symbol would have a general meaning. For instance, ɭ might equal temperature, while ɭ̥ might indicate the degrees Centigrade above absolute zero. The name of the type might be the name of the physical units which it represents. For instance, ϟ might be read "volts."

The British Electrotechnical Commission invites writers and others who have some definite views as to the best method of devising an international system of symbols, to communicate with its secretary, Mr. Miles Walker, The Cottage, Leicester Road, Hale, Altrincham, England, if they wish to assist in solving some of the many difficulties which arise in connection with this matter.

The question of an adequate system of notation is really one of great importance to engineers. Everyone who has to deal with handbooks, and with formulas found in various text-books, is familiar with the annoyance of finding a formula, and having difficulty in locating the exact meaning of the various terms used to express the quantities involved. A universal system of notation, when once adopted by the engineering profession, would make it possible to make more concise and precise statements in shorter space, and at the same time misunderstandings would be largely avoided. It is to be hoped that the commission referred to above will be successful in adopting some standards of notation for the electrical quantities, and that engineering societies in various countries will also take up the matter, and, acting in unison, agree upon an international system of notation which would be adopted as the standard, thereby eliminating the present confusion.

A MODERN STEEL-HARDENING PLANT.

The illustrations, Figs. 1 and 2, show two views of a hardening plant installed by Wheelock, Lovejoy & Co. (selling agents for Firth Sterling Steel Co., McKeesport, Pa.) in the basement of their New York store at 23 Cliff St. The equipment is interesting in that it represents the latest development of gas furnace hardening and tempering baths. Fig. 1 shows a general view of the plant looking toward the street, while Fig. 2 is a view taken from the street end. The furnace in the rear, with a hood similar to the one in the foreground of Fig. 1, is for heating a chloride of barium bath, this being very successfully used for hardening "Blue Chip" steel, and the following notes relate to the practice:

The business of the company is selling tool steel, but in order to secure the best results and common satisfaction, it was found desirable to educate users to a knowledge of modern methods of heating and hardening high-speed steel. The plant was installed for this purpose and is used chiefly for hardening and tempering samples of work submitted by customers, thus demonstrating the capability of the steel for a multitude of purposes, and the best methods of treatment. An inspection of the plant gives proof of the great advance made in recent years in methods of heating, hardening and tempering. Nothing now need be left to chance or guesswork; every step can be made with absolute certainty as to the results. Thus have scientific methods and instruments practically eliminated the mystery and uncertainty attending the manipulations of the old time tool-smith who, working in his grimy dark corner, was one of the last members of ancient crafts to yield to the march of improvement.

Fig. 1. Hardening Plant, Wheelock, Lovejoy & Co., looking toward Street.

The tools to be hardened are first pre-heated, using a small American gas furnace shown next to the chloride of barium furnace. The pre-heating saves time in the barium bath, and is absolutely necessary to avoid checking or cracking the tools, as will be conceded when it is known that the temperature of the barium bath is kept at between 2,100 and 2,200 degrees F. After the tools are pre-heated, they are immersed in the barium bath, being suspended by an iron wire, or, in the case of small parts, in sheet nickel baskets. The reason for using sheet nickel for the baskets is that chloride of barium has a slight dissolving effect on iron and the exposure of a large area of sheet iron in the bath would eventually destroy the baskets. Nickel is not affected, nor is the thin iron wire used to suspend ordinary tools, to a perceptible extent.

The temperature of the barium bath is regulated by a Bristol thermo-electric pyrometer. This instrument, shown at the left in Fig. 3, is similar to a Weston ammeter or voltmeter, and the fire end is a thermo-electric couple. The heat of the bath effects the thermo-electric couple and generates a current that deflects the indicator of the indicating instrument to correspond with the temperature. For convenience of operation, the indicating instrument is provided with a double hand, one hand, *A*, being controlled by the temperature of the bath, while the other, *B*, is a marker set by the operator to indicate the temperature which he desires to carry. This marker is made with a disk at the end that covers a hole in the indicating hand when the two coincide, as they do when the temperature has reached the predetermined point. Thus, an operator whose eyes are dazzled by the heat of the bath does not have to painfully study the graduations to see whether the pointer has reached the correct position, but by glancing at the instrument he can readily determine when the indicator is directly beneath the marker referred to.

The immersion of a piece pre-heated to a dull red immediately causes the indicator to drop, the temperature of the bath falling perhaps 30, 40 or even 50 degrees. The fall in temperature is due to absorption of heat by the piece, being the same as the refrigerating effect of a lump of ice thrown into a pot of boiling water, and several minutes may be required to raise the temperature of a large piece to the temperature that is required. For hardening "Blue Chip" steel, a temperature of 2,120 to 2,140 degrees F. has been found most suitable. After this temperature is attained, the part is allowed to soak for a few moments, then is lifted out and dipped into the cooling bath shown at the right, Fig. 1, and left in Fig. 2, which consists of cotton-seed oil agitated by compressed air admitted at the bottom. The cotton-seed oil is contained in a large iron barrel surrounded by water in a wooden tub. The part hardened is allowed to remain in the bath until it is quite cold. In practice, the operator hardens a batch and then removes the pieces by means of a wire basket hanging immersed in the oil. It is recommended that milling cutters, end mills, slitting saws, etc., made of "Blue Chip" steel, be used, in general, without drawing the temper. They will have the requisite hardness and toughness to stand up to the majority of work. However, an oil bath heated by gas and regulated by a thermometer is provided for tempering such tools as require it.

Fig. 2. View of Hardening Plant, taken from Street End, shown in Fig. 1

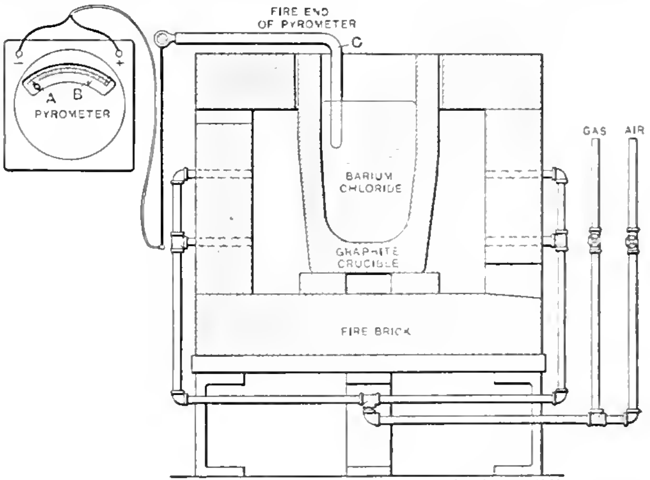

Fig. 3. Vertical Cross-section of Chloride of Barium Furnace.

Chloride of barium is a white transparent salt ($BaCl_2OH_2$) which melts at a temperature of about 1,700 degrees, the

water of crystallization being driven off at a much lower heat. The salt volatilizes at an extremely high temperature, the loss at the temperature required for heating high-speed steel being negligible. The waste because of volatilization is, say, two pounds from a mass of barium weighing 75 pounds when held at a temperature between 2,000 and 2,300 degrees for five hours. This property of the chloride of barium bath of standing high temperatures without rapid volatilization is joined with others equally important. The piece heated is protected from the atmosphere during the heating period by the bath, of course, but the protective influence extends still further. A thin coating of barium clings to the piece when it is lifted out for immersion in the cooling bath, thus preventing oxidation. The effect of the barium on the steel seems to be limited to a slight mottling that quickly disappears under the action of cleaning and buffing wheels. The coating of barium remaining when dipped, prevents the coating of burned oil so troublesome to remove, so that on the whole the process probably produces the cleanest work of any bath known.

Wheelock, Lovejoy & Co. have improved the furnace and crucible used for the chloride of barium bath. The common form of furnace and crucible in use employs a comparatively shallow crucible, which necessitates making a joint between the top of the crucible and the fire-brick cover. This gives trouble by loosening and permitting the hot gases to escape around the edge of the crucible. The improved construction illustrated in Fig. 3 utilizes a deeper crucible, the top of which comes flush with the fire-brick cover and simplifies the construction. The deep crucible also gives a greater volume of chloride of barium, consequently the refrigerating effect of the pre-heated steel parts when immersed in the bath is not so great. This illustration also shows the fire end, C, of the pyrometer immersed in the bath. It has been found advisable to employ crucibles made for steel melting, the ordinary graphite crucible used for brass melting giving trouble by flaking off into the barium.

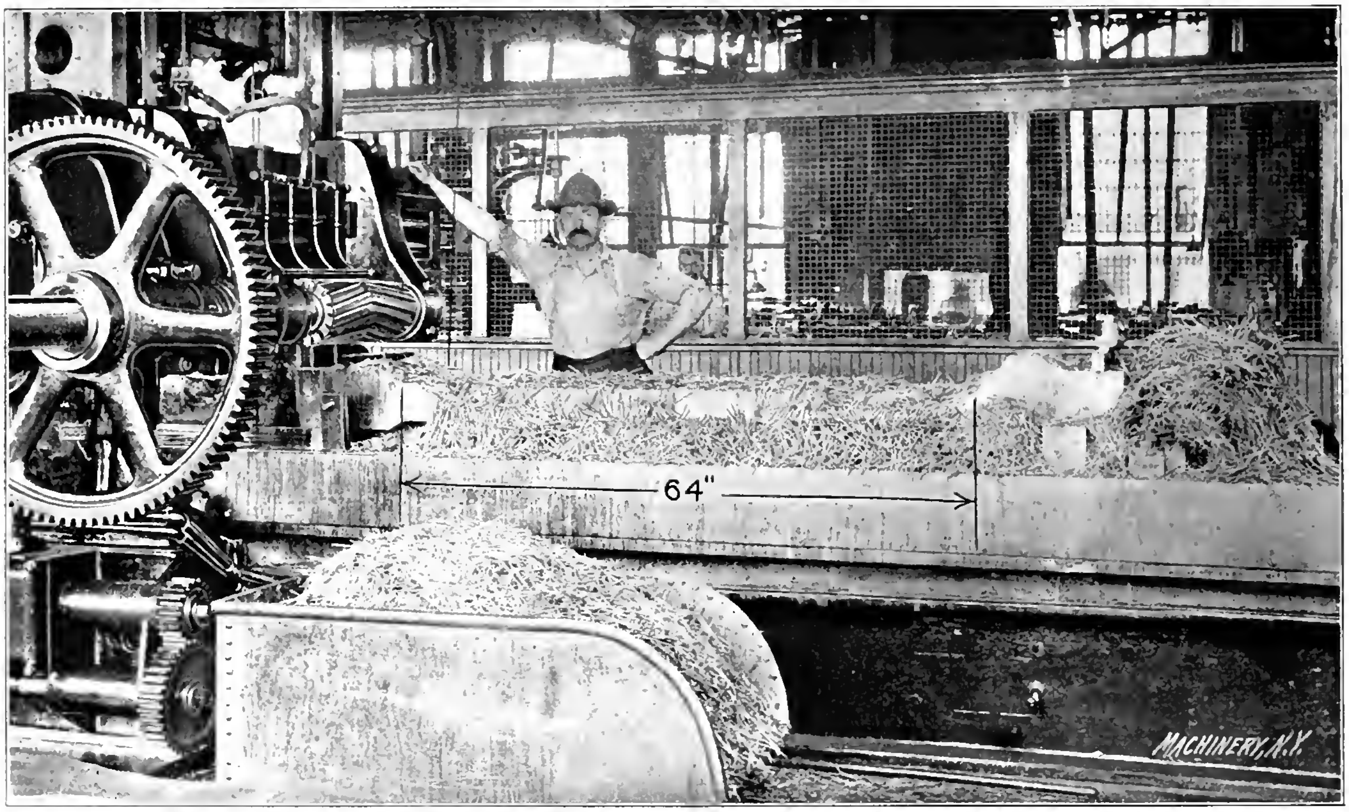
The equipment of the plant includes an air compressor and exhauster, the former being required for the air blast in the furnaces and for agitating the oil bath, while the exhauster connected with the smoke pipes and hood, draws off the hot air and gases, thus keeping the working conditions fairly comfortable, even in the hottest weather. An efficient ventilating system is a prime requirement, inasmuch as the fumes of the barium are somewhat noxious and besides would have a serious rusting effect on the steel stock if permitted to pervade the basement where it is stored. The chloride of barium process is used by the Boston and Chicago selling agents of the Firth-Sterling Steel Co., also.

* * *

HIGH-SPEED MILLING ON LOCOMOTIVE PARALLEL RODS.

The illustration does not show a hay-cutter nor a tooth-pick machine; it is a Bement-Miles milling machine, milling four heavy locomotive parallel rods, in a well-known locomotive works. These parallel rods, as well as many other locomotive forgings, are only roughly forged, it having been demonstrated long ago that it is cheaper to rough forge in the blacksmith shop to approximate shape and dimensions, leaving plenty of stock to finish up on the machines. The labor and fuel in the blacksmith shop are much more expensive than the labor and machine service in a well-equipped modern machine shop. It is on forgings of this and heavier types that high-speed steel has made its greatest records.

The rate of traverse on the middle portion of the rods was 5 inches per minute, 13 minutes being required to mill the straight part, which is 64 inches long between the end bosses. The bosses or end sections of the rod, which are enlarged for the reception of the crank-pin, are about 17 inches long and the profile is a combination of curves and straight surfaces. These sections were milled in 28 minutes each, the additional time per lineal inch of traverse being due, of course, to the greater amount of material removed and the repeated settings of the cutters required for the forming operations.



An Example of High-speed Milling on Locomotive Parallel Rods.

The milling cutter is composed of two parts having straight teeth set at an angle with the axis, the teeth being high-speed steel. The parallel rods shown in the illustration are 54 points carbon. The quantity of chips shown on the table gives a hint of the amount of metal removed from the top surface of the rods. Repeated tests made on heavy milling machines of the type shown, indicate that from 1½ to 2¼ horse-power is required for one cubic inch of steel removed per minute.

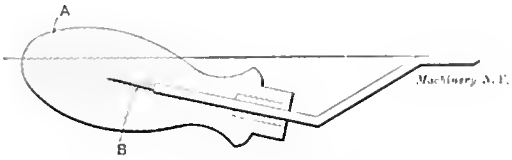
* * *

An ill-natured reprimand, an unexplained promotion, a summary dismissal—all these put emery powder in the grease-cups.—*The Silent Partner.*

ITEMS OF MECHANICAL INTEREST.

A HANDY SCREW-DRIVER.

A contributor to *Wood Craft* calls attention to a simple little tool which is handier than the ordinary screw-driver, particularly for putting in small long screws. It consists of a handle *A* in which is drilled a hole, so that a wire, say 3 inches long, will revolve in it without much friction. Into the bottom of the hole is driven a small brad *B* which is used as a bearing for the end of the rod constituting the screw-driver proper.

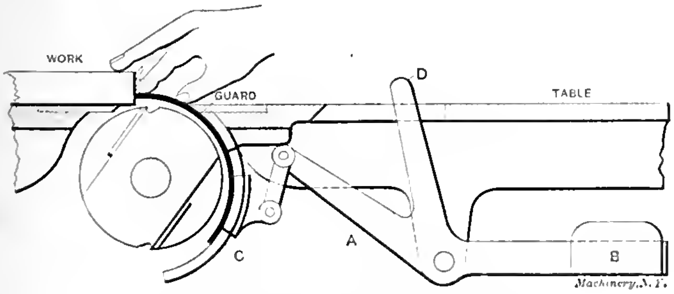


Screw-driver for Rapid Action.

The outer end, of course, is flattened to suitable dimensions. It will be seen that the tool constitutes a very neat little screw-driver, which will sink small screws very rapidly by simply revolving the handle like a crank, in the proper direction. A number of wires with different sized ends can be kept on hand, and interchanged as conditions require.

SAFETY DEVICE FOR BUZZ-PLANERS.

An interesting and effective safety device for buzz-planers has been patented by Mr. Lundberg, of Wernamo Mekaniska Verkstad, Wernamo, Sweden. The general arrangement of this device is illustrated in the accompanying line engraving. The principle of the device is that plates or guards *C*, of a semi-circular form, are held up against the end of the work when it passes over the cutter, by a weight *B* on the end of lever *A*, suitable linkage connections being provided between the lever and the guard. A number of these guard plates are placed side by side across the full width of the planer. It will be noticed that one arm *D* of lever *A* extends up through the table of the machine when the guard is in action, but when the work entirely covers the opening over the cutter, having pushed the guard clear back, this end of the lever is turned below the surface of the table. The handle of the lever serves the purpose of hand adjustment of the guards. It will be noticed that the cutter is covered at all times, either by the work, the work and guard in combination, or by the guard alone, so that at no time is any part of the cutter exposed. The weight *B* on the end of the lever makes the action automatic.



A Swedish Safety Appliance for Buzz-planers.

This guard fills also some of the very most important requirements of safety devices for machines of any type. In the first place, it is unobstructive to the working of the machine, and for that reason there is no incentive for the workman to remove it. Not only is there no incentive for the workman to remove it, but it is also very difficult to remove, and practically impossible to keep inoperative while in place. As the guard is made in sections, each of which covers a part of the full width of the table, it covers the cutter not only in line with the work, but completely on each side of the work as well. The simplicity of this construction, the ease with which it can be temporarily withdrawn for the changing of cutters, and the way in which it prevents dust and chips from entering into and obstructing the working of its own mechanism, are all factors which indicate the thoroughness of design, and that all the requirements have been well taken care of.

A SLIDE RULE FOR TRIGONOMETRICAL PROBLEMS.

A slide rule which is specially graduated for convenience in solving trionometrical problems is illustrated in the accompanying half-tone engraving. It is the invention of Mr. M. J. Eichhorn, 5759 Aberdeen St., Chicago. As seen from the engraving, this slide rule is constructed in the same manner as an ordinary calculating rule, but it is graduated in an entirely different manner, so as to be especially adapted for the solution of the formula

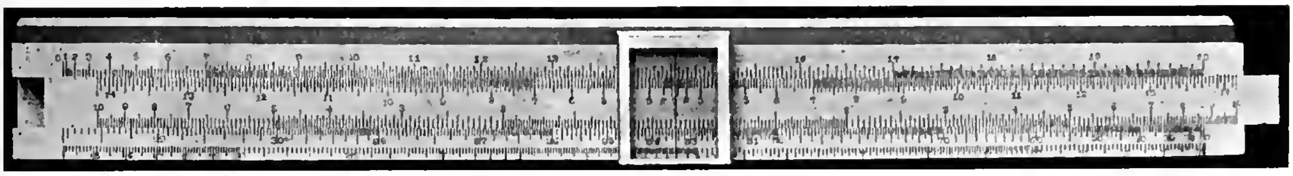
$$C^2 = A^2 + B^2 + 2AB \cos c$$

which is the well-known expression for the value of the third side in any triangle, when the two other sides and the angle between them are given. It is clear that this formula can be transformed so as to give an expression for practically the entire range of plane trigonometry, as either *A*, *B*, *C*, or *c* can be considered as the unknown quantity, and the equation can be solved for the same, thus giving a solution for any of the four basic classes of trigonometrical problems. Of course, the main reason why the formula is not used ordinarily for the sides *A* and *B* when transformed for solving either of these, is because it becomes rather cumbersome, and is not adapted for direct use of logarithms, thereby involving a considerable amount of ordinary figuring. When triangles are to be solved, however, and an approximation of three or four figures is sufficient, such as may be obtained within the length of a slide rule, the formula above can be so transposed as to permit of an easy solution on a slide rule specially graduated for the purpose and as shown in the illustration. For this purpose, we substitute as follows in our equation:

$$X^2 = 2AB \cos c$$

and

$$C^2 = A^2 + B^2 - X^2$$



A Slide Rule for solving Trigonometrical Problems.

The latter formula gives an expression which permits of solution on the trigonometrical slide rule. The slide is set in relation to the scales on the main body of the rule so that the known values of *A*, *B*, and *X* are taken care of, and *C* can be read off directly on the rule.

To permit of solving so complicated a problem, the instrument is, of course, provided with a rather ingenious system of graduation, and it suggests the idea that special slide rules can be constructed for the solution of rather complicated formulas, which are used very frequently in certain classes of work. The relation that such slide rules would have to the ordinary slide rule would be the same as that of special machinery to more or less universal machines. The ordinary slide rule, like the universal machine, is adapted for a great number of different operations, but is not adapted to carry out any one of them with particular speed, while a special slide rule, like a special automatic machine, would be suited to one particular operation only, which, however, could be carried out accurately, easily and rapidly.

* * *

Some concerns are so busy getting new customers that they have no time to take care of their old ones. Somebody ought to call around and recite that old saying about the value of a bird in the hand.—*The Silent Partner.*

DESIGN CONSTRUCTION—OPERATION.

PUBLISHED MONTHLY BY

THE INDUSTRIAL PRESS,
49-55 LAFAYETTE STREET, CORNER OF LEONARD,
NEW YORK CITY.

Alexander Luchars, President and Treasurer.
Matthew J. O'Neill, Secretary.

Fred E. Rogers, Editor.
Ralph E. Flanders, Erik Oberg, Franklin D. Jones, Associate Editors.

The receipt of a subscription is acknowledged by sending the current issue. Checks and money orders should be made to THE INDUSTRIAL PRESS. Money enclosed in letters is at the risk of the sender. Changes of address must reach us by the 15th to take effect on the following month; give old address as well as new. Single copies can be obtained through any newsdealer.

We solicit communications from practical men on subjects pertaining to machinery, for which the necessary illustrations will be made at our expense. All copy must reach us by the 5th of the month preceding publication.

NOVEMBER, 1908.

PAID CIRCULATION FOR OCTOBER, 1908, 20,439 COPIES.

MACHINERY is published in four editions. The practical work of the shop is thoroughly covered in the Shop Edition—$1.00 a year, comprising more than 430 reading pages and 36 Shop Operation Sheets, containing step-by-step illustrated directions for performing 36 different shop operations. The Engineering Edition—$2.00 a year, coated paper $2.50—contains all the matter in the Shop Edition, including Shop Operation Sheets, and about 250 pages a year of additional matter, which includes a review of mechanical literature, and forty-eight 6 x 9 data sheets filled with condensed data on machine design, engineering practice and shop work. The Foreign Edition, $3.00 a year, comprises the same matter as the Engineering. RAILWAY MACHINERY, $2.00 a year, is a special edition, including a variety of matter for railway shop work—same size as Engineering and same number of data sheets.

SYSTEMATIC STUDY.

From time to time we receive letters from subscribers asking for advice in regard to the best methods of increasing their knowledge along mechanical lines. It would be difficult to give an absolute rule to be followed for self-education, or to say which subjects are of the greatest importance, and which should be studied in preference to others. It all depends upon the work in which the person asking for advice is engaged, or for which he intends to fit himself, and upon his own mental make-up. There is, however, one rule that can be given without qualification or limitation, to everyone, and that is, *study systematically*. Do not take a book and read one chapter, and then turn to another and study up a different question, unless the foundation on which you build is already of such proportions as to permit adding to the structure in this haphazard manner. Start with some good book on the fundamental principles of the work you are engaged in, or of the work for which you intend to fit yourself, and study systematically and earnestly. Do not jump certain parts, because they do not, at the time, directly interest you. Make it a point to have certain hours which you devote to study, and certain hours to recreation. If this general advice is followed, at the end of each year you will find that you have stored up a great amount of knowledge which you would not have been in possession of had you not followed a method in your study. After a while systematic study will become a habit, and then your mental capacity will increase, and your ability to grasp and understand will be so developed that study is no longer an effort, but largely becomes a diversion.

RELATION OF EMPLOYES TO TRADE SECRETS.

The question of trade secrets has of late attracted some attention, particularly on account of the recent petition for an injunction brought by a well-known manufacturing company against two of its former officials. Another litigation, which merits attention by both employers and employes, is that in which a recent decision has been rendered by a New Jersey court. The complaining company had been engaged in making a special alloy steel, and a person in the employ of the company had made a contract that he would not at any time, directly or indirectly, during the term of the agreement or afterwards, divulge to any person, firm or corporation, except to officers of the firm with which he was employed, any information of any nature, known to him or thereafter acquired by him during the term of the agreement, relating to or regarding any process of steel making, or molding or treating steel, that may have been, is, or might be, during the term of the agreement, used by the company. The court, however, ruled that a contract of this form cannot be enforced, as it not only forbids the defendant to disclose any secret of the complainant, but also any knowledge that he may have relating to steel making in general. The necessary results of the enforcement of the contract would be that the defendant must either work for the complainant or remain idle, and since the restraint is unlimited as to time and place, he might at the option of the complainant, after the expiration of the term of the contract, be without employment for the rest of his life at the only calling he knows. Such a restraint, the court said, savors of servitude, unrelieved by an obligation of support on the part of the master. Comment seems unnecessary. Any reasonable minded man, whether employer or employe, will grant that contracts of this kind are disgraceful to the party demanding them.

MECHANICAL FLIGHT.

The year 1908 will be remembered for the extraordinary progress made in mechanical flight. The present stage of development of the aeroplane by the Wright brothers, Farman, Delagrange, Curtiss, and others is such that we may truthfully say that the possibility of mechanical flight has been conclusively demonstrated. The step from the ignorance of centuries to the present knowledge of the laws of flight and the structural requirements of the flying machine doubtless is greater than for all future knowledge that will be acquired in the complete mastery of aviation. The conquest of the air is a matter of satisfaction for the machinist and machine designer. The Wright brothers' experiments which, doubtless, have been more thorough and comprehensive, than those of anyone working on the problem of aeroplane navigation, were made with a skill and insight into mechanical principles derived from their experience as bicycle builders. The design of the extraordinarily light and powerful gasoline motors that develop a horse-power for each three pounds of dead weight, or even less, is in itself a great achievement, and is one that has contributed in no small degree to the success of the heavier-than-air machines. It is to the machine designer that we owe thanks for this wonderful motor construction.

The mechanic has had a greater part in the present triumph than the theorists who have attempted to formulate laws of flight by mathematical analysis and deduction. The experience of the Wright brothers shows that practically nothing was known of the action of the atmosphere on moving planes, especially when these moving planes were propelled by motors. Experiments with kites, while useful, have led to many wrong deductions. The tables of wind pressures per unit of area for various velocities appear to be all wrong when it comes to bodies standing at angles in the air. The unit wind pressures vary according to the size and shape of the wings. The Wright brothers say, in their article in the September *Century*, that the wind pressures on squares are different from those on rectangles, circles, triangles, or ellipses; arched surfaces differ from planes, etc. They found, "contrary to the teachings of the books, that the center of pressure on a curved surface travels backward when the surface was inclined, at small angles, more and more edgewise to the wind." A great many other confusing and contradictory facts were discovered in their experiments at Kitty Hawk, N. C., which demonstrated how little really was known about the mechanics of the atmosphere. It is gratifying, however, to learn that the theories advanced were of value to experimenters, although in many cases, wrong. The theories served at least as something to grasp at and thus in a degree did illumine the dark way of the youthful investigators. The problem of aerial navigation is tremendously complicated by many unknown factors, and it is no wonder that mathematical analysis and deduction were found at fault in many vital respects.

AN ABUSE OF PATENT RIGHTS.

Some time ago an infringement suit was brought by an Eastern company against another firm manufacturing a like product, in which the court had to decide the question: Can a manufacturer buy a patent, never make use of it, and still sue for infringement? The decision, as rendered by the Supreme Court of the United States, was to the effect that the owner of a patent, after having bought it, has an absolute property right in it whether he uses it or not, and has a right to withhold from the public the benefits derived from the invention. This decision, no doubt, conforms with our present patent laws, but it is safe to say that laws so enacted and interpreted do not carry out the original purpose of patent protection, which was simply to insure to the inventor the right of deriving full benefit from the invention, by exclusive privilege to use or manufacture for a certain number of years, and by no means included the right to prevent others from deriving a benefit from something which he did not care to use himself. The present patent law appears to operate merely to restrain others from making and using for a limited period a certain device covered by a patent, whereas it is clear that patent laws were originally framed with an entirely different conception of the rights of the inventor. The question of patent right has an entirely different aspect whether we examine it from the point of view of exclusive right to make or use for a number of years, or of a right not to use it but at the same time prevent the whole world from using and deriving benefits from the invention as well. The inventor is given a monopoly by patent with the idea of encouraging him to expend energy and capital in its perfection, and to benefit the public by his invention, he himself being assured a reasonable profit for a reasonable number of years. The idea of permitting an absolute monopoly of a patent, even though the patentee or owner of the patent refuses to make any use of it whatsoever, is very similar to our harmful and vicious policy of legalizing monopolies in natural resources with the result of benefiting a few who render no service to the community at the expense of the community itself. From a moral point of view there can be no exclusive right to a patent, excepting if it be used, any more than there can be exclusive right to the bounties of nature, excepting if they be put to their best use, so that they benefit the community at large.

AUTOGENOUS WELDING.

During the last ten years several interesting and valuable processes for joining metal parts have been developed. The processes of welding, soldering, and brazing are very old, having been used from time immemorial. Welding is applicable only to the joining of wrought iron, low carbon steel and a few alloys. For the sake of accuracy we must except gold which in the pure, clean, annealed state has the curious property of welding cold under pressure; but commercially speaking, welding is limited to wrought iron and mild steel. Soldering can be used only on small, light work for joints which are exposed to ordinary temperatures and those slightly above the boiling point of water, inasmuch as the melting point of solder is about 400 degrees F. Brazing, that is, the joining of parts by the fusion of a spelter, is applicable to iron, steel, copper, brass, and other metals. On many kinds of work it is a process rather uncertain in results, even in the hands of experts, unless a good equipment is provided for controlling the heat and manipulating the work.

Until within a few years, cast iron could not be brazed successfully because of the presence of the free carbon in the iron. The brazing of cast iron was made possible by the "ferrofix" process, which first decarbonizes the joint, placing the metal in much the same condition as wrought iron, so far as the action of brazing is concerned, and then brazing follows in the usual manner. Prior to this discovery had been developed the Thompson electric welding process, by which almost all commercial metals except cast iron are quickly and homogeneously welded together, the joint being raised to incandescence by the flow of the electric current. This process has had a very successful commercial development, and now is used for making thousands of welds daily. It and the other electric welding processes are essentially autogenous, as will be explained further on.

The thermit process developed by Goldschmidt was unique. Intense heat is produced by the chemical reaction of pure aluminum and iron oxide in a finely divided state, the temperature rising as high as 5,400 degrees F. One product of the reaction is pure molten iron or mild steel so hot that when poured upon the broken ends of a forging, surrounded by a suitable mold, the parts are instantly melted, and the whole fused together with a mass of hot metal which, as it cools, binds the joint together with a perfectly homogeneous union.

The latest development in the joining of metals, which is now assuming important commercial development, is the so-called autogenous gas flame process. The term autogenous welding is in some danger of becoming applied exclusively to various systems of gas flame welding. The flame produced by the combustion of hydrogen and oxygen, or acetylene and oxygen, is so hot that the parts adjacent to the metal joint are quickly melted together, forming a perfect union. But the meaning of autogenous welding is simply a welding of its own kind, the parts being joined together without the introduction of spelter, solder or any foreign material. Hence any method of joining metals by fusion of the joint which does not require the introduction of foreign material to make the weld, is autogenous. Right here it may be said that the autogenous weld is the only reliable joining of aluminum parts that has been discovered.

An autogenous joint, when properly made, must be as strong as the adjacent metal, provided no change has been made in the characteristics of the metal because of the heat. A broken forging that has been subjected to special heat treatment to improve its physical characteristics could not be autogenously welded and made as strong in the joint as before, without, of course, again being heat treated.

The importance of gas flame autogenous welding in jointing of boilers, drums, receivers and thousands of other manufactured articles, which are now brazed, riveted or bolted together, is obvious. It would seem that a revolution would be worked in the manufacture of steam boilers. The weakness of joints in boilers is more than that of simple reduction of tensile strength. A riveted joint is a section subject to deterioration, because of localized stresses through bending, corrosion and the action of the fire. The ideal boiler shell is that in which every part is as strong as another part, and which is of uniform thickness throughout. The autogenous process bids fair to make the realization of this ideal possible.

* * *

It is stated on good authority that more than a hundred cylinders for the engines ordered in Germany some time ago for the East Indian and the Assam-Bengal Railways were condemned because of faults. Of these, eighty-eight were condemned in one day by the English inspecting engineer at the works. Further, after all the engines were finished, it was found that the transverse framing, a steel casting, ordered outside, would not permit the rocker-arms to work, hence must be replaced. These engines were promised, under fine for delay, to be delivered in May, but were delivered about a year late. The fault in the cylinders was mainly one of the method of casting. It would have been by far better to have cast only one pair of cylinders and tested these both before and after machining, to see if the metal was sound, the coring accurate, and the dimensions correctly given and worked to; then if a fault in any one of these particulars had been discovered, it could have been remedied on the next pair, or if not, at least there would have been less loss on the two trials together than on the eighty-eight. The trouble with the cross-girts was one either of the drawing-room, of the foundry, or of the machine shop; and would have been readily traceable; and in any case a little careful inspection would have revealed that the motion work would not clear, and the engine, consequently, could not make a single turn.

On the same set of engines the safety-valve springs were not of the right length, and a batch of six hundred bolts did not fit their nuts.

All these things reveal the desirability—indeed the necessity—of careful inspection all along the line.

ENGINEERING REVIEW.

CURRENT MECHANICAL EVENTS—LEADING ARTICLES OF THE TECHNICAL PRESS.

The increase in the lumber cut in the United States in 1907, over that cut in 1906 was over 7 per cent. The average lumber cut in the United States has increased from 250 feet per capita in 1850, to 480 feet per capita in 1907. There are nearly 30,000 saw mills in the United States.

One of the causes of pin-holes in aluminum castings is, according to the *Brass World*, that the metal is allowed to remain in the fire for some time after it has melted. Aluminum should never be allowed to remain in the fire more than the time required for melting, and overheating should be carefully guarded against if a good casting is expected.

That the aeroplane has been developed to the point of commercial importance is indicated by a cablegram from Le Mans, France, stating that a French syndicate has offered Wilbur Wright $100,000 for the sole right to construct the Wright type of aeroplane in France and the French colonies. It is also alleged that fifty aeroplanes of the Wright model have been ordered and that construction will be begun soon.

A patent has been granted to Henry V. Draper, of Springfield, Mo., for a process of hardening copper. The copper is melted in a crucible, and one pound of alum and four ounces of arsenic are introduced for every 20 pounds of copper. After stirring for some time, the copper is poured. It is claimed that copper thus treated is of great density, toughness and hardness, and that the copper may be melted a number of times without injury.

In the March issue of MACHINERY reference was made to the construction of boats and barges of reinforced concrete in Italy. According to *Engineering News*, reinforced concrete boats similar to these in use in Italy are to be manufactured for use on the Missouri river by Moechel & Lowther Engineering Co., of Kansas City, Mo. This firm has made a model of a 300-ton boat in 1/60 size, and of a 300-ton barge in 1/45 size, each to draw 3½ feet of water for the full-sized boat. Tests made on the models have shown very favorable results, but as yet the large vessels have not been built.

On October 3 the nine-hundred thousandth patent was issued from the U. S. Patent Office. It was an improvement on traveling stairs, such as are used in hotels and other large buildings. Patent Commissioner Moore estimates that the one millionth patent will be issued in the year 1911, and he calls attention to the fact that the total number of patents issued by the United States, is not very far below the total number for all other countries for all time. The issuance of foreign patents up to the date of the last report, was 1.135,000, or only 235,000 in excess of the total for this country.

The construction of the two new White Star liners, previously referred to in MACHINERY, is, we understand, to be commenced in January by Messrs. Harland & Wolff. The definite plans are now laid down. The steamers are to be 860 feet long and of a gross tonnage which is 8,000 tons in excess of that of the *Lusitania* and *Mauretania*. The names of the two vessels will be the *Titanie* and the *Olympic*. There speed is to be practically that of the *Oceanic*, or 21 knots. The first of the two vessels is expected to be ready in about two years, and the second in somewhat less than three years.

The shop structure of the Lucas Machine Tool Co., of Cleveland, Ohio, is built with a saw-tooth roof, and extensions have been made from time to time by adding saw-tooth roof units as the business has grown. To reduce the fire risk, the roof of the last section erected is made of 12 × 18-inch hollow tile, supported by structural steel, and covered with asbestos roofing. The floor is made of cinder concrete about 4 inches in thickness, laid on the natural sand foundation. Two-inch planks are spiked to the concrete, and ⅞-inch maple boards are laid on the planking. This combination makes a shop floor which is believed to be superior to any other construction of equal cost.

The effects of the new British patent law, which provides for the actual working of all British patents within the British Islands, are now commencing to be visible. The law became operative on August 28, 1908. It is stated that 30 foreign firms have completed arrangements to open factories in Great Britain for the working of their patents, and that a number of these are American concerns. Still other firms in the United States and in Germany are negotiating for factories or sites for plants. The principal articles which American firms will manufacture in England are telephones, typewriters, phonographic records, and shoe machinery. It is estimated that about 2,000 patents are now within the scope of the law, and that the effect of the law will be to give employment to from 30,000 to 40,000 people.

The development of scientific instruments, such as the scleroscope and Brinell machine for testing the hardness of metals, may lead to some astonishing and highly desirable discoveries. In an address delivered before the Institution of Civil Engineers, London, Prof. Henry Louis said that one of the greatest needs of the present time in mining is a strong tough metal considerably harder than quartz, which can be used as a substitute for black diamonds or bort for cutting hard rock. It is not impossible, so far as we know, that such a metal will be developed or discovered. Hardness of steel is a quality not fully understood. Manganese steel, for example, resists all steel cutting tools, yet it seemingly is not "hard." It can be bent without fracture and even twisted into corkscrew form. Scientific testing methods may lead to the discovery of steels having as surprisingly superior qualities over those now known as high-speed steel had above the carbon and tungsten steels of a decade ago.

On September 17th, Mr. Orville Wright, who had previously broken the world's records for flights with a heavier-than-air machine, while making a trial flight at Fort Myer, met with an accident which resulted in serious injuries to himself, and the death of Lieut. Selfridge, of the U. S. Signal Corps. The aeroplane was about 75 feet high, when one of the propeller blades broke. Mr. Wright lost control of the machine, which rapidly descended, striking the earth with terrific impact and burying the two men beneath the debris. A few days after the accident the broken blade was brought to Mr. Wright and he discovered an indentation in it which proved conclusively that the accident was due to the propeller coming in contact with a steel stay which was near it, but which was not supposed to be close enough to interfere with its movement. At the time the blade broke the aeroplane was on a curve, and the cause of the tragedy is attributed to this fact, as the machine cannot glide in a curve or spiral.

A paper was presented before the Franklin Institute April 15, 1908, on the theory of shooting, and the evolution of the Spitzer bullet, by L. H. Hartmann. The author briefly traced the evolution of the shoulder arms, mentioning how important is a flat trajectory on the accuracy of shooting. The introduction of smokeless powder by Noble made possible very flat trajectories for long ranges. A further improvement has been made by the Spitzer bullet, which is made with a sharp, approximately conical point, instead of the well known rounded point in common use. So marked is the difference between a round-nose bullet and a Spitzer bullet that the muzzle velocity produced at the same charge in present government rifles is 2,000 feet in the first second with a round-nosed bullet and 2,800 feet with a Spitzer bullet, the gas pressure being 42,000 pounds per square inch. The shape of the point of the Spitzer

bullet in longitudinal section is a sharp ogive. Tests made by the United States government, at Springfield, Mass., confirmed the results that have been experienced abroad.

Lieutenant-Commander Davis, of the United States Navy, has invented a new type of torpedo, which, judging from experiments, will prove very destructive. The torpedo contains a tube of vanadium steel, weighing about 40 pounds, and when the torpedo strikes the side of the vessel a shell is discharged from this tube, through the opening made in the vessel, with a velocity of 600 feet per second. The shell is charged with high explosive and equipped with a time fuse so that when it reaches the interior of the vessel it will explode, doing the greatest possible damage. In this way the protection now given by the water tight compartments, bulkheads and layers of coal will be overcome, and the vessel damaged very much more than when the explosion takes place on or near the exterior. In a trial at Sheep Island in Massachusetts Bay, a torpedo of this type was sent 120 feet to a steel tank 15 feet in diameter, with three bulkheads of ⅝-inch plate, and the torpedo shell passed entirely through the tank and bulkheads, going 100 feet beyond. There was no explosive in the shell used in this trial.

It has been stated by newspaper reports that Professor Wood, of Johns Hopkins University, has designed a new type of astronomical telescope, by means of which he expects to obtain results far in advance of any obtained by telescopes of ordinary construction. The principal feature of Professor Wood's telescope is the mirror, which consists of a basin of mercury set spinning by means of an electric motor. The mercury in the basin assumes a concave surface when the basin is rotated, the concavity being proportional to the speed. The surface obtained is theoretically more correct and brighter than that of any ordinary reflector. By varying the speed of the basin it is possible to alter the focal length of the instrument at will. The only difficulty, so far, has been the impossibility of eliminating slight vibrations of the machine, so as to preserve an absolutely perfect surface of the mercury. At the present time Professor Wood is having a telescope constructed with a 7-inch reflector, and if the instrument fulfils his expectations, it is stated that he will proceed to construct a giant telescope along the same lines.

The beneficial effect of reforestation on water power is vividly illustrated in the case of Miller's River, Mass. A number of concerns, including the L. S. Starrett Co. and the Union Twist Drill Co., of Athol, Mass., have water power derived from this river, and both concerns have auxiliary steam power to help out during the dry season. A few years ago the water would fail almost entirely in July and August, requiring the maximum capacity of the steam plants to run the works, but during the last two or three years the volume of flow has been almost equal to the normal demand for power during the whole summer, and the steam power has been required for a minimum period. The reforestation of the uplands of the drainage area that has been going on rapidly during the last twenty or twenty-five years has restored the old conditions, and now the rain-fall is held back by the trees, shrubbery, leaves and moss, the whole acting like a huge sponge to absorb and feed out the water instead of precipitating it at once into the water courses. In our generation it is common experience that water power, except on large rivers, is very uncertain and unreliable, but with reforestation of the upland areas we may see our streams in a few years restored to the equable flow all the year round that existed in the days of the early settlers. The benefit of conserving forests on the uplands and replanting lumber areas cannot be over-estimated from almost any point of view.

An electric recording target, designed by Mr. Sydney A. M. Rose, A.M., I.E.E., which records each shot, or series of shots, accurately and automatically, is, according to *Engineering*, being introduced by the Rose Recording Target Co., Ltd., 14 Abchurch-lane, E. C. It consists of a traveling target of the usual size, in conjunction with a miniature recording replica of same, located at the firing-point; the motions of both the target and replica synchronize, and when the former is hit, a mark is recorded on the corresponding part of the replica. The target consists of a paper or paper-covered canvas band, marked with the required aims, and is actuated by an electric device which unrolls the band on one side and winds it up on the other. The endless series of targets can travel in either direction and operates synchonously a roll of paper at the firing-point on which the records are made. Across this paper, and at right angles to the direction in which it travels, is arranged a set of contact-making devices placed 1/16 inch apart, and for individual firing connected through a resistance and a line-wire to the marking mechanism of the recorder. An auxiliary line-wire is provided for synchronizing purposes. For volley firing the contact-levers are each connected by a separate wire to a corresponding pencil or marker. When the target is being used, any hole passing under the contact devices immediately closes a circuit, thus transmitting and reproducing the hits.

As we mentioned in the September issue of MACHINERY, the state of New York has organized a new division of trade schools in the Education Department, and Mr. Arthur D. Dean has been made chief of this division. This new inauguration in the Education Department of the state is intended to further the organization of two classes of schools: in the first place, factory or apprenticeship schools, which will train men in factories for the various trades; and in the second place, trade schools of the ordinary type. The new schools will be a part of the regular school system, and subject to its management, but the work will not be mingled or confused with the work of the ordinary public schools. The state will make an allotment of $500 to the Board of Education for each of such schools giving instruction to not less than 25 pupils, provided the school is maintained for a minimum period of 40 weeks in one school-year. The state will also contribute an additional $200 for each teacher, after the first, employed in such a school for the same period. Among the rules laid down by the Department of Education is that for these schools no teacher will be approved of who is not a recognized mechanic. It is advised that the system be organized upon an economical footing, it being suggested that often an idle building, erected for a factory, or some other purpose, may be used. All correspondence regarding this new departure will be welcomed by Mr. Dean; address Division of Trade Schools, Education Department, Albany, N. Y.

A test was made August 24 at the Springfield Armory of the noiseless rifle invented by Hiram Percy Maxim. The test demonstrated that the report of a service army rifle was so reduced by the device as to be inaudible at a distance of 150 feet from the person firing. The invention is of a nature similar to the muffler of a gas engine. Its essential parts are a valve that closes the bore of the gun immediately after the projectile has passed the valve. This closure of the valve prevents the sudden expansion of the gases, the gases being emitted slowly. The result is that the characteristic report of a rifle is reduced three-fourths in loudness, it being judged by the officials who were present that the efficiency of the apparatus was about 74 per cent. In the report of the test it is stated that upon firing, the report was like the snapping of one's fingers accompanied by a slight hissing as the gases escaped. The sound of the hammer striking the firing pin was much sharper than the report of the piece. The invention appears to be entirely practicable and it is thought that it will work a revolution in warfare. The firing line of an army equipped with noiseless and smokeless rifles will be very hard to locate, as there will be neither noise nor smoke to guide the observer as to the position of the enemy. A dangerous feature of the new weapon is that it lends itself admirably to the cowardly assassin. With a noiseless gun it will be possible to shoot down a man in the street without alarming the police. On the other hand, as a game gun the new rifle will be highly prized, it being possible with it to shoot an animal without scaring the remainder of the herd, but even that has its drawback as it will tend to make the business of pot-hunting more successful.

MAKING CONCRETE TELEGRAPH POLES.

An interesting process has lately been adopted by an English firm for manufacturing hollow, tapering, concrete telegraph poles as well as pipes for conveying water, gas, oil, etc., under pressure. It has been customary to regard concrete as a material which has to be cast in a mold, but this machine uses the concrete as a plastic material, somewhat like clay, and the poles and pipes are not cast in a mold. In general, the process of manufacturing concrete poles, as described by *Page's Weekly*, is as follows:

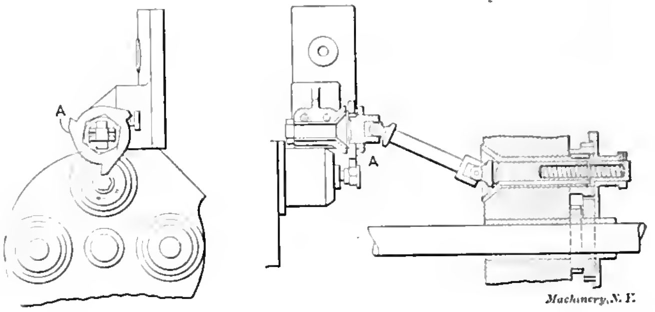
A long core of sheet iron is mounted on two trestles running on rails so as to be capable of rotation and longitudinal movement. Upon this sheet-iron core longitudinal steel rods of small size are fixed. This core is drawn through the machine employed, which is stationary. Concrete made of clean screened grit and Portland cement is discharged into a hopper or drum, in which rotating paddle wheels regularly discharge the concrete upon a bandage of coarse cloth webbing laid on a conveyor belt that takes one lap round the core. This continuous traveling conveyor belt is stretched so that it wraps the concrete round the core under great pressure. As the core issues beyond the conveyor belt, steel wire is fed spirally round it so as to press into the concrete wrapping, and small rollers then apply great pressure by working on the webbing, the slack of which, produced by the reduction in circumference and external diameter resulting from this pressure, is taken up by another contrivance. The core, therefore, as it issues from the machine is wrapped round spirally with a bandage of cloth containing the concrete. The machine pulls the trestles with the suspended core regularly forward, so that the core passes through it as the concrete is wrapped round it, and when the core has passed completely through the machine, it is lifted by an overhead traveling crane and placed on one side for the concrete to harden. In about twelve hours the interior sheet metal core is reduced in diameter by a screw attachment inside and withdrawn from the pole. After hardening for about six days, the bandage of webbing is removed and the pole is then complete. The thickness of the shell of the pole is from one to two inches, according to the height and the strength required, and the reinforcement is likewise varied according to circumstances. Poles are made by the machine above referred to up to 39 feet long, and pipes up to 20 feet long and 2 feet in diameter. Pipes are manufactured in the same way as poles, the smaller pipes withstanding pressures up to twelve atmospheres, and the larger pipes up to six atmospheres.

ATTACHMENT FOR CUTTING SQUARES AND HEXAGONS IN AUTOMATIC SCREW MACHINES.

Practical Engineer, August 7, 1908.

A device has just been patented by Messrs. J. H. Hopkins and H. J. Smith, of Manchester, England, consisting of an attachment for automatic screw machines for cutting flat surfaces, such as squares and hexagons or other polygons, on work produced from a bar, directly in place, so as to save a second handling of the work after leaving the automatic machine. The attachment, as designed, is particularly intended to be applied to a 4-spindle automatic screw machine, and provisions are included for driving a milling cutter of special design, as described later, by means of which flat surfaces are cut, and also for feeding this cutter past the revolving work. It should be understood that the work revolves while the flat surfaces are cut, to provide for which, of course, required some ingenuity in the design. As shown in the illustration, a hexagon is cut on the end of one of the bars in the machine, the cutting tool being the cutter *A*, provided with three teeth. This cutter is placed on a supplementary slide, mounted on the work-carrying head of the machine, and fed by the work by means of a leverage system adjustable to suit the requirements of different work. When the device is in operation, the work and the cutter revolve in the same direction in relation to their axes, so that at the cutting point the directions of the surfaces which are in contact are opposite, but the cutter is geared to revolve at twice the speed of the work to be provided with the hexagon, and as the cutter has three cutting points and revolves very rapidly, it produces a polygon with six equal sides when it has traversed the full width of the flat. If the cutter had only two points, it is clear that a square would be produced. Were a cutter having only one point used, the gearing being the same, two flats only would be produced, and the remaining portion of the circular surface would remain curved. It is clear that the same results can be obtained by gearing of other ratios than two to one, provided the number of teeth in the cutter is selected to suit the ratio of revolutions. The sectional view shows how the drive is transmitted to the cutter from the main drive of the machine.

It may well be remarked in this connection that when any devices are applied to automatic machines which in a certain sense belong outside of the original territory of the machine, it is very important to take into consideration whether these devices require a stoppage of the regular functions of the machine, and thereby rob the machine itself of the efficiency of which it is capable, or whether these extra devices perform their work simultaneously with the performance of certain of the legitimate functions of the tool. In the former case it is often doubtful whether the introduction of such devices is economical. Tying up an automatic machine for such operations as screw slotting, milling, etc., which prevent the continuous working of the machine, is sometimes questionable economy. On the other hand, if the devices are so designed that operations which of necessity must be performed on the machine can still be carried on while the device performs its own functions, then the introduction of such devices is of distinct advantage. If we analyze the conditions attending the device just described we will find that one of its strong features consists in the fact that the work is provided with its flat surfaces while it still continues its rotary motion, thus permitting other cutting tools to perform their functions without interference. There is no stoppage of the machine whatever required. Of course, in the present case another very important fact to consider is that a second handling of the work for milling purposes is saved, and it is often the handling of the work for the performing of various operations, rather than the time occupied by the operations themselves, that determines the cost of the product.



Attachment for Milling Squares and Hexagons while Work is revolving for Other Machining Operations.

RELATIVE ECONOMY OF STEAM AND GAS POWER WHEN EXHAUST STEAM IS USED FOR HEATING.

F. W. Ballard in the *Engineering News*, August 15, 1907.

The present time offers a good opportunity for making a comparison between the cost of power generated by the gas engine and the cost of power from steam when the conditions are such that either the heating of the building, or the carrying on of some of the processes of manufacture, can be accomplished by the use of exhaust steam from the steam engine. It is generally conceded that when the power alone can be used, and the waste heat from the steam engine and gas engine is not utilized, doubtless the gas engine is the more economical power producer. This can hardly be disputed because not only is the gas engine cheaper as far as fuel consumption is concerned, but in a well-designed gas engine plant the cost of maintenance need not be more than one-half the cost of repairs in a steam power plant of the same capacity, and the total cost of labor for the running of the plant would probably not run very much over one-half what the service would cost in a steam plant. The feature, however, which

gives the steam plant a decided advantage over the gas plant in economy is the possibility of using the exhaust steam from the steam engine for heating. This precludes, of course, the use of the condensing apparatus in connection with the engine, and consequently lowers the economy of the steam plant itself, but since the latent heat contained in exhaust steam amounts to about 80 per cent of the total heat of the steam when going to the engine, the lowering of the efficiency incident to running the engine non-condensing becomes of minor importance. Not only can the exhaust steam be used for heating the whole manufacturing plant, but in addition to the heating of buildings, a great many manufacturing concerns can make use of the heat of the exhaust steam for the carrying on of certain processes necessary in the work, thus saving the use of live steam; and, in cases where the temperature necessary is higher than that of the exhaust steam, it is not only possible, but perfectly feasible, to use the exhaust steam for bringing the temperature up to a certain point, and then to supplement by the use of live steam, thus effecting a great saving of what might otherwise be a very expensive operation.

As examples of uses for exhaust steam, we may mention drying ovens for various kinds of manufacture. If in such cases gas engines were used for power, it would be necessary to operate a special boiler plant to generate steam for drying purposes and for heating. There are also great possibilities along the line of using high-pressure compound engines for power, which can be operated condensing or non-condensing, so that they can be run condensing in the summer time or whenever the exhaust steam is not needed for heating, and operated non-condensing the balance of the time. Of course, there is a possibility of using the exhaust gases from the gas engine for the heating of buildings, but its possibility is very limited, first, because of the low fuel consumption of the gas engine per horse-power hour, and second, because of the large percentage of the heat units contained in the fuel which are converted into power. In a simple non-condensing steam engine we may say that there are about 30,000 heat units contained in the exhaust steam for each horse-power hour, while the waste heat in exhaust gases from the average gas engine would contain only about 6,000 heat units per horse-power hour. In conclusion, therefore, in any comparison between the relative economy of steam and gas power, due consideration must be given to the fact whether or not the exhaust steam from steam engines can be used for heating or other purposes. If it can be so used, the steam engine is likely to be the more economical of the two power producers.

CLUTCHES FOR POWER PRESSES.

Mr. Frank Mossberg, at the June Meeting of the American Society of Mechanical Engineers.

Clutches for power presses must be so constructed as to disengage from the driving wheel and allow the driven shaft to stop in the same fixed position whenever disengagements are made. For quick running presses the clutch parts must be light enough to respond promptly when the trip lever is actuated, otherwise their inertia will so retard the action that the clutch will not properly engage with the driving wheel.

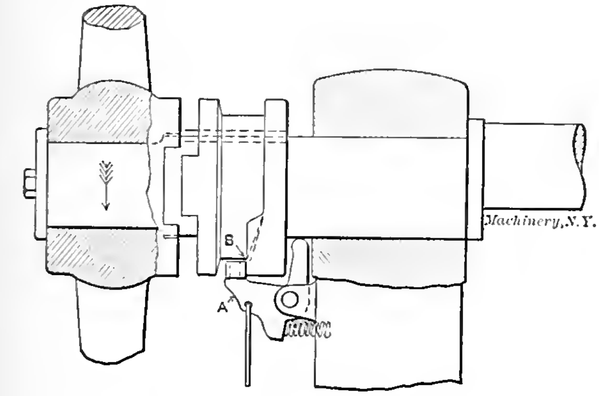


Fig. 1. Plain Jaw Clutch.

Perhaps the oldest clutch used for power presses is the simple jaw clutch illustrated in Fig. 1, in which the construction is so fully shown that no explanation is necessary. This clutch, while it may have proved useful for comparatively slow power presses and for light work, has been largely superseded by more improved types. The principal objection to this clutch is its heavy parts, which make it slow to respond, and sometimes when the speed is up to 100 revolutions, difficulty is found in making the clutch jaws enter the driving recesses in the wheel.

Fig. 2 shows a form of clutch used largely by several Connecticut press manufacturers. This consists of a sliding key *B* fitted to move freely in a slot or pocket in the crank-shaft, and controlled by a wedge shaped cam *A* connected to a treadle or hand lever. To lock the clutch to the driving wheel, the cam is released and the spring forces the key into engagement. Simplicity and low manufacturing cost are points in favor of this clutch, but it requires considerable repairs.

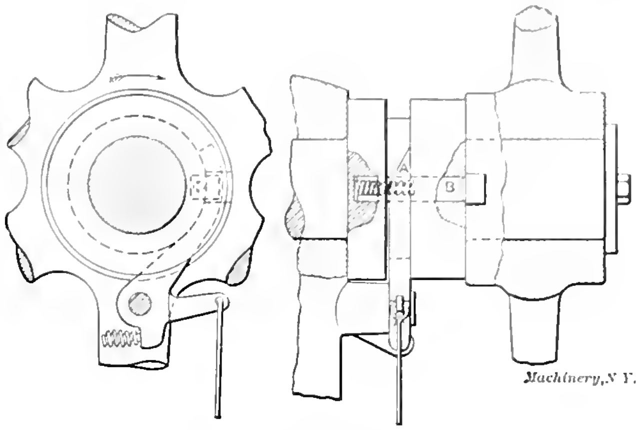

Fig. 2. Sliding Key Clutch.

Fig. 3 illustrates a form of clutch used extensively by the Stiles & Parker Press Company, and probably originated by Mr. Stiles. It was developed some thirty years ago, and yet is still used on a large number of presses where it appears to work satisfactorily. In this clutch the locking pins *A* are located in the driving wheel, and held in position by the trigger block *B*. To operate the clutch the cam segment *C* is slightly depressed. When held in this position the trigger block located in the driving wheel will come in contact with the cam lever, releasing the clutch pin, which in turn drops into recess *D* in the crank shaft. The cam lever is now returned to its normal position, and when the shaft revolves, the clutch pin *A* will be drawn out of the recess of the crank shaft by this same cam, thus stopping the driving shaft in its original position.

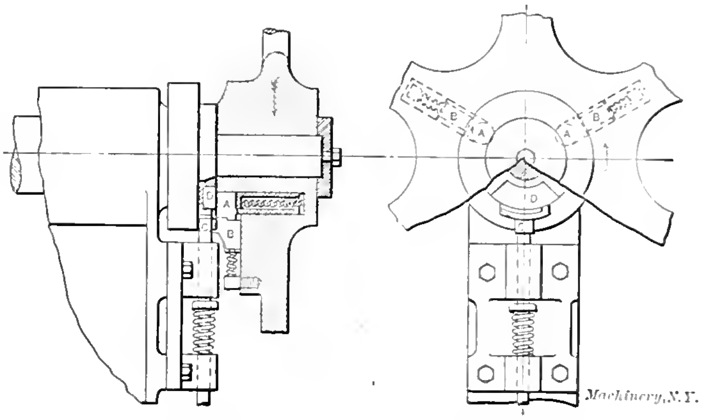

Fig. 3. Stiles & Parker Press Co.'s Clutch.

Fig. 4 shows a clutch used by one of the large press manufacturers, which commends itself for its simplicity. Owing to the peculiar construction, however, whereby a considerable part of the bearing in the hub of the driving wheel is cut away, the bearing is liable to wear rapidly. Its operation is as follows: The lever *B* is swung out of contact with clutch arm *C*, allowing clutch arm and key to be acted upon by the spiral spring shown in dotted lines. The continual revolution of the driving wheel will promptly bring one of the recesses

E in front of the half round locking key, allowing this key to make one-fourth turn in its socket and thus lock the driving wheel to the shaft. When the shaft reaches the original point of starting, the clutch lever *B* being in its normal position will obstruct the clutch lever *C* and cause the clutch key to return to its original position, allowing the driving wheel to pass over it freely.

Fig. 5 shows a form of clutch used on presses made by the Stiles & Fladd Press Company. The clutch pin *B* in this construction is placed in a pocket in the driving shaft in which it moves radially. A spring forces this pin outward to engage with a lug in the driving wheel when the release lever is actuated. This actuating mechanism will also cause the clutch pin to recede into the pocket in which it is held by the releasing cam out of contact with the driving wheels. This clutch, having two or more contact points in the driving wheels, is a very satisfactory working mechanism, and has proved very durable.

Fig. 6 shows a form of clutch used by the Ferracute Machine Co., and designed by Mr. Oberlin Smith. This clutch is used to a large extent on punching presses. It is rather complicated, especially in the form applied to larger presses. A desirable feature is that it is usually made with several contact points in the driving wheel which are of tempered tool steel. These contact points are so constructed that when the clutch is engaged, the wheel is locked in both directions. The illustration shows the working of this clutch.

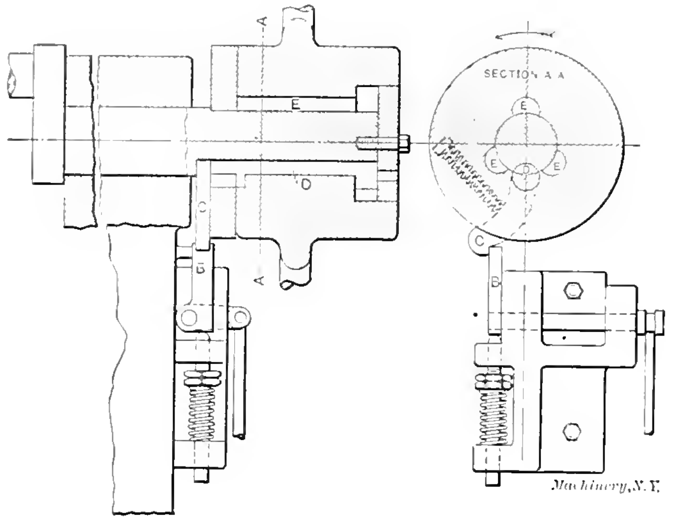

Fig. 4. Bliss Clutch.

Fig. 7 shows a form of clutch designed by the author and intended especially for large presses. It has two large engaging pins of tempered tool steel, which act together. These are located radially opposite each other and far enough from the center for good leverage. This clutch can be made to connect at each half revolution of the driving wheel. It is one of the strongest made and has proved serviceable in practice, requiring very little repairs. The clutch pins *G* connected with sliding collar *C* are mounted to move freely, and revolve with the driving wheel at all times. To operate the clutch, the locking pin *E* is pulled out off the cam *D*, allowing the collar *C* and pins *G* to move into engagement with the clutch lugs *H*, which lock the driving wheel and the shaft together. When the shaft returns to its original position the clutch pins are withdrawn by the action of the cam *D*.

A total departure from all the clutches previously described is a clutch invented by Mr. James A. Horton, of Boston, some years ago. Fig. 9 shows this clutch, which consists mainly of a hardened steel cam *A* keyed to the crank-shaft; a clutch ring *C* mounted to turn slightly on the shaft; a series of rollers *B* held loosely in slots in the ring, and a spring *G* acting on the clutch ring and causing the same to turn, carrying with it the rollers *B* towards the high point of the clutch cam *A*. The balance wheel is recessed to receive this clutch mechanism, this recess being lined with a hardened tool steel ring *D*. The diameter of the recess is such that when the rollers *B* reach a point about half way between the lowest and highest point of the cam they come in contact with the clutch ring *D*, and act as wedges to lock the clutch. Release of the clutch is made when the lug *F*, fastened to the clutch ring, strikes against the stop lever *E*. This will throw the clutch rollers out of engagement and allow the wheel to pass freely. This clutch we may term as a positive friction clutch. It is instantaneous in its action and can readily be disengaged at any predetermined position on the shaft.

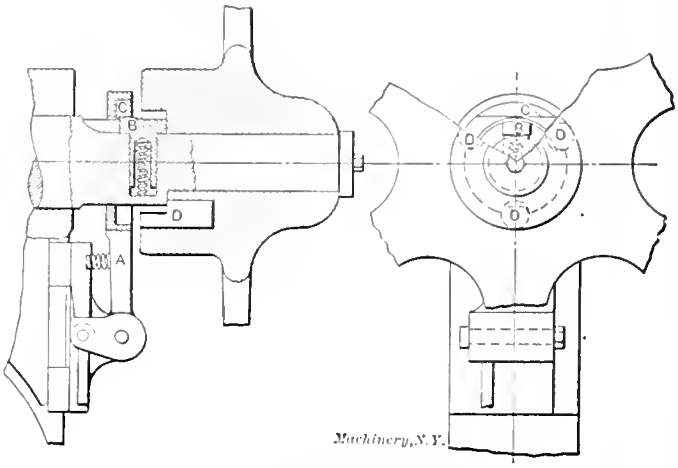

Fig. 5. Stiles & Fladd Clutch.

A desirable feature peculiar to this clutch is that it can be released with ease under full load. In other words, with this clutch it is possible to cause the slide of the press to descend on the work such as in embossing; release the clutch when the embossing dies act on the work; and then when the desired time has elapsed for the embossing tools to act, again engage the clutch and cause the press slide to return to its normal or up position.

This clutch has been extensively used for power presses by the Standard Machinery Company of Providence, R. I., and is one of the most durable forms yet produced for this purpose. It is suitable for the lightest as well as the heaviest press made and works well for speeds from the slowest to 500 R.P.M. The instantaneous action of this clutch when the trip lever is actuated enables the operator to run a press fitted with it faster and keep more perfect time than with any other. In the ordinary clutch, the operator presses the treadle which actuates the fixed locking or catching key. The balance wheel is revolving around the shaft and may be just past the locking point, requiring almost an entire revolution to return to the fixed point in the wheel, while at another time the fixed point in the wheel is in such a position as to engage the locking point instantly; thus we have a stroke of the press taking practically two revolutions of the wheel in one case and only one in the next, this variation making it impossible to perform operations in unison with the ordinary clutch. These clutches are made in various sizes to transmit from ½ horse-power up to 1,000 horse-power

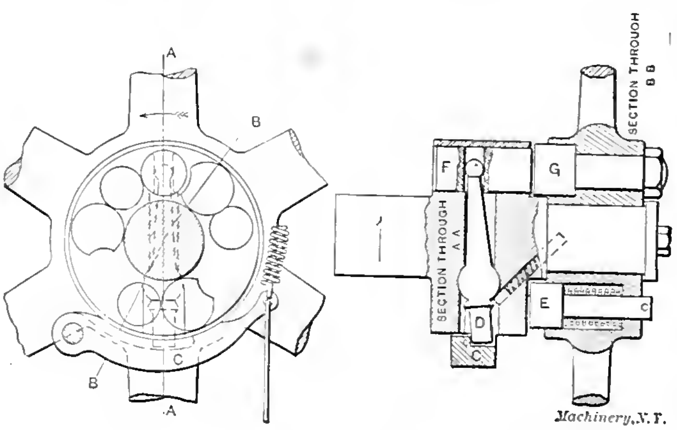

Fig. 6. Ferracute Clutch.

Fig. 8 shows the Horton clutch applied to a punching press. It also shows the tripping levers and automatic safety device which guard against the press making more than one stroke at a time, excepting by tripping the starting lever

for each stroke. To make the press run continuously, the clamp *D* is raised to the top of the vertical rod shown and fastened with a thumb screw. The operation and function of the mechanism is so plain that detailed explanation is unnecessary. The safety device described is only one of many for use in connection with a press and a press clutch and by no means confined to the Horton clutch. The high speed at which small hand operated presses are run makes such a device very desirable for the protection of the operator's hands and fingers. Without it a press will frequently make a second stroke unexpectedly, when the operator is putting in or removing from the dies the piece which has been operated upon, and this is the time when accidents usually happen. Small presses run at a high speed, and fed by hand, especially, should be provided with clutches that will not start the press until the operating lever is tripped.

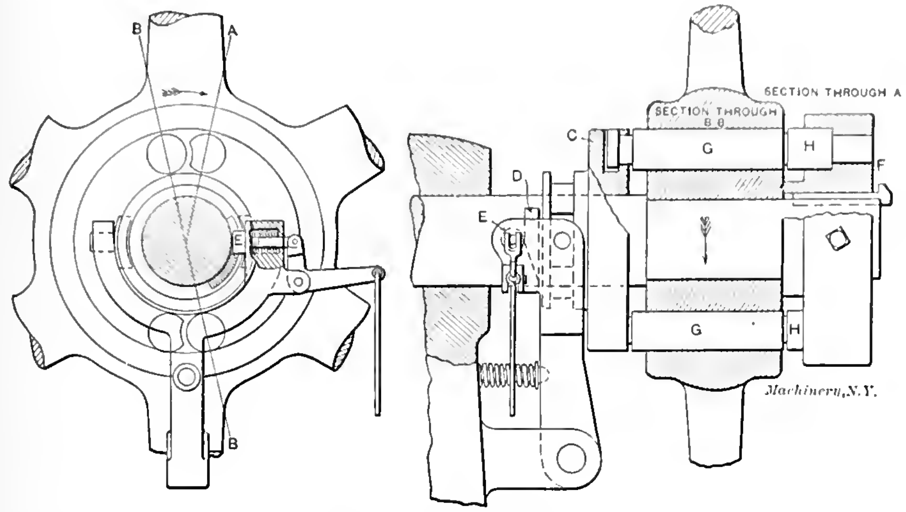

Fig. 7. Mossberg Clutch.

Press clutches must endure exceptional strain and abuse. Often a press with its heavy fly wheel will be brought to a standstill by the operator's placing the work in the die in such a way that the press cannot make the full stroke. With a fly wheel weighing seven or eight hundred pounds and 30 to 40 inches in diameter, the strain on the clutch is enormous; but a clutch that will not stand this abuse occasionally, without breaking, is not considered desirable or practicable. Several of the clutches described are capable of meeting these conditions.

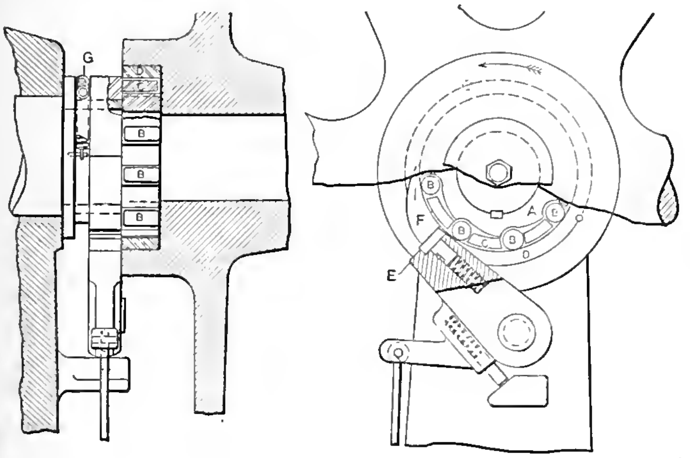

Fig. 9. Design of Horton Clutch.

* * *

Reference was made some time ago in MACHINERY to the trackless trolleys in operation in several places in Europe. Such a trolley line has now been projected from Chattanooga, Tenn., to the top of Walden's Ridge, a distance of about fifteen miles. It is stated in the *Engineering News* that the cars will carry thirty passengers, and each have starting arrangements similar to that of an ordinary automobile.

CALCULATIONS FOR CONE DRIVE AND BACK-GEAR DESIGN.

ALBERT CLEGG [*]

One of the first problems met with in the design of a machine tool is that of determining suitable spindle speeds. In a correct design the various speeds must have a fixed relation to each other, this relation being that of geometrical progression, and the problem is to find the intermediate speeds, the various diameters of the cone steps, and the back-gear ratio, when the slowest and fastest speed and the diameter of one of the cone steps are given. The calculations for finding these speeds are rather lengthy, and the machine designer will no doubt appreciate any method which permits him to save time and work in the laying out of his drive. The table given in the current Supplement will be found to be very valuable for this kind of work. This table gives a number of geometrical progressions ranging from speeds decreasing by 15 per cent to speeds decreasing by 50 per cent.

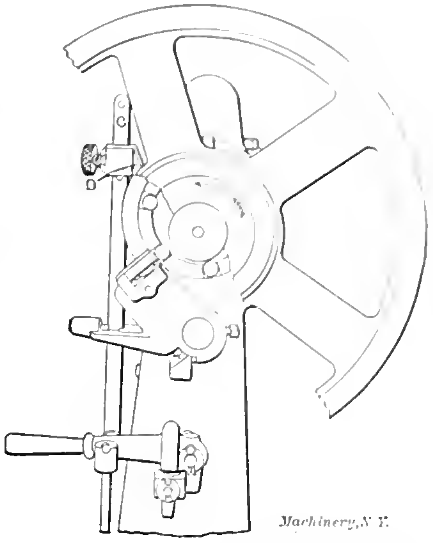

Fig. 8. Horton Clutch applied to Power Press.

The simplest way to describe the advantages of this table will be by a practical example. Assume that the spindle of a lathe requires 18 speed changes, varying from 6 to 250 R. P. M., that the cone has three steps, the largest step being 15 inches in diameter, that the lathe is double back-geared, and that a two-speed counter-shaft is provided. The questions to be answered are then: What are the intermediate speeds between 6 and 250 R. P. M.? What are the diameters of the two remaining cone steps? What are the back-gear ratios? and what should be the counter-shaft speeds?

If we turn to the table given in the Supplement, we will find that the maximum speed in every case is given as 1,000, which, in the case of the lathe we are to design, is four times greater than the maximum speed of the spindle. In order to reduce the figures given in the table to correspond with those of our example, we must divide the speeds given in the table by 4 ($1,000 \div 4 = 250$); our slowest speed, given as 6 R. P. M., will then correspond to a speed given in the table equal to 24 R. P. M. ($24 \div 4 = 6$). It will be seen that 24 and 1,000 are in exactly the same ratio as 6 and 250. The number of spindle speeds being 18, we now follow the horizontal line from the figure 18 in the left-hand column of the table, until we reach the number nearest to 24, this number in this case being 22.5 in the 20 per cent column. The figures in this column, divided by 4, will give us the range of the speeds desired, these speeds being as follows:

250	65.5	17.17
200	52.5	13.7
160	42	11
128	33.5	8.8
102.5	26.75	7.04
82	21.5	5.62

The speed ratio for the first back-gears is obtained by dividing 250, the fastest open belt speed, by 65.5, the fastest first

---

[*] Address: 22 Cartmel Road, Keighley, Yorkshire, England.

back-gear speed and the second back-gear ratio is found by dividing 250 the fastest open belt speed, by 17.17, the fastest second back-gear speed. These two ratios are then found to be 3.82 to 1, and 14.6 to 1, respectively. The counter-shaft speeds will be found to be 200 and 102.5 (the speeds of the middle cone steps), if consecutive spindle speeds are obtained by moving the belt from one step on the cone to another; but if consecutive speeds are obtained by shifting the counter-shaft, then this latter would be required to run at 160 and 128 R. P. M., which would then be the speeds of the middle cone steps. The diameter of the smallest cone step, if consecutive speeds are obtained by changing the counter-shaft speed, will equal $\frac{15 \times 160}{250} = 9.6$ inches. The diameter of the middle step would then be 12.3 inches. It will be seen that the table in the Supplement diminishes the actual work required for calculating geometrical speed progressions to a large extent, and that the various quantities to be settled upon can be determined with very little arithmetical work.

If it be required to lay out a drive with four cone steps instead of three, the calculations for the counter-shaft speeds, of course, become a little more complicated, as there is then no middle cone step, but the use of the table for finding spindle speeds, and back-gear ratios will eliminate a great amount of work even in this case.

* * *

COMPUTATION TABLE FOR REGULAR POLYGONS.

W. L. BENITZ *

The object of the two tables relating to regular polygons, in the Supplement, is to simplify the necessary calculations for any required dimensions of polygons. If the area, or any dimension of a regular polygon of a specified number of sides, is given, all the other dimensions are thereby determined in amount, and the proportion which the known part bears to each of the unknown parts will vary with the number of sides of the polygon. A knowledge of trigonometry is a requisite in determining the required proportions of these parts, and the accompanying tables were prepared not only to facilitate the trigonometrical work, but, at the same time, to simplify the process down to plain multiplication, or, where the area is the given dimension, to the extraction of a square root. The case in which the number of sides is required cannot be directly solved by elementary trigonometry, but is easily found by means of the tables.

Table I in the Supplement gives the symbols by which the various parts are designated, as well as all the necessary formulas needed for any computation. In addition to the symbols indicated at the top of Table I, there appear the letters B, F, M, K, and H, which are calculated in Table II for the proper value of N, the number of sides of the polygon, which heads the first column. These letters represent the following quantities: $F = N \tan \frac{180°}{N}$; $M = 2N \sin \frac{180°}{N}$; $B = \frac{1}{N} \operatorname{cosec} \frac{180°}{N}$; $K = \frac{N}{4} \cot \frac{180°}{N}$; $H = \frac{N}{8} \sin \frac{360°}{N}$. The logarithms of these quantities are given in each succeeding column for convenience in logarithmic calculation. The use of the tables may be partly illustrated by the following simple applications.

Example 1.—What size octagon steel will have a sectional area of 2 square inches?

We know $A = 2$, $N = 8$, and must find d. In Table I and in the column headed A, we run down the column until we find d on the left-hand side of the equation, giving the formula $d = \frac{4\sqrt{AK}}{N}$. The value of K is taken from Table II in the line beginning with $N = 8$, giving us $K = 4.82843$. Substituting these values of A, K, and N in the formula gives:

$$d = \frac{4\sqrt{2 \times 4.82843}}{8} = \frac{\sqrt{9.65686}}{2} = 1.554 \text{ inch, which is the}$$

proper distance across the flats to give a sectional area of 2 square inches.

Example 2.—What is the size of the round bar from which the octagon bar of the preceding example could be milled?

It is now required to find D, with $N = 8$, as before, and $A = 2$, or we may use $d = 1.554$, as already found. If the latter is selected we know d, and selecting the last formula in the column headed d from Table I gives $D = BFd$. B and F are selected as before, but if we use logarithms this time we will take our values from the tabulated logarithms of those quantities, giving us in the line for $N = 8$, Table II, log. $B = \bar{1}.51407$; log. $F = 0.52031$; and log. $1.554 = 0.19145$, from table of logarithms.

Then log. $D =$ log. B + log. F + log. $d = \bar{1}.51407 + 0.52031 + 0.19145 = 0.22583$, and $D = 1.682$ inch.

Example 3.—What is the area of a segment of a circle, 66 inches in diameter, lying between the circumference and one side of an inscribed polygon of 5 sides? The area required, which is similar to the shaded area in the figure of Table I in the Supplement, will be one-fifth of the difference in areas between the circle and the inscribed polygon. Knowing D, we find the area of the polygon from the formula $A = HD^2$, using the value of H for $N = 5$, which is 0.59441. The area of the polygon is then $A = (66)^2\ 0.59441 = 2589.3$ square inches. The area of the circle is $\frac{\pi}{4}(66)^2 = 3421.2$ square inches. Taking one-fifth of the difference we have

$$\text{Area of segment} = \frac{3421.2 - 2589.3}{5} = 166.38 \text{ square inches.}$$

Example 4.—If each side of a polygon is 4 inches long, how many sides must it have to make the area 99 square inches?

In this case both C and A are known and N is to be determined. Selecting the formula for A when C is known, we have $A = KC^2$, and solving for K gives $K = \frac{A}{C^2}$. Substituting the known values of A and C we have $K = \frac{99}{(4)^2} = \frac{99}{16} = 6.1875$. Running down the column headed K in Table II, we find the nearest value to this is 6.18182, which corresponds to the value 9 for N. The figure would then have 9 sides.

These are only a few of the many applications that may be made of the tables, and as indicated by the number of formulas, there may be twenty different problems stated, all of which are taken care of. These formulas and tables are also adapted to the solution of isosceles triangles in which the vertical angle approximates that in column Z, Table II.

* * *

TWO-CYCLE AND FOUR-CYCLE GAS ENGINES.

The growing importance of the gas engine as a motive power for all services makes the application of the terms "two-cycle" and "four-cycle" peculiarly aggravating misnomers. The word "cycle" means a chain of events that follow one after another until completion, when the same chain of events is repeated. In the action of the so-called four-cycle engine, the mixture of atmosphere and combustible gas is drawn into the cylinder by the induction stroke. The next stroke of the piston compresses the mixture of combustible gas and air into the clearance space of the cylinder, where it is exploded by a spark. The next stroke is the power stroke, following which is the stroke which exhausts the spent gases from the cylinder. Following this stroke is the induction stroke again. Thus four strokes of the pistons are required to complete the cycle.

In the two-cycle engine there is the induction stroke and the firing stroke, only two strokes being required to complete the cycle, the exhaust gases being expelled at the same time that a new charge is forced into the cylinder. The particular descriptive terms which apply to the two types of internal combustion motors and which are coming into use to some extent are "two-stroke cycle" and "four-stroke cycle," these terms clearly describing the action of the respective types.

GRINDING THREADING CHASERS FOR BRASS WORK.

ETHAN VIALL *

From time to time a correspondent will tell of his trouble in obtaining a smooth thread on machine or tool steel when using the self-opening type of die heads; but when a person has been working with tools of this description on brass of varying grades of hardness he comes to the conclusion that dealing with machine or tool steel is what might be called a "soft snap." When the brass worked upon is reasonably uniform, the difficulty of grinding threading dies to suit the work is not so pronounced. But when all kinds of brass, scrap as well as new brass, is used, only long experience will enable a man to sharpen the thread cutting chasers so that they will give satisfaction. Definite rules that will cover all cases cannot be laid down, but a few general principles applying to the grinding of these tools may be of value.

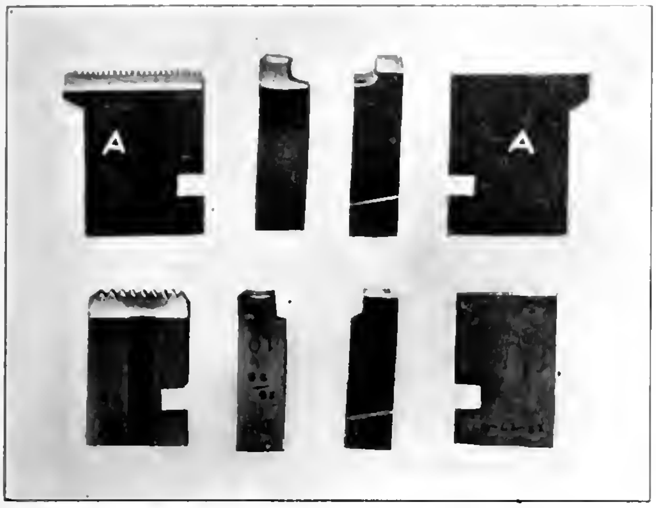

Fig. 1. Threading Die Chasers used for Brass Work.

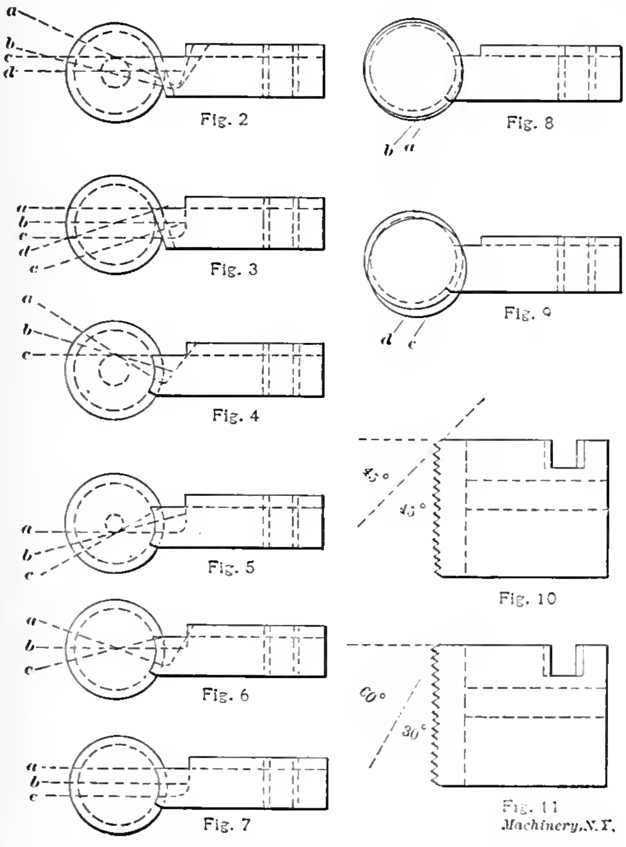

Figs. 2 to 11. Different Ways of Grinding Rake and Chamfer on Threading Die Chasers.

That difficulties will arise on account of ununiformity in the texture of the brass to be worked upon is, of course, evident. Another difficulty to be contended with is the wear of the die heads. When the die heads are new the chasers are held reasonably solid, but when the heads wear, the chasers become loose and must be ground so that they will not dig into the brass and produce a torn or imperfect thread. In the following the writer will describe the practice of grinding chasers in a certain shop where a great deal of this work is done. All chasers used in this shop are made in the toolroom from Jessop steel, and the threads are cut and relieved on Hendey-Norton lathes. They are then hardened and sent to the grinding room to be sharpened. The first cost of the chasers is higher than that for which they could be bought from firms making a business of die making, but these chasers give better satisfaction than any that could be obtained in the market, and besides, any faults discovered in actual use may be corrected in the next lot, which is not the case when the chasers are purchased.

In making brass chasers it is absolutely necessary that the threads be relieved; otherwise clogging will result. In the class of work just referred to, most of the threads are run up close to a shoulder, and, as a consequence, a very sharp chamfer must be ground on the chasers. It is not good policy to grind the chamfer any oftener than is absolutely necessary, because each grinding of the chamfer will shorten the life of the chasers in those cases where the die cuts close to a shoulder. When chasers show a tendency to break off at the chamfer or to get dull quickly at this place, they may be made with an extension as shown at *A* in Fig. 1. When made in this way the chasers are usually worn out by the time the extensions are ground off flush with the face of the body.

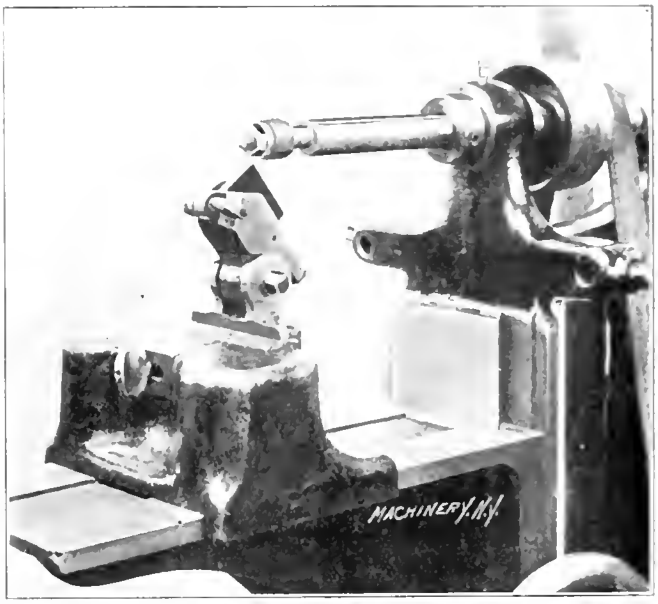

Fig. 12. Grinding the Chamfer on the Chaser.

Referring now to the principle of grinding thread chasers, a number of conditions are shown in Figs. 2 to 11. Our discussion will probably be clearer if for the time being we consider the chasers as lathe tools. In Fig. 2 is shown a chaser with milled threads. This is extremely difficult to use on brass work. When ground as shown at *c* it will dig into the work; when ground down still further as at *d* it still has the same tendency. To grind it as shown at *a* and *b* would produce impossible angles for brass work. In Fig. 3, *a*, *b*, and *c* are the same angles as *c* and *d* in Fig. 2, and *d* and *e* show the teeth ground without rake. When ground as shown at *d*, the cutting edge being on the center line, the tool has still a tendency to dig in. If ground as at *e*, it is obvious that this angle is undesirable. The writer's experience points toward the fact that it is useless to experiment with this kind of chaser on brass work, as it is impossible to grind it so as to be able to use it any great length of time.

Fig. 4 shows a chaser ground to angles advantageous for very hard brass. The angle is so determined that the face of the cutting edge is 1/16 inch ahead of the center at the successive grindings. In Fig. 5 the chaser is ground with a negative rake, the cutting edge being 1-16 below the center. This

---

* Address: 805 N. Mercer St., Decatur, Ill.

is used occasionally for certain classes of work, such as very soft "greasy" brass. In Fig. 6 is shown a chaser ground in a way to give the best satisfaction for all-around work. The cutting edge is ground so that a line passing through the face also passes through the center of the work. Finally, in Fig. 7 is shown a very poor way to grind a chaser whether for brass or steel, as the angle of the cutting point changes with each successive grinding, and while such a chaser may cut satisfactorily on some work when nearly new, it is not likely to do so after one or two grindings.

In grinding the chamfer on a brass cutting chaser a wheel about the size of, or very slightly larger than, the piece which the chaser is intended to cut, should be used. The relation of the wheel to the chaser when grinding the chamfer is indicated in Figs. 8 and 9. In Fig. 8, *b* represents the stock to be cut, and *a* the emery wheel used for grinding the relief of the chamfer. As will be seen, the center of the emery wheel is a trifle below the center of the stock, and somewhat toward the right. In Fig. 9 is shown the relation when grinding a chaser for hard brass, such as shown in Fig. 4. Extreme care must be taken, in grinding, not to draw the cutting edge or chamfer of the teeth.

In Fig. 10 is indicated the angle at which the chaser should be set in the fixture when grinding the chamfer for a uniform run of thread cutting. Fig. 11 gives a little more bevel or angle of chamfer. As a general rule, except for the very hardest brass, as little relief as possible back of the cutting edge of the chamfer should be used, as it steadies the chasers when starting the thread. It is of advantage when grinding new chasers to set the chaser well over to the left of the wheel, using a fixture such as shown in Fig. 12, and just touch the edge of the chamfer furthest away from the cutting edge, with the wheel; then gradually move the wheel over until there is a slight relief all the way up to the cutting edge. A fixture or jig used for grinding the faces of chasers is shown in Fig. 13. Both of these fixtures are made by an outside company (The Modern Tool Co., Erie., Pa.) especially for this purpose. It is necessary to use some kind of a fixture, as it is impossible to get good results when chasers are ground by hand.

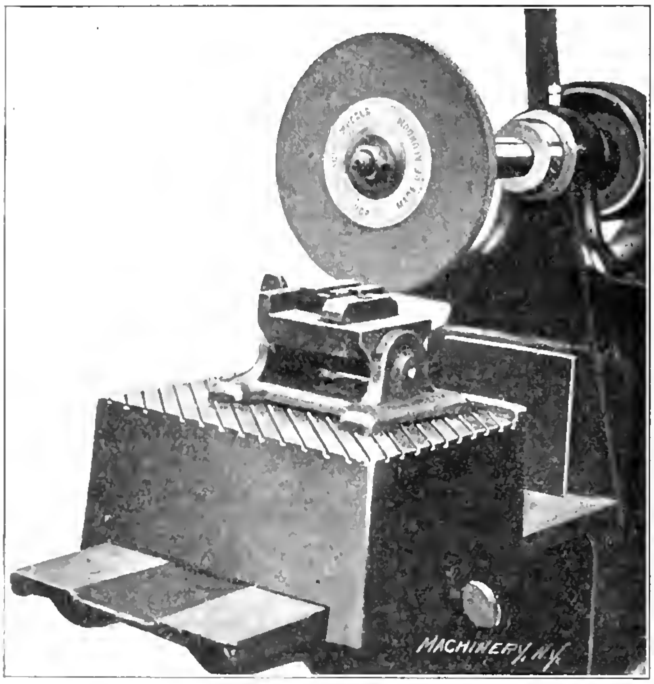

Fig. 13. Grinding the Cutting Edge of the Chaser.

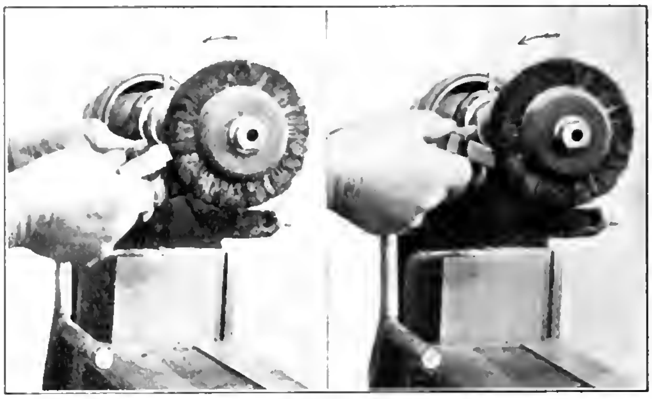
Alundum wheels of rather fine grade and known as elastic bond, have given better satisfaction for grinding chasers than any other wheels, but no matter what wheel is used there is a fin left on the cutting edges of the tool, which is a source of trouble if not removed. Lapping in various ways was tried for removing this fin, but the most satisfactory, as well as the quickest way, is to use a very fine three-cornered file and just draw it lightly down each V-groove of the thread at an angle of about 45 degrees, not pressing hard enough to more than take away the fin and slightly dull the cutting edge. An oil stone should then be run lightly over the edge of the chamfer to dull it just enough, so that it is not entirely sharp. The chaser threads are then dipped in a little flour of emery and oil, and brought up against a wire brush, as shown in Fig. 14. They are then turned over and brought up against the wire brush as shown in Fig. 15. This should be done very lightly, and has the effect of smoothing the edges the right amount. A little practice soon enables one to determine the proper amount for this. The wire brush is 6 inches in diameter, made of fine wire, and runs 3,400 revolutions per minute.

As a rule, a brass cutting chaser will chatter when too sharp. When the thread cut becomes torn, it is evidence that the chasers are dull, or that they feed too fast. Burrs in the thread tend to have the same effect as increasing the pitch in many cases. Chasers generally tend to feed too fast rather than too slow, and the remedy is the judicious removal of burrs or dulling of the cutting edges, provided, of course, that the teeth are already ground to the right cutting angle. When a set of chasers feed too slow the cause is usually that there is not enough clearance back of the cutting edges of the chamfer. Whether chasers feed too fast or too slow is easily determined by examining the thread cut. If the side of the thread next to the turret is smooth, and the side next to the chuck is torn or ragged, the chasers feed too fast, and vice versa.



Figs. 14 and 15. Revolving Wire Brushes which smooth the Cutting Edges of the Chaser.

* * *

At the October 13 meeting of the gas power section of the American Society of Mechanical Engineers in New York, a plan of action was presented in a paper by Mr. H. L. Doherty. It briefly reviewed the subject of gas power and pointed out some of the fields of activity that are now in embryonic state. He warned the members of the section in regard to unpromising fields and unnecessary duplication of work. Much duplicate work could be avoided if the present state of the gas power art could be quickly brought before the membership and provision made whereby all progress in the state of the art would be quickly reported. As an example of an unpromising field of experiment and invention, Mr. Doherty quoted the so-called gas turbine as distinguished from the mixed turbine, that is, a turbine using both gas and steam. To construct an actual gas turbine on ordinary lines requires the transformation of heat energy to work energy at a temperature and blade velocity beyond the strength of any material now known. In spite of this fact, however, thousands of dollars have been wasted in the vain attempt to solve the problem.

* * *

The general development of the gas engine has taken little account of the heat of the exhaust, the exhaust generally being allowed to go to waste. However, there is a growing disposition now to utilize the exhaust heat for water heating and steam generation. Experiments made abroad indicate that the heat of the exhaust will evaporate from 1.1 to about 1.5 pound of steam per horse-power per hour, or it will raise from 600 to 820 pounds of water from 32 degrees F. to the boiling point. The value of this heat from a large gas engine is apparent.

A PROPELLER PLANING MACHINE.

NOSMOT.

The accompanying half-tones and line engraving illustrate a machine designed to dispense with considerable hand labor in the finishing of large propeller blades. Up to the time that this machine was put in operation, all blades were finished by chipping, grinding with a flexible shaft grinder, scraping and filing, and the time consumed was considerable. The blades were not uniform when thus finished, and consequently did not balance when under pressure.

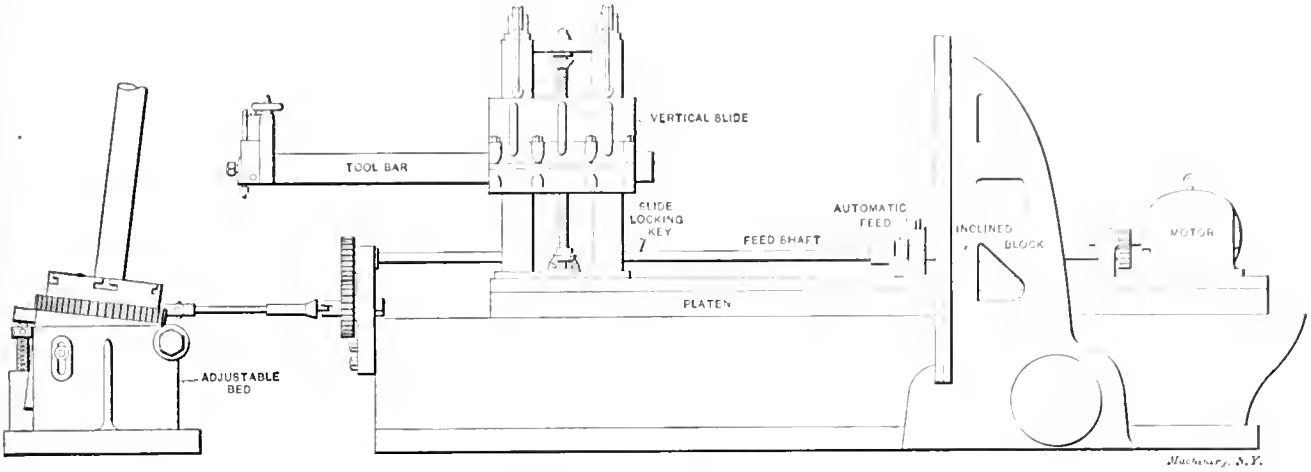


Fig. 1. General Arrangement of Propeller Planing Machine.

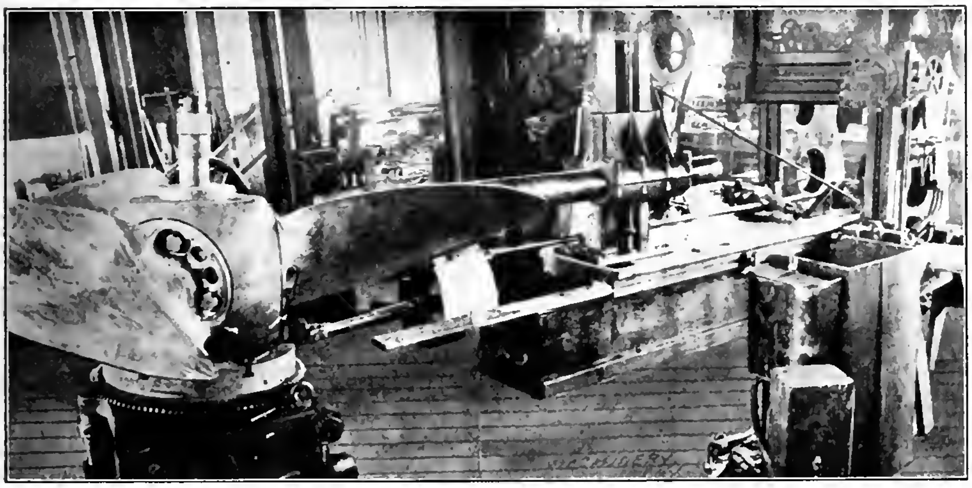

Fig. 2. Propeller Planing Machine in Operation.

The propellers are now cast, the hub bored, and, in the case of the one shown on the machine in Fig. 2, the blades are fitted to the body. The body in this case is finished on the boring mill with the exception of the screw holes, which are drilled and tapped in the radial drill. The blades are tested on the surface plate and the pitch line marked. The shanks are also laid off and prick punched around, after which they are centered in the horizontal boring mill and finished in the lathe.

The blades and body are assembled on the erecting floor and then placed in position on the planing machine. This machine, as shown in Fig. 1, consists of a regular planer on the platen of which is bolted an upright carrying a slide. The tool-carrying bar is fitted into this slide, the vertical movement of which is governed by the lead-screw shown. The slide is balanced by weights at the back of the upright, for the purpose of taking the strain from the screw. A motor driving the feed shaft is also bolted to the platen and used for quickly running the tool either way over the work. A ratchet and pawl arm carrying a roller is bolted onto one of the housings and this, in conjunction with the inclined plane block shown gives an automatic feed. Bevel gearing between the feed shaft and vertical slide screw gives the up and down movement of the tool, at the same time as the propeller is revolved by means of the worm and worm-wheel driven by gearing from the feed shaft. The revolving table is set upon an adjustable bed for the purpose of lining up the tool and its motion to the shape of the propeller and its angular deflection.

The propeller is firmly clamped to the table in such a position that the center of one blade is in line with the tool bar. A key locking the feed shaft to the slide screw is pulled out, and the tool is brought nearly to the surface of the blade. The locking key is then driven in, and the tool passed over the blade. The tool is tried in several positions by a small movement of the planer platen for each, and the adjustable bed inclined until the movement is about in line with the casting. The tool is then moved close to the propeller body and a slot planed around the hub for clearance for the tool, by passing the tool over the blade by the feed motion, the propeller meanwhile rotating; during this the platen remains stationary. When this slot has been cut to a sufficient depth—about $\frac{1}{8}$ inch to $\frac{1}{4}$ inch deep—the tool is raised to its highest point, ready for operation.

The platen movement is governed in the regular way by stops. It is set in motion, and the tool brought to its cut by the feed shaft motor. The inclined block is set in such a position that the roller will move one or two teeth on the ratchet as desired. All small adjustments are made with the hand-wheel shown on the tool head. Usually two cuts are necessary to finish a blade. The gearing is so arranged that the tool moves down a corresponding distance when the propeller blade rotates around its center. After finishing the first blade, the slide locking key is removed and

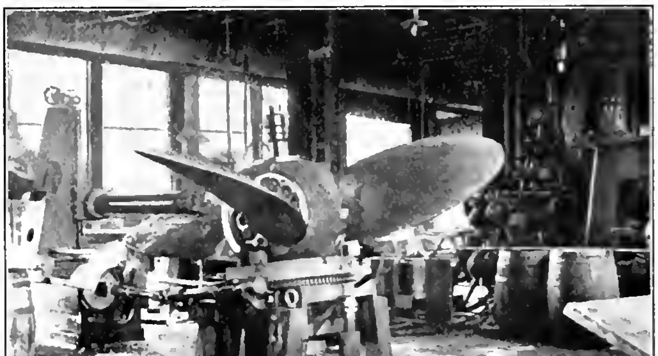

Fig. 3. Propeller Mounted on the Revolving Table.

the propeller revolved by motor into position, after which the operations previously described are carried out.

When finishing the blades, the propeller is carried to the erecting floor, where hand labor is employed to scrape and file-finish the surfaces. As the back is not planed, it takes some time to smooth it, but the face requires very little attention. Ordinary scrapers and bent files are used. Propellers made by this method have been tested and found far superior to those made by any other method known to the writer.

* * *

MACHINING FLY-WHEELS FOR GASOLINE ENGINES ON THE POND RIGID TURRET LATHE.

In the July, 1908, issue of MACHINERY we described and illustrated the operation of finishing automobile fly-wheels on a Libby turret lathe. In the present article a similar class of work is dealt with, the illustrations showing how fly-wheels for gasoline engines are finished all over on a Pond rigid turret lathe. Operations of this kind can be carried out easily on this machine also on account of its construction, which permits the carriage to be run under the chuck, so that wide facing tools may be bolted directly to the broad faces of the turret, thereby making a stiffer arrangement of tools than would otherwise be possible.

The work is finished in two cycles of operations, in the first of which the fly-wheel is turned complete on one side, the hole bored and reamed, and the outside circumference finished; in the second cycle the other side of the fly-wheel is completed. During the first operation, the work is held by the inside of the rim by means of a four-jaw chuck, using the hard jaws. The side of the rim, the tapering circumference of the recess, the web, and the hub are first rough-turned, using tools placed in the carriage tool-post.

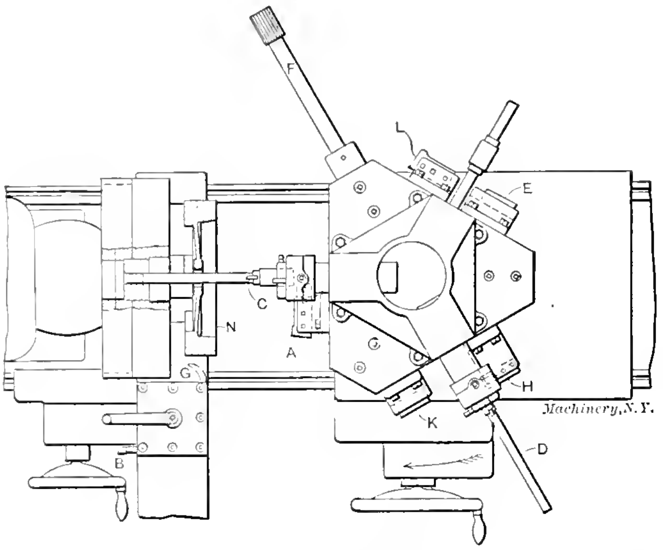

Fig. 1. First Cycle of Operations in Finishing Gasoline Engine Fly-wheels on a Pond Turret Lathe.

The hole is then rough-bored, using the bar *C*, supported in a bushing in the chuck, as shown in Fig. 1. The outside circumference of the wheel is rough-turned at the same time by a cutter, held in the extension turret tool-holder *T*, Fig. 3, and the taper fit on the inside of the fly-wheel is turned by means of cutter *A*, held in a facing head on the turret.

The outside diameter of the wheel is next finish-turned with a finish cutter *V* held in the same manner as the roughing tool for the same operation, in the extension turret tool-holder. At the same time the bore is finished, using a finish boring cutter in boring-bar *D*, supported in the bushing in the chuck in the same manner as the roughing bar *C*. The side of the rim and the hub of the wheel are also finished at this time by two facing cutters *H* and *K*, held in tool-holders on the face of the turret. When the finish cuts on the rim and hub are taken, the work is supported by a bushing on the boring-bar in the bore of the wheel, the boring cutter and facing tools being set in such relation to each other that the finishing boring of the hole is completed before the facing cuts are taken.

The web of the wheel is next finish-faced with the facing cutter held in the holder *E*, and the taper surface on the inside of the rim is finished by the tool *L* at the same time. While these last operations are performed, the work is supported by a bushing held on a supporting arbor, entering the bore of the wheel. In the next step, the bore is reamed, using a reamer held in a floating reamer-holder as shown at *F*. When the reaming operation is completed, a groove *N* is cut on the inside of the rim, using a tool *G* held in the carriage tool-post, as shown. The first cycle of operations on the fly-wheel is now completed.

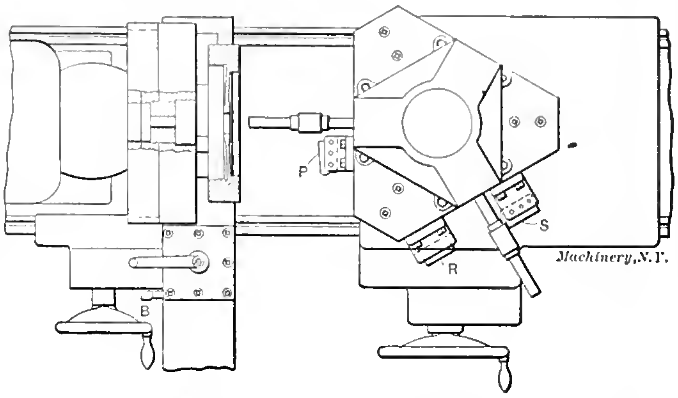

Fig. 2. Second Cycle of Operations.

The fly-wheel is then removed from the chuck, turned around, and held in soft jaws for the second cycle of operations, the jaws fitting the outside circumference of the wheel. The operations on this side are very similar to those performed on the other side, excepting that they are fewer, and therefore less complicated. In the first place, the side face and the inside of the rim, the web, and hub are rough-turned, using tools held in the carriage tool-post. In the next place, the inside of the rim and the web are finished, using the cutters held in the tool-holder *P*, Fig. 2, screwed to the face of the turret. The work is supported during this operation by a bushing held on a supporting arbor, having a pilot supported in a bushing in the chuck, the same as already referred to in the first cycle of operations. Finally the rim and hub are finished, the facing cutters held in the facing heads *R* and *S* being used, the work being supported as before.

The time required for performing these operations is about one hour. It should be noted that the design of the turret lathe permits several cuts to be taken on different parts of the work, simultaneously, thereby saving a great amount of time. While these operations are simple, they illustrate in a very practical manner the advanced labor-saving methods employed in automobile factories, and in other shops where large numbers of gasoline engines are built, and also how the cost reduction of machining the fly-wheels has been given special attention.

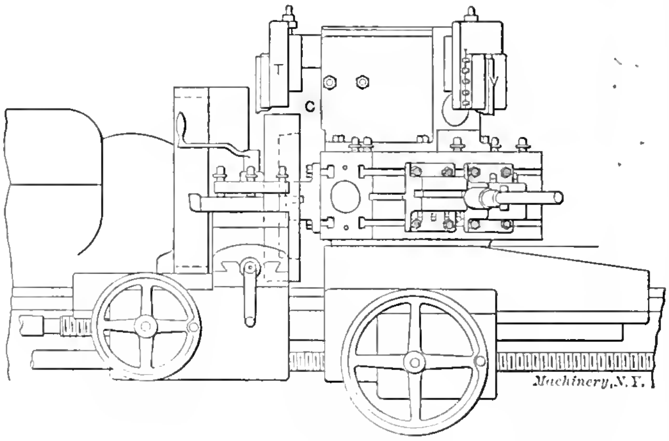

Fig. 3. Elevation of Turret and Tools for Finishing Fly-wheels, First Operation.

* * *

Use a keen knife to sharpen lead pencils. The tensile strength of the graphite core is very low, and a dull blade breaks it by pulling it in two, thus causing excessive waste of pencils.

SOME INTERESTING AUTOMATIC SCREW MACHINE WORK.

The automatic screw machine has, during the last few years, proved itself capable of performing a great many operations which but a short time ago were considered as properly belonging to the province of the engine lathe. This is true not only with regard to the size of the work operated upon, but also in regard to the number of operations, and the complication of the design of the piece of work to be machined.

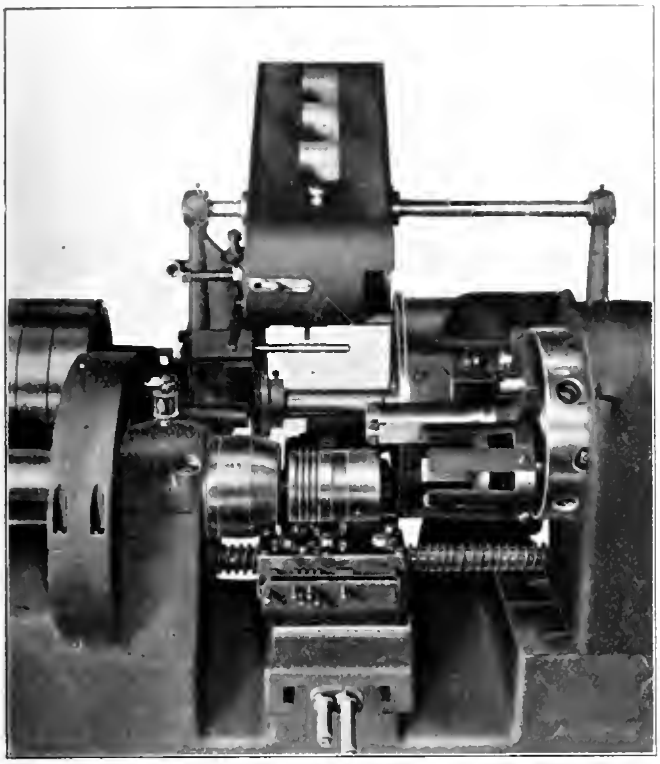

Fig. 1. Cleveland Automatic Screw Machine operating on Piston shown in Fig. 2.

In the present article some interesting work of this class performed on a Cleveland automatic screw machine, manufactured by the Cleveland Automatic Machine Co., Cleveland, O., is illustrated.

In Fig. 2 is shown a section and end view of a piston finished on a Cleveland 2-inch automatic machine in but a small fraction of the time which would be required to turn and bore the same piece by any other method. This piston is made from cast iron, and is finished on the various surfaces, as indicated by the finishing marks in the engraving, in eight minutes, after which, of course, it is ground on the outside. Two cuts are taken over the entire length of the piston, one for roughing and one for finishing. A forming tool on the front of the cross-slide faces the ends of the piston proper, and roughs out the grooves shown on the cylindrical surface. Then a forming tool on the rear of a cross-slide finishes the grooves in the ring; it has been found that one single roughing cut does not leave them quite smooth enough for the purpose for which they are intended.

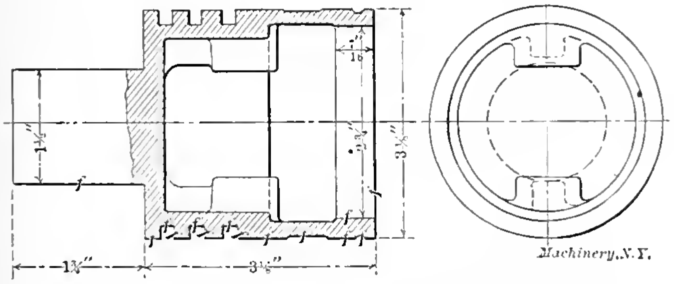

Fig. 2. Piston finished on a Cleveland 2-inch Automatic Screw Machine.

In Fig. 1 part of the machine on which these operations are performed, is shown, together with the tools employed, and with the work in place. It will be noticed that the machine is provided with a tilting magazine attachment, into which the rough castings are fed, and from which the machine receives the castings automatically as the work progresses. If the cast iron from which these pistons are made is not too hard, it has been found that it is not necessary to grind the tools employed any oftener than once every two days. It is of the greatest interest to note the extreme cheapness of cost of producing work in a machine of this kind. It is estimated that the operating expense for the machine is only one mill a minute, so that the piston shown being finished as it is in eight minutes, is produced at an actual labor cost of only 8 mills, or 0.8 cent. Of course, this means that the operator runs a considerable number of machines, which he can easily do, inasmuch as the machine, when properly set, requires very little attention.

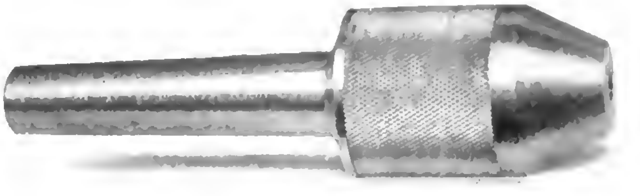

Fig. 3. Chuck shown in Detail in Fig 4, finished in 40 1-2 minutes

In Fig. 3 is shown another interesting article produced on a 4¼-inch Cleveland automatic screw machine, and which, as will be seen, is to be a drill chuck when completed. The parts of this drill chuck which are made in the screw machine, are shown in detail in Fig. 4. The work consists of four pieces: a shank or stem, a nut, a collar, and the chuck proper, all produced in the screw machine in 40½ minutes These pieces are all made from machine steel and are therefore finished all over. While this work was performed on a 4¼-inch machine, it would have been even better to employ a 3¼-inch screw machine, but in the present case the machine was to be employed for work of larger sizes as well, and therefore a large size machine was fitted up so as to be able to perform operations on smaller work also. It will be noted that the diameter of the stem is very small, considering the size of the machine, and it was required to arrange the machine so that it would give the correct speeds for small diameters as well as for large ones. Considering the time used in finishing the piston, as already stated, it will be seen that the actual labor cost is only 4 cents, and that if allowance is made for the time required for changing over from one class of work to another, after a number of pieces of one kind have been made, the total labor cost of the four parts would still be less than 5 cents.

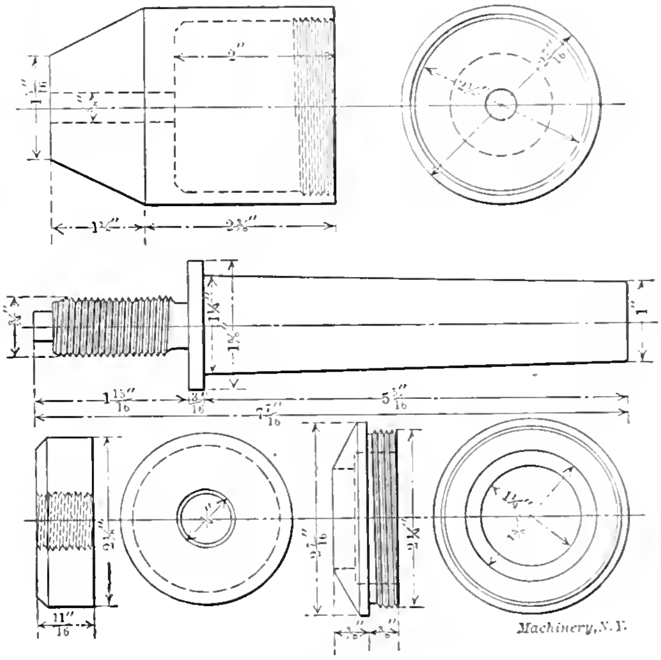

Fig. 4. Details of Chuck in Fig 3.

One of the most interesting operations in connection with the making of the chuck shown is the making of the stem. This, of course, must be made with the threaded end headed

out, and, [illegible] mean that it is not possible to produce the tapered part with tools placed in the turret. The taper end, therefore, is produced with a forming tool in the cross-slide, taking a cut the full length of the shank, which is over 5 inches, the steady-rest supporting with rollers the end of the bar on the part on which the thread is to be cut.

Fig. 5. Forming-tool Chips resulting from turning Shank of Chuck in Fig. 3.

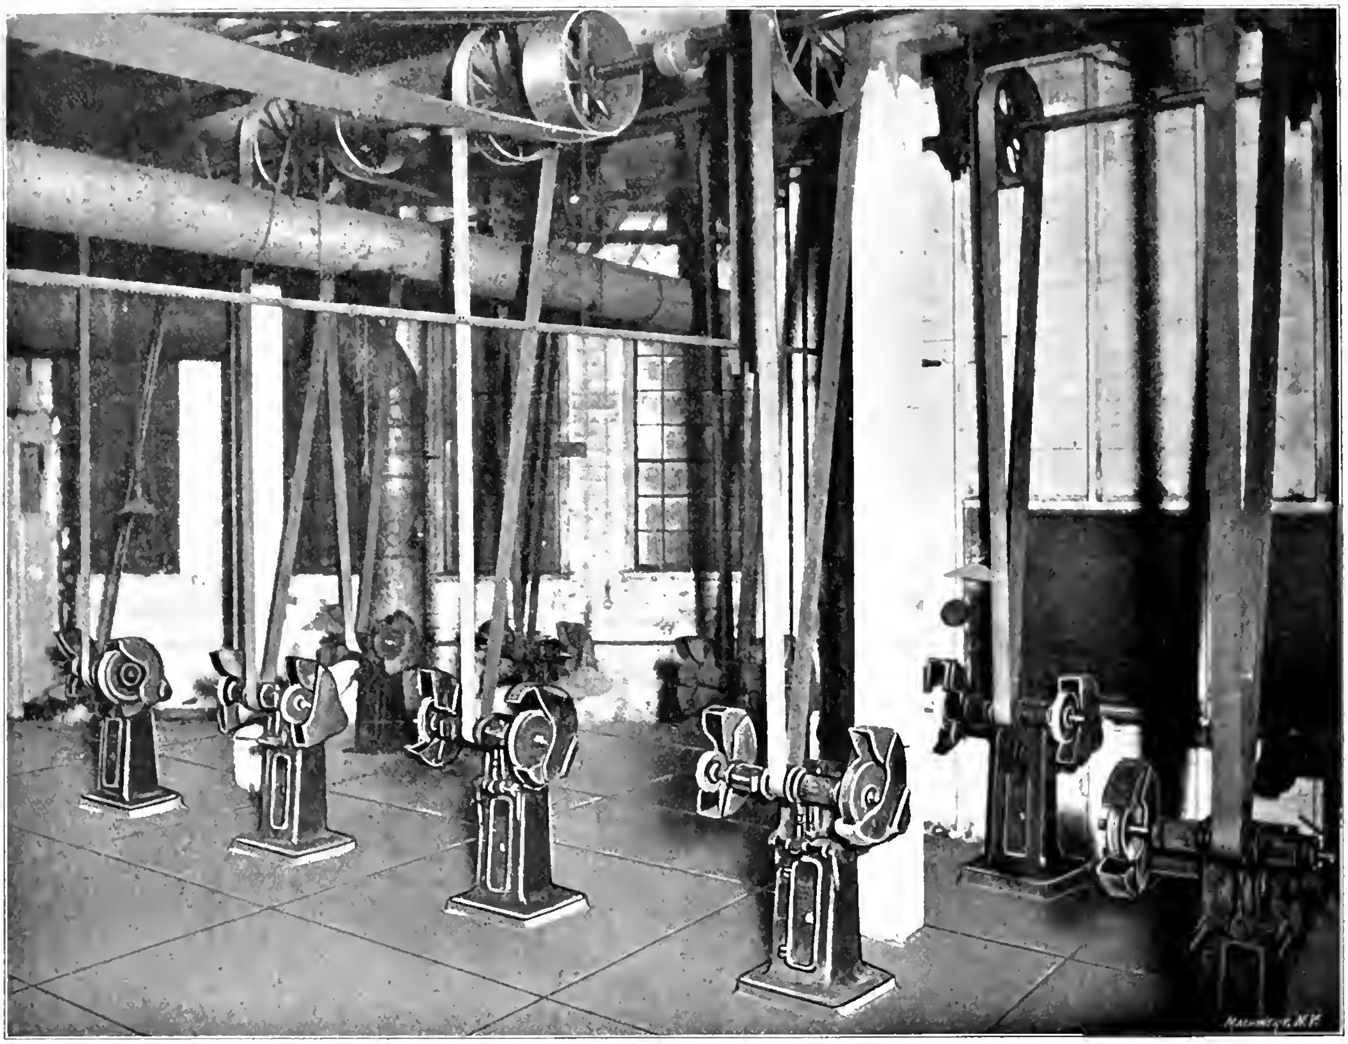
Chips have been removed from the tapered shank, the full width of the piece, and 20 inches long, without breaking. In Fig. 5 a photograph of one of these chips is shown. The possibility of obtaining such long chips, without breaking, indicates that in spite of the width of the forming tool, the cut is very steady, as otherwise the chips would break off as soon as they were removed from the piece.

The illustrations shown give a general idea of the possibilities of the large size automatic screw machine. It is interesting to speculate upon how long it would take even an expert mechanic to turn up the different pieces shown in Fig. 4 on an engine lathe, boring and threading them as indicated, and finishing them with the same accuracy that an automatic screw machine is capable of. When this time is compared with the time taken by the screw machine for performing the same operations, we have a good example of the labor-saving qualities embodied in modern automatic machine tools.

THE POLISHING ROOM OF THE FOX MACHINE CO.

The polishing room of the Fox Machine Co. is notable for its neatness and convenient arrangement. As may be seen in Fig. 1, this is quite largely due to the fact that the polishing stands are equipped with an exhaust system which is laid beneath the floor of the room, so that the ceiling and floor are not encumbered by unsightly pipes. It will be noticed, also, that there are no counter-shafts, the design of the machine used (see department of "New Machinery and Tools" for this month) permitting the spindles to be started and stopped without the use of clutches or tight and loose pulleys.

There are, in this room, ten double-end Fox polishing machines in position, with space for ten more. They are arranged in two rows of five each, all facing the same direction. The polishing department is a one-story building connected to the machine shop on one side and the rough store department on the other, so that the natural flow of the material to be treated passes through it. The plating department is also connected with it on one side. The building has windows on three sides and is also lighted by four large skylights directly over the machines, providing an abundance of light. The building has a cement floor in which the proper provisions have been made for installing additional machines as they are required.



The Polishing Room of the Fox Machine Co., which is equipped with an Exhaust System laid beneath the Floor.

As stated, the exhaust system is laid beneath the floor of the room. The dust is drawn into the column of the machine and thence into an opening in the cement floor, through ducts leading to the main header, indicated at the top of the diagram in Fig. 2. The ducts are made of galvanized steel and are entirely surrounded with concrete, so that even though the steel should rust out, the duct will still be complete. These run directly under each line of machines. The main header tapers from 18 inches in diameter at the end, to 30 inches diameter at the outlet. It is provided with a manhole at one

end, and at the other it leads into the upright exhaust pipe seen in the background of Fig. 1, connecting with a 40-inch exhaust fan.

The power for driving this lot of ten machines is taken from a 15 horse-power motor. The line of shafting runs over each row of machines and is belted direct to them without the use of counter-shafts. The amount of power consumed is small, especially when it is considered that most of these machines employ two men at a time. The use of roller bearings in the machines and in the line shafting will account largely for the small power consumption, which is sufficient for running all of the machines at their full capacity. This means not only a direct saving in the cost of the current, but also in the maintenance expense.

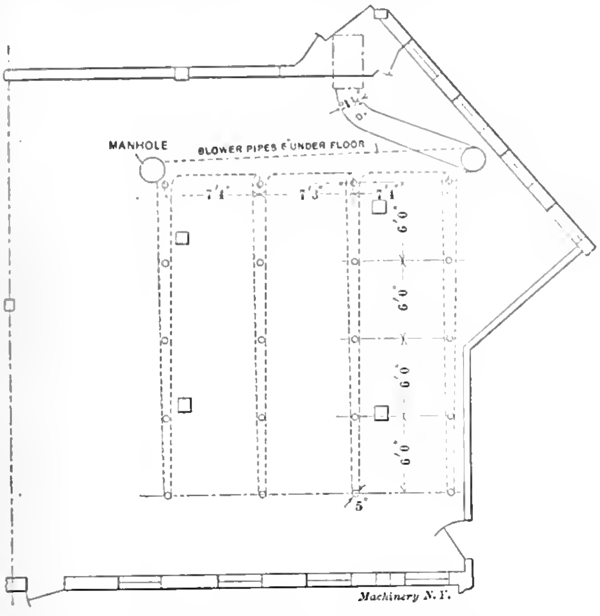


Fig. 2. Plan of the Fox Machine Co.'s Polishing Room.

Polishing rooms such as this present a marked and agreeable contrast with the unsightly and unhealthy conditions which existed almost universally in such work ten or fifteen years ago, and which have not by any means been yet entirely done away with.

* * *

An electric light plant in Rue Saint Roch, Paris, was built with its foundation and the facade of heavy masonry continuous with the walls of an adjacent house, the division walls being separate. The vibrations of the engines and dynamos so affected the adjacent property that the tenants were unable to sleep nights, and it became imperative to separate the foundation of the power plant from the tenement building so as to reduce the tremors. The company's engineer, Mr. Friese, conceived the idea of sawing the building foundations and facade apart. This was done with thin wire rope and wet sand. An elaborate frame-work was erected upon the sidewalk, having pulleys and counter-balancing weights and a traveling electric motor. A well was dug to receive the water and sand, and a horizontal hole was bored at the top of each pier of the foundation. A continuous steel rope was threaded through these holes and then carried back over the building to the motor and machinery on the sidewalk. The operation was successful, the foundation being cut at the rate of three or four inches per hour. After the cut had been carried clear down to the bottom, a second cut was made two inches from the first, thus leaving an isolated section which was easy to break down and clear away. A rope lasted about twenty hours. The facade was cut away in the same manner without interruption of the power plant or damage to the buildings.

* * *

Roller back rests are successfully used in turret lathe practice. They offer a minimum resistance to rotation of the work and polish it, giving the surface a smoothness and density not possible to secure with a cutting tool. These rollers have to be made very carefully, having to be hardened and accurately ground on the exterior and in the bore.

MACHINE SHOP PRACTICE.*

BORING AND PLANING CORLISS ENGINE CYLINDERS

M. B. STAUFFER†

The Corliss engine cylinder is a difficult piece to cast correctly, and have it free from defects in regard to soundness, etc., and the inexperienced man will often have difficulty in securing satisfactory results. The writer was connected with a firm which subjected all cylinders to a hydraulic test before any machine work was done on them. The cylinders were not made in this firm's foundry, and when the first ones were received from the independent foundry, they were machined in the usual manner, but on the testing block they showed leaks. The firm not being desirous of patching them and sending out defective castings, had to reject them. After this experience the hydraulic test was made. To close the cylinder for testing, strong wooden heads can be made to bolt or clamp over the openings, suitable packing being used on the joints to make them tight.

On the Shop Operation Sheet accompanying this issue, the method of boring a Corliss engine cylinder is given. The various steps in this operation are there described as applied to a regular Corliss engine cylinder boring machine, which is, of course, best adapted to the work. Such a machine, however, may not be available, and, therefore, it will not be out of order to give another method of doing this work.

If a vertical boring mill, having sufficient vertical tool travel, is at hand, the cylinder may be bored on this type of machine. The casting is set on the table of the mill and is trued by the periphery of the flanges on each end. The end resting on the table of the machine can be set by the concentric circles on the table. Both ends must run true, and the cylinder must be securely clamped, because the tools are to work at a considerable distance from the table, which gives a great leverage against the clamps. All the work that can be performed on this end of the cylinder may now be done, including the boring, counter-boring, and facing of the flange. The cylinder is then inverted, and it may be centered on the table with a special centering plate which fits into the finished counter-bore and which has a projection fitting into the hole in the spindle, which sets the plate concentric with the table. The counter-boring on the opposite end may now be done and the flange faced.

The port faces or seats for the bonnets may also be trued up on the mill, but if a double or four-head planer is available, it will be found more economical to plane these faces, and also the steam and exhaust flanges. In planing the port faces, the cylinder must be so set on the platen that its center will be level or parallel with it. If the casting is true to the pattern, it may rest on the rough port faces, though, of course, it will be necessary to test the other parts before it is machined, so as to make sure that there is sufficient stock to finish to all required dimensions. If the planer is provided with side heads, the flanges for the steam and exhaust pipes may be faced at the same time that the port faces are being planed.

The next operation to be performed is boring the valve ports. The finish lines for the holes may now be laid out with reference to the center line and crank end of the cylinder. In this case it will be necessary to lay out lines on each end of the ports. The holes which are to be drilled for the bonnets and the back caps should also be laid out. These holes should be drilled and tapped; then the ports are ready to be bored. A boring outfit which is commonly used, consists of a suitable bar for carrying and guiding the cutter; a lead-screw for feeding the bar, which extends to the end of the bar and usually has a star feed arrangement to actuate it; and two bonnets, with adjustable brass bushings, to act as bearings for the bar. These bonnets are fastened on the ends of the ports by studs inserted in the holes which were previously drilled and tapped. The stud holes in the bonnets are extra large to allow for the necessary adjustment. After the bar has been accurately centered with the lines previously laid out, the bonnets are securely fastened in place, and the

---

* With Shop Operation Sheet Supplement.

† Address: Scottdale, Pa.

first cut started. The tool should have a square cutting face as the bar must necessarily be light and if the cutting edges of the tool are beveled to any appreciable extent, the bar will be deflected by the pressure of the cut. It is, however, essential that the corners of the cutting tool be slightly rounded, or they will soon be worn away. When the hole has been rough-bored, it should be carefully examined to see that the edges of the steam ports are perfectly sound and trued up properly. This can be done by having a light held at one end of the hole while inspecting the work from the opposite end. If the construction of the boring bar is such as to permit its removal without disturbing the setting, this should be done and the edges of the port slightly beveled with a file inserted in an extra long handle. This is desirable because it prevents the finishing cutters from coming in contact with any scale. The port may now be finish-bored, and if the bar is well constructed and the work carefully done the ports will not require subsequent fitting or scraping. After all the ports are finished, the cylinder may be drilled for the frame, head, and wrist plate stud if the cylinder is of the wrist-plate type. The drilling and tapping for the indicator pipes should also be done, after which the cylinder may be sent to the erecting floor for fitting and testing.

* * *

HOW A BIG BOILER STACK WAS ERECTED.

The improvements to the plant of the Crecker-Wheeler Company, of Ampere, New Jersey, manufacturers of electrical machinery, have reached the stage where work is being started on the new power house, which, when completed, will have a capacity of 4,800 boiler horse-power. This entire capacity will not be installed at once, and to furnish draft for the boilers temporarily, until the complete plant is installed, the company has just erected a steel stack, 72 inches in diameter and 105 feet high, having a total height of 125 feet when on the foundation.

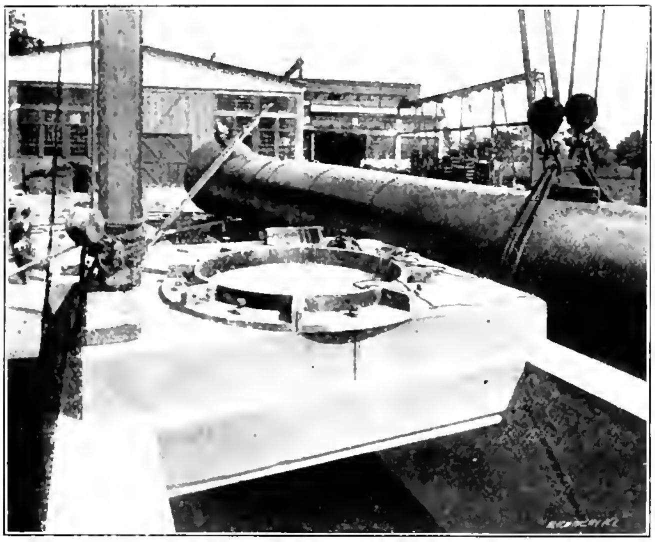

Fig. 1. Steel Stack 72 Inches in Diameter and 105 Feet Long, which was hoisted into Position in One Piece.

The engraving, Fig. 1, shows the stack lying alongside the concrete foundation; Fig. 2 illustrates the method of lifting, while Fig. 3 shows it in place. As will be seen, two large gin-poles were first erected, one on either side of the foundation, and supportd by steel stays leading from their tops to various anchorages. To the top of each pole powerful tackle was attached which was connected to a hoisting engine. The stack was first lifted in a horizontal position onto its foundation, after which the gin pole on the side of the foundation formerly occupied by the stack, was moved in as close as possible, so as to obtain a more nearly vertical pull on the poles. The tackle was then attached to the stack at a point slightly above the center of gravity and it was slowly lifted high enough to permit the bottom to clear the foundation. To facilitate the hoisting and at the same time prevent the bottom of the stack from being injured, it was supported upon a platform mounted on rollers as shown in Fig. 2.

This stack will supply natural draft to 800 H.P. water tube boilers (burning No. 2 buckwheat coal) with an ultimate capacity under artificial draft of 1,600 H.P. The boilers are of the modern high-pressure water tube type for generating steam at 200 pounds pressure. The furnaces of the boilers are each 9 feet 8 inches wide by 10 feet deep. The breeching connection between the stack and the boilers is 6 feet wide and increases in height as it reaches the stack to provide for future installation of boilers. The breeching is built of the arched top and bottom plate construction to make it self supporting. The weight of the stack and breeching is approximately 18 to 20 tons, and the stack was hoisted into position in one piece, which attests to the progress of engineering construction, as this would have been impossible a few years ago. The present stack is to be used temporarily until further development of the plant, at which time it is contemplated to erect permanent brick chimneys. For that reason it is located at present in position to provide for future development until the last boiler installation is made, and is erected on one of the future boiler setting foundations. The connection to the foundation is provided by means of a cast iron sectional annular ring which is bolted to the foundation and also to the stack. The stack was designed and erected by the engineering construction office of Mr. Walter Kidde, New York City, and was built by the Dover Boiler Works, Dover, N. J.

LETTERS UPON PRACTICAL SUBJECTS.

Articles contributed to MACHINERY with the expectation of payment must be submitted exclusively.

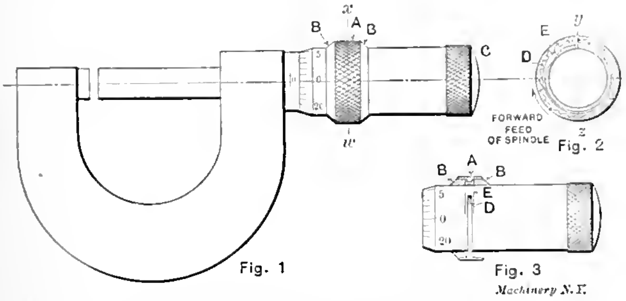
MICROMETER RATCHET STOP.

The accompanying illustration shows an improved form of ratchet stop or sensitive feed which I am using on my micrometer. It is more conveniently located than the ordinary form at the end of the spindle, so that it can be operated by the fingers of the hand that holds the micrometer, leaving the other free to hold the work being measured. This cannot be done with the ordinary stop, and, consequently, as careful inquiry has shown, a very small percentage of micrometer users ever make any use of this feature, an extremely desirable one, particularly in these days when the micrometer is no longer confined to the tool-maker, but is being introduced so largely into the machine shop and into the hands of less skilled workers. With many of these, unless the ratchet stop is used, the micrometer is very likely to be unduly strained, and the measurement taken will be incorrect; this will not occur with the form here shown, since as the micrometer is usually held in the right hand, the thumb and finger will naturally grasp the knurled operating ring *A*, Fig. 1.

Fig. 2 shows a section of the sleeve or thimble *C*, and ring *A*, on line *x-w*, with the spring or spring pawl *D* between them; and Fig. 3 is a section, on line *y-z*, of ring *A* and the retaining collars *B*, which latter are made a light force fit on the thimble. As will be seen in Fig. 2, one end of spring *D* is bent inward and held in a hole drilled in the thimble. The other end of the spring, which, as will be noted, nearly encircles the thimble, is bent outward and engages the teeth cut on the internal rib of operating ring *A*. In use, when the spindle is fed down on the work, continued turning of *A* causes the teeth to depress the free end of *D* into the recess *E* cut in the thimble, thus allowing the latter to remain stationary; reversal of the motion of *A* obviously causes positive engagement between ring and thimble, through spring pawl *D*, and consequent withdrawal of the spindle. An additional feature of value is that this form can be applied equally as well to the other forms of the micrometer, depth gages, etc., for which no ratchet stop has hitherto been available. Its satisfactory working in daily use for several years is sufficient proof that it is a good thing. I may add that the improvement is patented.

C. W. PITMAN.

Philadelphia, Pa.



Figs. 1, 2 and 3. Improved Form of Ratchet Stop which can be Operated by the Fingers of the Hand holding the Micrometer.

PROGRESSIVE PUNCH AND DIE.

In the engraving (Fig. 2) is shown a punch and die for making a complete piece such as shown unblanked at *A* in Fig. 1, at every stroke of the press. The strip is put into the die up to the first former, and at the first trip of the press two holes *B*, are pierced. These holes are then placed over the countersink punches *C* in the former and, at the second tripping of the press the plate is formed and the center hole pierced by punch *D*, and a second pair of holes pierced. The strip is again shifted, bringing the second pair of holes over the countersink punches and the formed part in the strip over the blanking die *E*. At the next stroke the formed part is blanked out, and at the same time a new part is formed and other holes pierced; this is continued until the strip is run through.

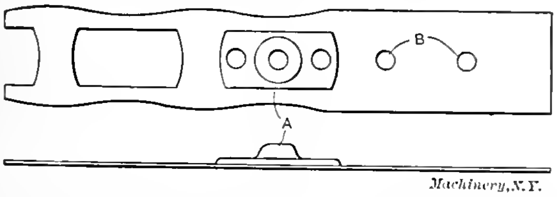


Fig. 1. Appearance of the Stock from which Plates A are Blanked

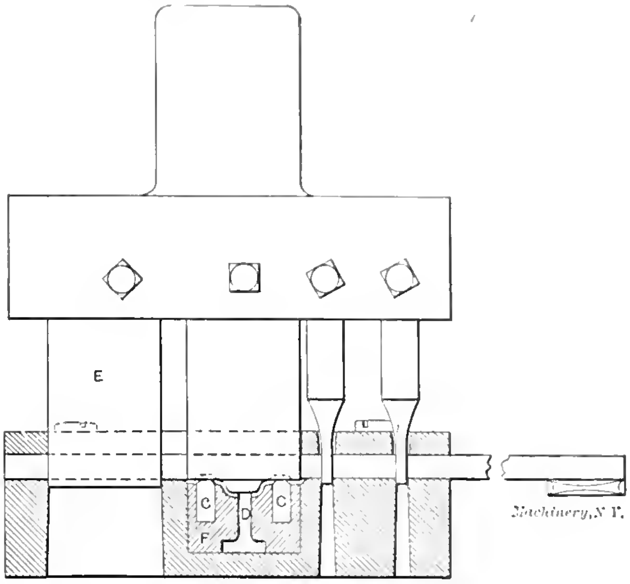

Fig. 2. Progressive Punch and Die for Forming Plates shown at A in Fig 1.

In laying out these dies, care must be taken to have the distances between the center lines to correspond, as otherwise the work will not come through the die perfect. There will also be the danger of breaking the countersinking forming punches, owing to the strain due to the irregularities in laying out. The die is so constructed that the former *F* can be removed when grinding. After the die is ground, the difference between its height and the original height is ground off the bottom of the former.

GEORGE CULLEY.

Springfield, O.

SIMPLE BUT EFFICIENT MILLING FIXTURE.

The accompanying illustrations show a piece of work, and the method employed for finishing the bosses on same by milling. In Fig. 1, which shows the work, the surfaces finished are indicated by the letter *f*. The fork end of the work is finished by the cutters *A*, *B*, and *C*, Fig. 2, while the other end is finished by the cutters *D*, *E*, *F*, and *A*, in the same figure. In Fig. 2 is also shown a plan view of the device which supports the work when being milled, Fig. 3 being a side view of the device. It will be seen that the fixture for holding the work is very simple, consisting simply of three V-block supports, one at *G* supporting the casting near the fork end, and two at *H* supporting the hub at the other end. There are two vertical standards *K* which are mortised for a key which clamps the work down on the V-blocks. The par-

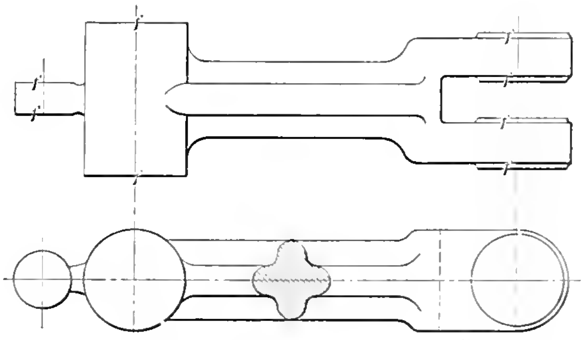

Fig. 1. The Work to be Milled.

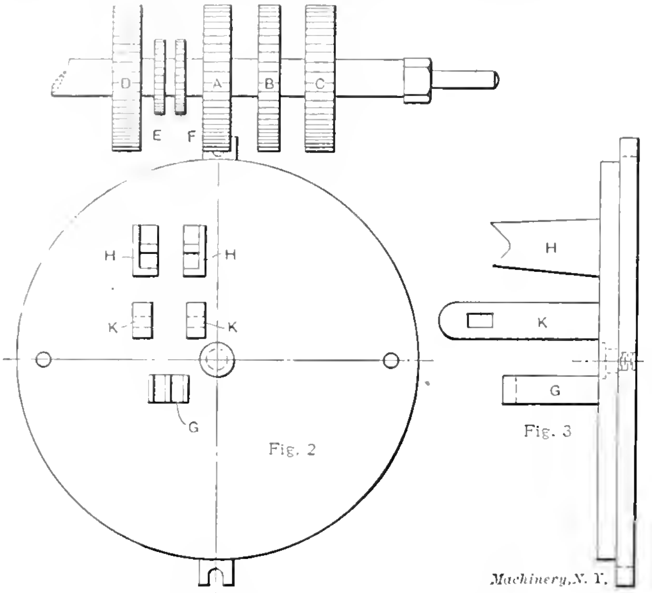
ticular feature of this device is that the V-blocks are located at such a distance from the center that, when the hub is milled and finished, and the upper plate of the jig revolved one-half of a revolution, the center cutter *A*, which has been previously employed for finishing one side of the hub, will be in correct position to mill one side of the fork end, the spacing collars between the cutters, of course, being made to take care of the required distance. The stop pin is used for keeping the upper revolving plate in the correct position in regard to the lower bed-plate.

A milling fixture of this description can be used advantageously on a great number of pieces which are ordinarily jigged two or three times. One great advantage inherent in this class of fixture is that the work is finished at one setting, thus insuring that all the machined surfaces are in proper alignment. Another advantage is that the work is handled only once at the milling machine, while if milled in the usual way, the hub end would be milled with a straddle mill, and then the casting taken to the drill press, and after the drilling operation returned to the milling machine for finishing the fork end, the work being probably held on another milling jig, and located by a pin or stud through the hole in the hub. Y. ZIEGLER.



Figs. 2 and 3. Fixture for Milling Work shown in Fig. 1, at One Setting.

SELECTING A CYLINDER OIL.

In selecting an oil for cylinder lubrication, oil which is entirely free from any vegetable or animal fat should always be chosen; that is, only a pure mineral oil should be used for this purpose. Vegetable oils oxidize at comparatively low temperatures, becoming thick and gummy, and have no lubricating properties whatever. Animal oils also act in a similar manner when subjected to heat. Animal and vegetable oils are often mixed with mineral oil in order to form a cylinder oil having a high viscosity and fire test. Suspected compounds of this kind may be tested by adding a little soda ash or caustic soda, and shaking it up in a bottle. If it clouds up and looks soapy, it indicates the presence of animal oil. Such a compound should never be accepted at any price.

Paraffine is frequently added to cylinder oil, but this is also highly objectionable. Its presence may be detected by placing a bottle of the oil on ice for fifteen or twenty minutes. If it becomes cloudy, it shows the presence of paraffine, and should be discarded at once.

Engine oils having an opalescent green tinge when held up to the sunlight, instead of appearing clear red or yellow, contain either kerosene or some lighter hydro-carbon, which is not a lubricant, and which volatilizes as soon as it becomes heated. Oils showing this characteristic should be avoided. Ordinary lubricating oil for high-speed engines should have a viscosity ranging from 170 to 195 at an average temperature of 75 degrees. Its specific gravity should be between 29 and 31, and the flash test between 400 and 440 degrees.

When the steam pressure carried is less than 100 pounds per square inch, cylinder oil should have a fire test between 590 and 630 degrees. For pressures ranging from 100 to 200 pounds per square inch, the fire test may range from 600 to 660 degrees. The specific gravity of a cylinder oil having a fire test of 600 degrees should be from 26 to 27, and for 660 degrees, from 24 to 25. Sometimes when there is considerable moisture in the cylinders, it is desirable to use a small amount of animal oil in the lubricant. In this case refined and acidless tallow oil should always be used. Common lump tallow should never be employed for this purpose, as it contains an acid which corrodes the cylinder walls and also leaves charred particles in the steam. The amount of tallow oil to be mixed with mineral oil may be taken as follows: For steam pressures below 100 pounds per square inch, 8 to 10 per cent of tallow oil; and for pressures from 100 to 200 pounds, from 3 to 6 per cent. Cheap grades of cylinder oil are often adulterated with wool fat, which is used to cut the gummy ingredient and give the oil a good flow in a cold test. Wool fat causes the oil to separate and form a thick deposit at the bottom of the barrels. Oil containing this adulteration leaves charred particles in the steam the same as lump tallow. CHARLES L. HUBBARD.

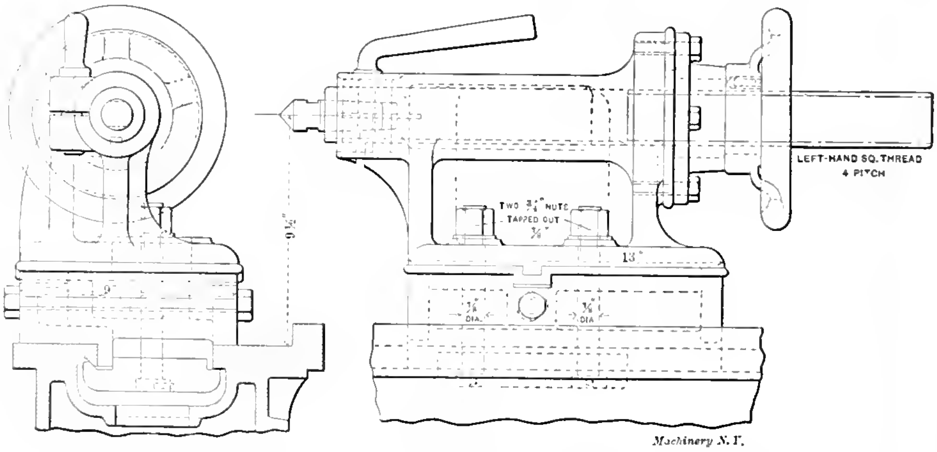
Auburndale, Mass.

A TAIL-STOCK DESIGN.

The engraving illustrates a new type (or rather an old type revived) of tail-stock, which has become popular in Europe, and in my opinion its superiority over the ordinary style is great enough to warrant its universal adoption. The bad feature of the ordinary tail-stock is that when the spindle is moved out, the bearing in the barrel becomes shorter, whereas to be right it should be longer.

This improved style, though it does not give more bearing the farther the spindle projects out, does the next best thing; it gives a uniform bearing whether the spindle projects more or less. The spindle is, of course, perfectly parallel, and is provided with either a square or Acme thread at the rear end. It will be seen that the screw (as a separate part) is dispensed with, and it isn't necessary to bore out the spindle to receive the screw, so that besides being more correct in principle, this design is cheaper to construct than the ordinary one.

Incidentally, the drawing shows one of the methods adopted in England, of always clamping the tail-stock in the same vertical plane. Of course, in America, with the inverted vee bed, this takes care of itself, but when a flat top bed is used, some means must be provided to ensure a proper location of the tail-center, otherwise taper work will result. I believe



Design of Tail-stock in which the Spindle Bearing is not affected by the Position of the Spindle.

that a method similar to this is used by William Sellers & Co. to overcome this difficulty.

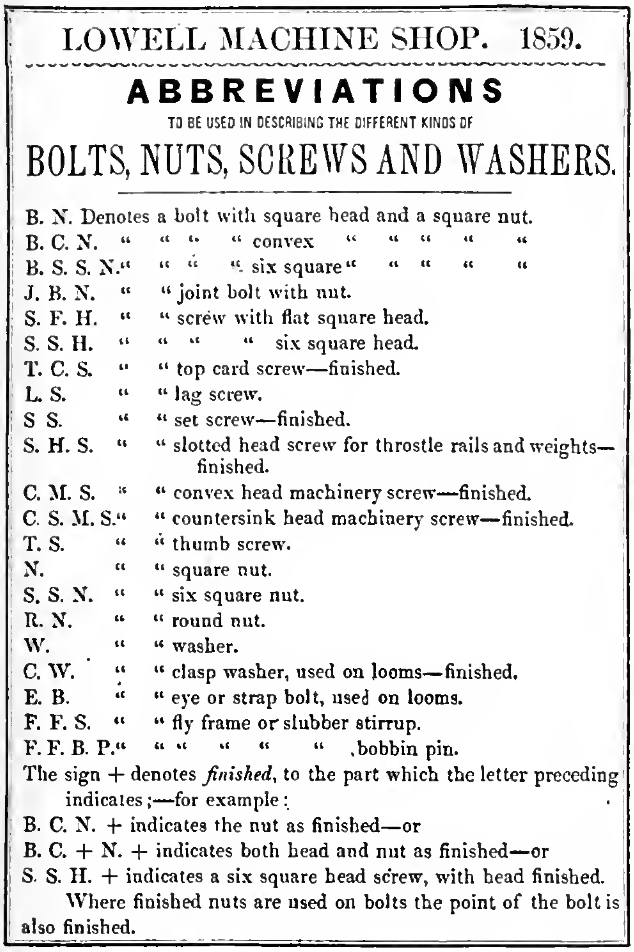
Another point, which, though insignificant in itself, is worth drawing attention to, is that the tail-stock clamping bolts are each ⅞ inch in diameter, with only ¾-inch nuts; this was done so that the wrench which tightens the tool strap bolts could also be used for the tail-stock bolts. As mentioned before, this is only a detail, but it is one that should receive more attention from machine tool designers, so that a machine will not have a set of wrenches which takes up as much room as itself. RACQUET.

[Our common form of engine lathe tail-stock is a good example of the sacrifice of utility in machine design to mere prettiness. The above design, which aside from minor details is essentially the same as that generally used by early lathe builders here and abroad, is much superior to the modern type, in rigidity and wearing qualities, no doubt. Its drawback is ugliness, and that seems to have been sufficient to discredit it in America notwithstanding its manifest superiority.—EDITOR.]

ABBREVIATIONS FOR BOLTS, NUTS, ETC.

The accompanying engraving shows an old list of abbreviations which is still used in ordering bolts from the bolt shop of the Lowell Machine Shop, builders of textile machinery. It is rather ancient history, but could hardly be improved on for brevity and clearness. Something of this sort is necessary on account of the large number of bolts used by the company, amounting to some 30,000 per week during the busy season of last year. PAUL W. ABBOTT.

Lowell, Mass.



LOWELL MACHINE SHOP. 1859.

ABBREVIATIONS

TO BE USED IN DESCRIBING THE DIFFERENT KINDS OF

BOLTS, NUTS, SCREWS AND WASHERS.

B. N.	Denotes a bolt with square head and a square nut.
B. C. N.	" " " convex " " " " "
B. S. S. N.	" " " six square " " " " "
J. B. N.	" " joint bolt with nut.
S. F. H.	" " screw with flat square head.
S. S. H.	" " " " six square head.
T. C. S.	" " top card screw—finished.
L. S.	" " lag screw.
S S.	" " set screw—finished.
S. H. S.	" " slotted head screw for throstle rails and weights—finished.
C. M. S.	" " convex head machinery screw—finished.
C. S. M. S.	" " countersink head machinery screw—finished.
T. S.	" " thumb screw.
N.	" " square nut.
S. S. N.	" " six square nut.
R. N.	" " round nut.
W.	" " washer.
C. W.	" " clasp washer, used on looms—finished.
E. B.	" " eye or strap bolt, used on looms.
F. F. S.	" " fly frame or slubber stirrup.
F. F. B. P.	" " " " " ,bobbin pin.

The sign + denotes *finished*, to the part which the letter preceding indicates;—for example:

B. C. N. + indicates the nut as finished—or

B. C. + N. + indicates both head and nut as finished—or

S. S. H. + indicates a six square head screw, with head finished.

Where finished nuts are used on bolts the point of the bolt is also finished.

List of Abbreviations for Different Kinds of Bolts, Nuts, Screws and Washers.

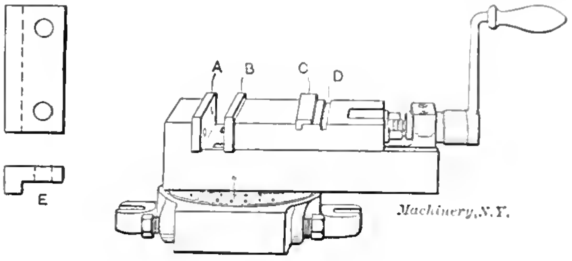
OBJECTION TO USING COPPER WIRE WHEN CASE-HARDENING.

Small soft steel or wrought iron parts should never be strung on a copper wire when case-hardening. The following incident will explain the reason why. A large number of small gears were to be case-hardened by the common process of enclosing them in an iron box filled with granulated bone, etc., and the person in charge thought it advisable to string the small gears on a wire, in order to prevent losing any of them. Not realizing that the fusing heat of copper is some 500 or more degrees less than that of steel, he picked up some copper wire and carefully strung all the small gears on this. The result was that when the box was put in the furnace, the copper wire melted and ran into the teeth and over the surface of the gears, so that it was necessary to put in two or three days of filing and scraping to remove the copper. Since the above incident happened, soft steel wire is always within handy distance of the hardening man when required for the purpose mentioned above. R. S. F.

AN ATTACHMENT FOR BROWN & SHARPE MILLING MACHINE VISES.

Referring to the illustration, *A* is the regular positive jaw of a milling machine vise, *B* the regular adjustable jaw, and *C* an attachment or false jaw to increase the capacity of the vise by using it instead of the jaw *B*, which is removed. In our shop we had occasion to hold work 3 inches wide, and the vise would only open 2¾ inches, so the above attachment, which we find very handy, was made, as it about doubles the capacity of the vise, especially on large flat work. An extra slot can be cut in the vise-back, as at *D*, and the false jaw can be used at either place. The jaw is shown in detail at *E*. It is held on by two filister head screws, and can be used on either the swivel vise, flanged vise, or on the tool-maker's universal vise. J. T. GEORGE.

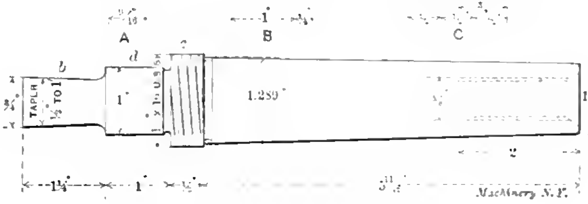
Attleboro, Mass.



Milling Machine Swivel Vise equipped with Attachment for Increasing its Capacity.

IMPROVED EXPANDING MILLING MACHINE ARBOR.

Having had considerable dove-tailing and end milling close to shoulders and walls of casting, and being caused much trouble with the old style split expanding arbors with the taper plugs and screws in the ends, I designed and made the arbor herewith illustrated. This arbor is made for a Cincinnati milling machine. The shank has a hole tapped in the end for drawing it into the milling machine spindle with a drawing-in rod. The threaded portion *c* is made to fit the hood or screw sleeve *C*. The straight cylindrical part *d* acts as a guide for *C*, and the tapered part *b* expands the



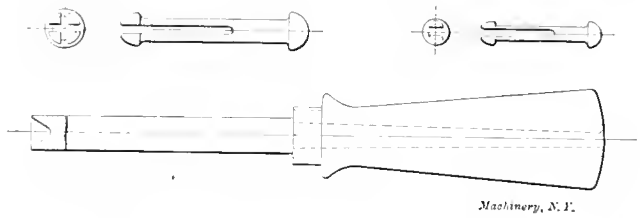
Details of the Expanding Arbor.

split sleeve *B*, which holds the milling cutter. This sleeve *B* is finished in one piece and a 1/16-inch radial slot is cut in from opposite sides to within about 1/16 inch of the bore. It is then hardened and ground all over on a tapered mandrel. The mandrel is then driven into the sleeve until it is parted, and the rough edges which are left are ground off on the side of the emery wheel. The taper of the split sleeve and the corresponding taper of the mandrel should be ground at one setting of the taper attachment, so they will coincide. The mandrel should be ground first, then sleeve *B*, until the large end of the tapered part *b* of the mandrel just enters the large part of the bore in the sleeve. It will be noticed that the hole in the collar or washer *A* is made a little larger in diameter than the part on the sleeve *B* over which it fits. This is done so that *A* will not interfere in the expanding of *B*. In assembling the arbor, the sleeve *C* is first screwed on, then the two halves of *B* are placed on the tapered part and the collar *A* passed over them to hold them in place. The diameter of the expanding sleeve *B* and the thickness of the collar or washer *A* should be made in proportion to the diameters of the holes and the thicknesses of the various cutters to be used. A spanner wrench is used on the sleeve *C* for drawing the arbor from the milling machine spindle and also for expanding *B* in the cutter to be used. It is evident that with this arbor a considerable pressure is obtained in the cutter, and a heavy cut can be taken. If the cutter slips, however, a slot may be cut across the end of the arbor, and a key long enough to project through the split bushing *B* and into a key-way in the cutter, inserted. This arbor has been in use for over a year on various jobs, such as dovetailing and general work, and it has paid for itself a number of times.

Lowell, Mass. FRANK G. STERLING.

SUBSTITUTE FOR COTTER PINS.

Referring to your article, "Substitute for Cotter Pins," published in the April issue, I beg to say that the pins there shown are not exactly like those which are used by Bofors-Gullspang Company, Sweden. These pins, which are shown in the illustration, are especially designed to connect certain parts in breech locks instead of using screws and nuts. They can easily be removed and there is one part instead of two or three as when a screw is used.



Substitute for the Ordinary Form of Cotter Pin, and Tool for Removing.

The smaller sizes can easily be removed with the fingers and also some of the larger ones. In order to more conveniently remove the larger pins, a special tool is made as shown in the engraving. JOHN INGBERG.

North Tarrytown, N. Y.

MAKING PISTON RINGS.

The making of piston rings is neither so small nor such an inexpensive item in the manufacture of gasoline engines, as it would seem to a casual observer. In the design of the ring itself, there are two main types: the concentric cast iron ring, and the eccentric cast iron ring. Of these two, the latter type is probably more used, at least by the more progressive gas engine builders. Again, in the splitting or cutting the ends of the rings there are two prevailing methods: one method being to cut the ends so that they are "jogged" like stair steps, the other being a plain diagonal cut. The last method is preferred by the majority of builders on account of the ease in making.

In the machining of the ring, before it reaches the splitting stage, we need but glance over the pages of almost any mechanical journal to find dozens of tools, jigs, and various contrivances for holding the casting, boring the inside, and turning the outside, to say nothing of the tools, single and in gangs, used to cut off the rings from the finished blank. In the boring tools, especially, has "genius" been busy trying to devise tools that will quickly and thoroughly remove the most valuable part of the ring. One firm that I know of, and I don't know how many more, bores out its rings and then peens the inside to make them stiff! Why so few firms have failed to notice and profit by the example of the largest gasoline engine factory in the United States, has long been a puzzle to me. This firm uses an eccentric ring and doesn't bore it out at all. In this way the ring is stiff just where it should be. The plain diagonal split is also used, it not only being the easiest to cut, but just as good as any other style. Why anyone should go on boring out rings when a moment's thought shows the advantages of not doing so, is beyond me. This way of making rings requires a little more care in the foundry, but this is nothing compared to the saving in the machine shop, not to mention the increased value of the ring itself. In making the castings, they are provided with the usual three lugs, and the inside is made the size that the rings would be bored to were they made that way. Extreme accuracy is not needed, for the piston grooves are always made deep enough to allow for slight variation.

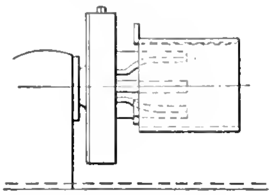


Fig 1. Long-jawed Universal Chuck used for Facing Ends of Ring Blank.

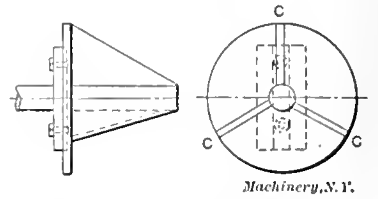

Fig. 2. Winged Center held in the Turret and used to set the Blank on the Face-plate.

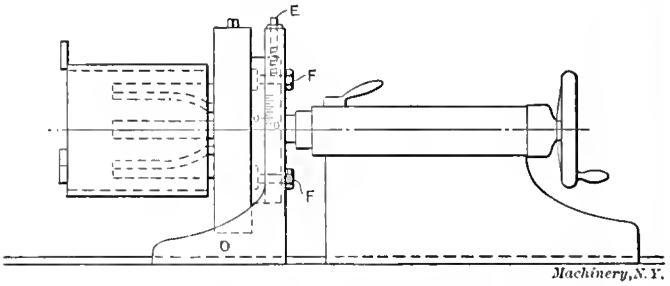

Fig. 3. Improved Device for Setting the Ring Blank.

In machining these rings, without boring, the first rig that I remember seeing was the one shown in Fig. 1. It was simply a three-jawed universal chuck, with extra long jaws fitted to it, as shown. The casting was placed on these, and the lugs faced off. The other end was slightly countersunk. This work being done, the casting was taken to a machine having a fixture in the turret such as shown in Fig. 2. This fixture was set the proper amount above the center to give the ring the required eccentricity. The casting was placed with the lugs toward the face-plate, and the turret, holding the fixture, run up so that the three rings came in contact with the slightly countersunk edge and held the casting against the face-plate. The turret was locked, and the lugs clamped to the face-plate. The turret was then run back, the casting turned and the rings cut off. This method, however, finally gave way to another, and the fixture shown in Fig. 3 was adopted. Less time was required, and all the work done on one machine. The body *D* of the fixture is of cast iron and is made to fit the ways of the lathe. A taper plug

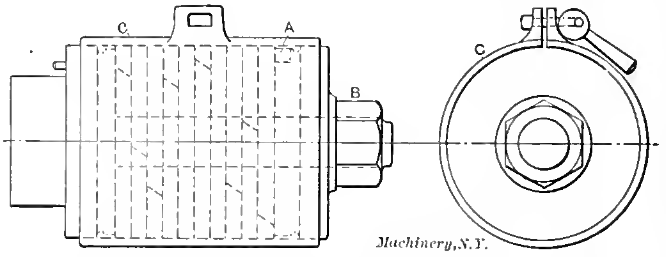

Fig 4. Fixture for Holding the Rings while finishing the Outside.

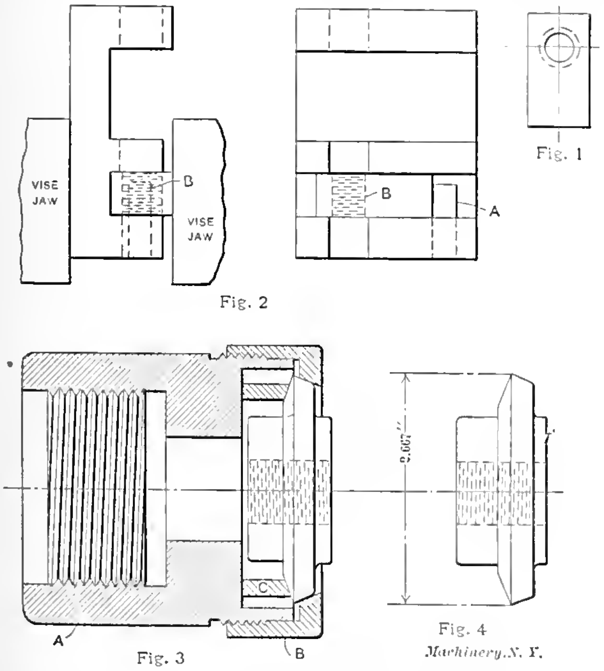
also connects it to the tail-stock spindle. The casting is held by a chuck similar to the one shown in Fig. 1. The amount of eccentricity given the rings is regulated by loosening the nuts *F* and turning the screw *E*, graduations which are provided, doing away with guess work. When the casting is placed on the jaws, as shown, the tail-stock and fixture is pushed forward until the lugs are a half inch or so from the face-plate. The tail-stock is then locked, and the fixture run up by using the hand-wheel. Paper is packed under the lugs where needed and they are strapped fast. The tail-stock and fixture is then run back out of the way, and the rings turned and cut off. After the rings have been ground on the sides and split in the milling machine, they are placed in the fixture shown in Fig. 4, and finished to the exact outside diameter. As will be readily seen, this fixture is of the ordinary type, the principal difference being the insertion of the hard steel block *A* used to set the tool to save calipering. After the nut *B* is tightened and the sleeve *C* removed, the point of the tool is run up against this block and the rings finished at one cut.

Another useless idea in connection with packing rings is that of putting a pin in the groove of the piston to keep the ring from turning. This is a relic of the old days, when cylinders had openings in them into which the ends of the rings were liable to spring and cause damage, and the pin was not originally intended to "stagger" the splits and thus prevent (?) the escape of gas, as many seem to think they were, or do.

Decatur, Ill. ETHAN VIALL.

DEVICES FOR HOLDING WORK WHILE TAPPING.

A simple and effective device for holding work while tapping often saves a great deal of time in the shop. In Fig. 1 is shown a piece of cold rolled steel ¼ x ⅜ inch, which is to be tapped as indicated. Fig. 2 shows the device which is used to act as a guide for the tap. The piece is inserted in the slot at *B*, and pressed up against the locating pin *A*, and then the piece with its guiding device is clamped between the jaws in a vise, as indicated to the left. This insures a straight tapped hole, and at the same time, if many pieces are to be made, the time saved is about fifty per cent. In Fig. 4 is shown a cast iron bevel gear which is to be faced and tapped as indicated. In Fig. 3 is shown the fixture used for holding this gear while facing and tapping. A holder *A* screws onto a spindle of a lathe, and the cap *B* holds the gear in position against the floating ring *C*. The cap locates the gear centrally and the floating ring takes the thrust and adjusts itself to the irregularities of the gear rim.



Devices for Holding Work while Tapping.

Alliance, O. E. D. GAGNIER.

NOVEL COMBINATION DIE.

In designing the combination die to produce the clip shown in Fig. 1, many things had to be taken into consideration. The clip had to be produced rapidly and cheaply, and therefore had to be done in a die that would produce a finished clip every stroke. The die had also to be arranged so that the brass strip could be fed in with the automatic feed. There were obviously two ways of feeding this clip: sideways, using 9/16-inch brass strip, and frontways, using 2 3/32-inch brass strip. The latter method was adopted because it would allow longer running of the press for each brass roll, as a 9/16-inch cross feed would only be required, against the 2 3/32-inch feed the other way; this method also made the die more compact, and brought the punches closer together. For cutting off, a shear punch was decided upon, thus totally avoiding any scrap except the four 3/32-inch punchings, which could not be avoided. As the stock was 22 B.W.G. it was not considered necessary to have a movable guide, but 5/16 inch was cut out at the side of the feed guide to allow the strip to bend down while the blank was sheared off. The shear *A* (Fig. 2) and the punches *B* were set at the same height so that punching and shearing would take place simultaneously. As the stroke of the press was not long enough to allow the forming punch *C* to push the clip right through the die, this punch was adjusted so as to force the clip in a forming slot 9/16 inch, which was enough to fold the sides up correctly. For stripping, a sliding, spring-return stripper *E* was used, which was forced downward by an adjustable set-screw *F*. The method of holding the punches, except the forming punch, is quite a departure from the usual method; they were simply made a slight taper, and fitted to the taper holes in the punch-holder block. Some might question the advisability of trusting to a taper to hold a punch during stripping, but in this case the resistance to stripping is comparatively slight and the punches are kept tight by the action of punching. To produce the catch *G* (Fig. 1) in the clip, the punch *H* was ground to the correct form, and a hole was cut clear through the die, thus allowing for grinding, and a small rubber actuated push-out was inserted which would lift the blank high enough to enable the catch, or step, to pass the edge of the die. This punch was made just long enough to cut the metal almost through, which gives a sharp, clear step as high as the metal is thick. At the bottom of the forming slot a rubber operated push-out was also placed. After the clip is formed, this works it upward about 1/16 inch, which is sufficient to loosen it owing to a slight taper in the forming slot. The clip holds to the forming punch and is drawn out and stripped. The most important practical points have now been described.

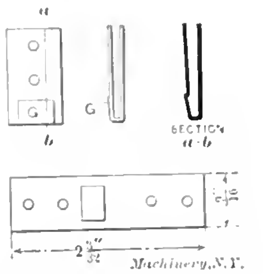


Fig 1. Clip formed by the Combination Die shown in Fig. 2.

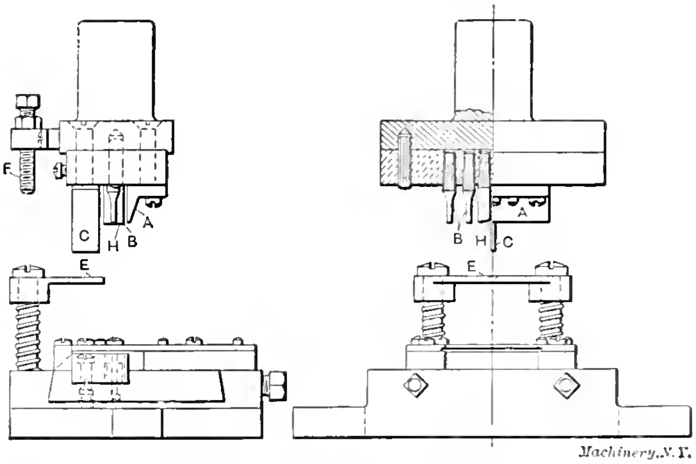

Fig. 2. Combination Die which produces a Clip such as is shown in Fig. 1, at each Stroke.

In operation, the brass strip is fed forward by the feed; then it is cut off by the shear *A*, and punched, simultaneously.

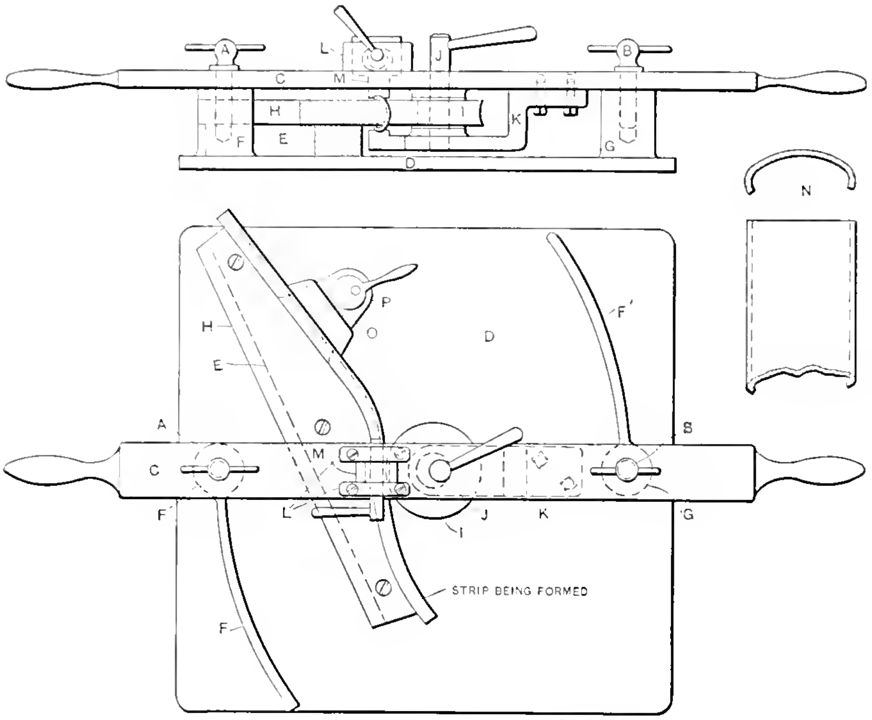
This loose piece is then pushed along over the forming slot, by the next feed of the brass strip, where it is folded by the forming punch C, after which it is withdrawn, stripped, and as the press is inclined, the clip falls clear of the die. The guides were made only slightly larger than the thickness of the brass strip thus avoiding any possibility of the pieces getting jammed, or riding.

GEO. P. PEARCE.

Exeter, N. H.

BENDING DEVICE.

The brass trimming used on an automobile dash is shown at N in the engraving. This strip is made of 18-gage brass, and is formed to the curve shown in the cross-section, under a punch press; it is then bent to conform to the curves on the dash. The strip shown in place in the bending device shows the shape of the bend. This is a difficult bending operation, as any change in the shape of the cross-section or marks or wrinkles of any kind will not pass inspection, so that the job requires more than the ordinary bar-and-roller former to turn the pieces out in large quantities and perfect.



Machinery,N.Y.

Device for Bending Brass Trimming similar to that illustrated at N.

Referring to the engraving, base plate *D*, bosses *F* and *G*, ribs *F'* and pad *E* are cast in one piece. A machine steel forming shoe *H* is fastened to the pad *E*. The clamping block *O* is mounted on the pad *E*, and is actuated by the eccentric clamping lever *P*. The cast iron bending lever *C* is drilled to receive the steel plugs *A* and *B*, these plugs acting as pivots about which the bending lever swings when forming the bend. An eccentric shaft is mounted in the pieces *L*, which gives a vertical movement to a pressure bar or foot *M*. A corresponding foot on the end of bracket *K* takes care of the bottom roll. A machine steel forming roller *I* revolves on an eccentric shaft *J*. By means of this eccentric shaft the pressure on the work can be regulated, and the roller can be backed away from the work when it is formed so that it can be removed. The thin ribs *F'* are machined on the top, and act as slides or rests for the bending lever *C*. The forming operation is done in the following manner: The first bend is made with plug *A* in place, plug *B* being removed. Bending bar *C* is moved to the starting position, pressure foot *M* is lifted and the forming roller *I* drawn back by means of the eccentric shaft. The strip is then inserted between the roller *I* and the forming shoe *H* and against a stop at the end. The stock is held in place by means of the clamping block *O*. The pressure foot *M* and forming wheel *I* are now brought against the stock and the first bend is made. The hole in the bar *C* now coincides with the one in the boss *G*, and the pin *B* is inserted and *A* withdrawn. Before starting the last half of the bending operation the forming wheel *I* is slightly released so as to relieve the sudden stretch in the metal, but during the bending the pressure is again applied. It will be seen that the stretching of the metal takes place on a line over the entire cross-section; however, owing to the temper of the brass a slight spring is bound to take place causing a difference in the pieces. After the bend is formed the foot *M* and the roll *I* are withdrawn by turning the eccentric shafts, and the strip is removed.

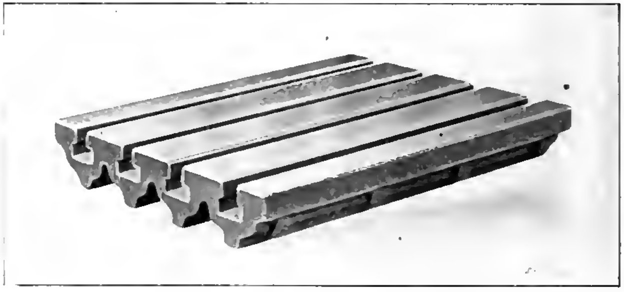
J. W. BROWN.

DRILLING PLATE, OR AUXILIARY DRILL PRESS PLATEN.

The accompanying illustration shows one of the handiest devices to be found in the machine shop, and one whose advantages are not appreciated to anything like the extent they should be. This device, which we call a "drilling plate," is a sort of supplementary table to use with the drill press. The upper face is provided with four T-slots to which the work is clamped by bolts and straps, or other convenient means. The bottom of the plate is formed by a planed ribbed surface, which rests on the regular table of the drill press. This ribbed base gives a much better bearing on the table than would be the case if the base had a full unbroken surface, as it permits the chips to be pushed to one side in the space between the ribs. The construction also makes a much lighter casting without sacrificing its rigidity.

The great advantage of this device is in connection with light work, in which two or more holes are to be drilled, reamed, faced or tapped, and which is of such shape as to require bolting down in order to keep it in proper position. Such work, if bolted on this plate, can be moved to bring it in correct alignment under the drill with the greatest ease, and in very much shorter time than is possible if the work is bolted to the drilling machine in the regular way. While the machine has all the adjustments required for centering the drill with the work, it is not always easy to make these adjustments; especially if the desired point comes near the center of the pivot of the table.

The device also permits the work to be shifted from one position to another with much greater exactness, thereby insuring more accurate drilling with less wear on the edges of the drill and the sides of the jig bushings. In such drilling as has been described, which easily comprises the majority of that found in the average shop, this plate will save from 15 to 50 per cent of the time consumed for the job, to say nothing of the saving on breakage and wear and tear of the drills and drill jigs. We have found that the workmen in our shop would do without any of the other conveniences of manipulation found in the modern drilling machine rather than forego the use of this device.



Auxiliary Drill Press Platen which Facilitates shifting Work in which several Holes are to be Drilled.

Notwithstanding its easy moving qualities, this plate has weight enough to prevent it from being whirled around, and also enough to keep the work from lifting and allowing the

drill to gouge in, with the attendant danger of breaking the tool. We make them in three sizes, 12 x 15, 14 x 18, and 16 x 20.

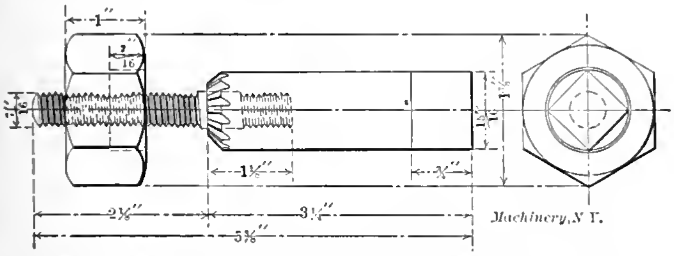
W. H. Shafer,

Cincinnati, Ohio. Supt. Cincinnati Machine Tool Co.

[Another use to which the supplementary drill press table may be put is that of increasing the product of a drilling department without increasing the number of machines. Two of these plates may be provided for each drill press, so that a workman may be setting up work on one plate, while the other is in position on the machine and the work is being operated on. A skillful man may be required for the setting up, as would be the case under any circumstances, while the actual using of the drill press may be entrusted to a workman of somewhat less ability, thus making a saving in wages as well as a saving in the capital invested in the machinery.—Editor.]

DEVICE FOR REAMING HOLES IN ECCENTRIC STRAPS.

In a great many railroad shops it is the practice, when resetting valves, to lengthen or shorten the blades of the eccentric by means of changing the holes in the straps. Under most locomotives there is very little room to work, and when it becomes necessary to change the holes in an eccentric strap arm a slight amount in order to lengthen or shorten the rod's position, the old way of chipping is often very tiresome, inaccurate, and the limited space between the eccentrics makes the whole work unsatisfactory. The little reamer shown in the engraving, was designed to be used in connection with this operation. After setting the valves and tightening the middle bolts, remove the others and put the reamer in place. Screw on the feed-nut and turn the reamer with a monkey-wrench. If the reamer feeds too fast, slack up on the feed-nut at the same time that the reamer is being turned. In this way the holes can be easily reamed.



Small Reamer which is handy for Reaming Holes in Eccentric Straps when setting Locomotive Valves.

Two Harbors, Minn. Austin G. Johnson.

CARELESS CIRCULAR DISTRIBUTION.

I have received circulars of woodworking machinery without any maker's name thereon. Probably the makers sent out a thousand or more in the same condition.

In this connection I would suggest that certain of the manufacturers revise their mailing lists. I get circulars sent to my 1894 Dresden address. Since then I have spent a year in Paris and six in Hanover. Robert Grimshaw.

Dresden, Germany.

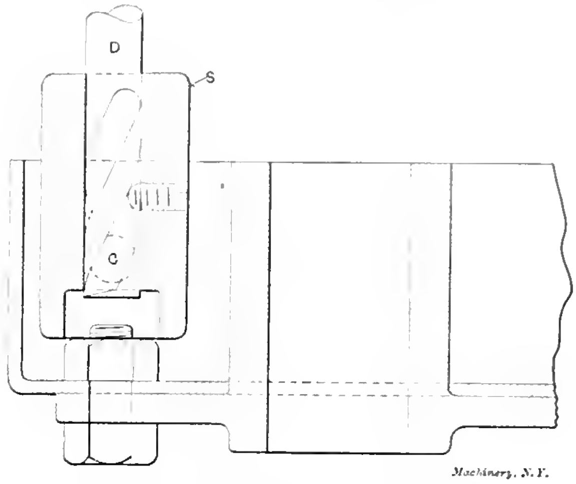
TOOLS WITH HIGH-SPEED STEEL CUTTING EDGES WELDED TO MACHINE STEEL SHANKS.

The welding of high-speed steel to tool shanks of cheaper steel has recently been spoken of as a novelty. That methods for accomplishing this are by no means new must be common knowledge to many practical men. At least one case may be mentioned dating as far back as 1904. The writer was being shown the locomotive works of Borsig at Tegel, near Berlin, and on questioning his guide as to the consumption of high-speed steel the latter replied: "A great deal, but comparatively little," and lifted the first planer tool in sight, saying, "We weld on that tip of high-speed steel; the weld, you observe, is quite invisible," and a rapid sketch in a note book showed the relative size of the welded tip. My informant added: "That is a trade secret. I am sorry I am not permitted to tell you more." From other remarks it appeared that the practice was very successful; but it does not seem probable that Borsig's was the only firm in the world welding high-speed steel tips to their tools in 1904, and it seems very unlikely that one would be justified in saying that, in the past, attempts to weld high-speed steel have been unsuccessful.

Staple Hill Park, Bristol, England. Charles R. King

CUTTING SCREW ENDS FLUSH WITH NUTS.

The accompanying engraving shows a section of a wheel hub and brake flange held together by eight ⅜-inch bolts, one of which is shown in the illustration. The location of the nuts is in the bottom of the recess formed between the brake band seat and the hub boss, and the end of each bolt stands out originally 3/16 inch outside of the nut. It was required that the bolt ends of these nuts be made flush with the nuts, and as there were a great many of these hubs made, the following process was employed in facing off the ends of the screws. Referring to the illustration, *D* is an ordinary twist drill, the cutting edges of which are ground at right angles to the center line of the body, regular clearance, of course, being given to the cutting edges. In drills of ½-inch diameter, or less, the thickness of the web at the bottom of the grooves is not sufficient to produce any appreciable difference in the pressure necessary for feeding the drills, but on larger drills it became necessary to make the web thinner by grinding the grooves deeper for a short distance back from the cutting edge. In fact, a great many tool-makers thin the web on twist drills regularly for ordinary drilling, because it lessens the pressure necessary to feed the drills into the work, and the drill is less liable to spring and drill a hole that is "out of true." In the illustration, *S* is a case-hardened steel sleeve which fits the body of the drill, and is held in place on it by a set-screw entering into the flute. The lower end of the sleeve is counterbored to a depth equal to the thickness of the nut, plus 1/16 inch, and with a diameter sufficient to permit it to pass over the corners of the nut. The cutting edges of the drill project into the counterbored space about 1/16 inch, leaving a distance equal to the thickness of the nut between the cutting edges of the drill and the lower end of the sleeve, which latter simply acts as a stop when facing off the ends of the screws. At *C* is shown a hole drilled through the sleeve to allow the chips to escape. By putting this simple tool into a drilling machine, the bolts are faced off flush with the nuts in a very short time. J. T. Grimshaw.



Method of Facing the Ends of Bolts with a Drill.

Detroit, Mich.

TAPER GIB DESIGN IN "JIGS AND FIXTURES."

In the August issue of Machinery in the fifth installment of "Jigs and Fixtures," by Mr. Einar Morin, two taper wedges or gibs are shown in Figs. 54 and 55. As shown in the illustrations, the wedge cannot be adjusted because it will bind, the screw being inaccurately shown. The usual and correct way of making a taper gib adjustment is to drill and tap for the screw at the same angle as the wedge, that is, parallel to the movement of the wedge. A makeshift method is to drill as shown in the sketch, and to enlarge the hole in the ear of the wedge so that side movement is provided for. Elmer G. Eberhardt,

Newark, N. J. Newark Gear Cutting Machine Co.

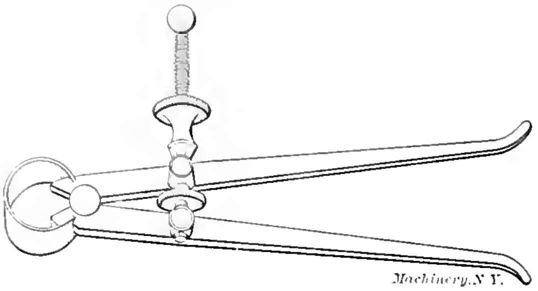
SHOP KINKS.

A DEPARTMENT OF PRACTICAL IDEAS FOR THE SHOP.

Contributions of kinks, devices and methods of doing work are solicited for this column. Write on one side of the paper only and send sketches when necessary.

LOCK-NUT FOR CALIPERS.

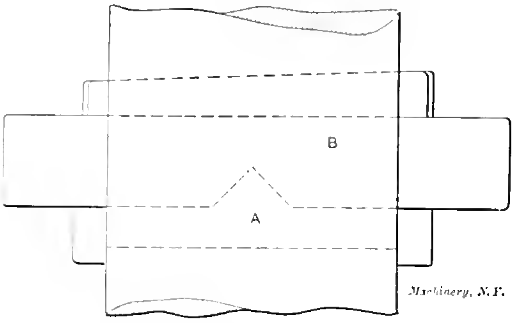
A simple and secure method of converting spring calipers into transfer calipers is shown in the illustration. An extra nut is placed between the caliper legs thus affording means of locking them. This nut can be taken from another pair having the same size fulcrum stud, but a special thin one permits the use of the calipers for smaller sizes. The two nuts can be locked and the calipers kept to the same diameter for any length of time, even though carried in the pocket or grip—something very desirable when fitting parts for a job that is far from the shop. Donald A. Hampson.



Middletown, N. Y.

CENTERING SELF-HARDENING CUTTERS.

Self-hardening cutters were to be used in the boring-bar of a large boring mill, and as I am foreman of the tool-room it was "up to me" to devise some way of getting the cutters central in the bar, as there was no way to machine them. This was accomplished as shown in the engraving. The bar was milled flat on each side of the slot, and the centering piece *A* carefully fitted to it. The V-shaped tongue on the centering piece, and the corresponding V-slot in the cutter *B* causes the cutter to be set central when it is keyed in place. This job is very satisfactory and preferable to annealing the self-hardening cutters as they are not as durable after having been annealed and hardened again. J. R. Weaver.



Plainfield, N. J.

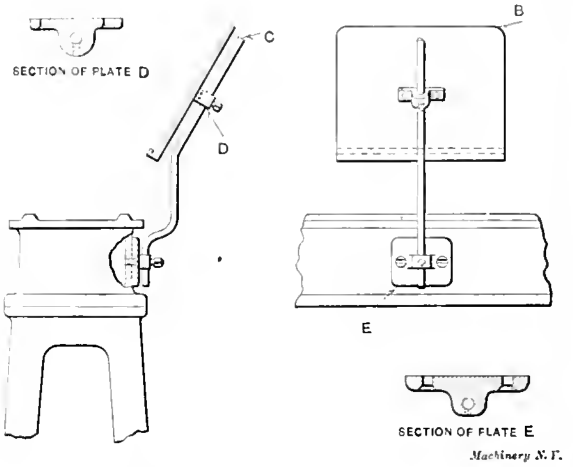
HANDY CENTER INDICATING TOOL.

A center indicating tool for locating the prick-punched centers of work true with the machine spindle on a boring mill or a milling machine, may be made as shown in the accompanying line engraving. The shank of the tool may be tapered or straight to be held in a chuck. The ball shown at the front end of the hole in the shank is ¾ inch in diameter, is hardened, and has a hole drilled through the center in which the pointer is inserted. When using the tool, the shank is inserted in the spindle of the machine, and the end of the pointer is placed in the center hole of the work to be centered. After having been thus located, the pointer is moved back out of the prick-punch hole in the work and the machine started up. If the end of the pointer wiggles or moves about in a circle, it indicates that the center of the work is not in line with the axis of the spindle. The cap *A* in the front of the hole is driven into the hole in the shank, and holds the ball in place. On the other side a bushing *B* is pressed up against the ball by the spring *D*, so that whenever the pointer is set out of line with the spindle, it will be held in this position by the friction between the bushing, ball and cap, caused by the pressure of the spring. There is a small hole through the entire shank to permit the pointer to be driven out of the ball, if required, for repointing.

Poughkeepsie, N. Y. W. W. Cowles.

LATHE BRACKET FOR BLUE-PRINTS.

The bracket shown in the illustration is very simple and will keep blue-prints or working drawings constantly before the mechanic. It is made of two cast iron plates *D* and *E*, rod-arm *C*, bent at any desired angle, and sheet iron holder *B*. The size of screws should be determined by the size of bracket made. As the reader will notice, there are no breakable parts, and very few loose ones. I would suggest that the surface on the arm *C*, which comes in contact with the set-screws, be filed or milled flat; this will keep the bracket from turning. By using a bracket of this description, the percentage of mistakes made will be greatly reduced and more accurate work done. L. H. Georger.



Buffalo, N. Y.

A BLUE-PRINTING KINK.

In the winter months it is hard to judge the time required to make sunlight blue-prints, and so I hit upon the idea of making a scale of colors with which to compare a test piece of paper. Take a piece of blue-print paper four inches wide and ten inches long. Cover all but one inch with a heavy piece of paper. Expose this one inch for say one minute in a mild light, then move the cover so as to expose one inch more for one minute, which exposes the first inch two minutes, and so on, inch by inch, until all ten inches have been exposed, and the first division has been exposed ten minutes. I used a light that I had previously found would print just right in a ten-minute exposure. Any other time interval could be used. Now wash the paper thoroughly, and when dry you have a scale with which to compare other prints. Figure out the relative times that would have been required to bring each color to a perfect blue-print, by dividing the whole time by the time exposed, and mark this number on the color, this number to be used as a multiplying factor. Now, in order to get a perfect print, put the tracing you wish to copy out with a small piece of blue-print paper, and leave it, say two minutes, until it would be printed some, but not enough. Then wash dry with blotters and compare with the scale sheet. Say it was like the fourth color from the bottom. The factor would be 2½. Multiplying this by the two minutes equals five minutes, the time required to make a perfect print in that light. I am pleased with the uniform results obtained. Austin G. Johnson.

Two Harbors, Minn.

NEW MACHINERY AND TOOLS.

A MONTHLY RECORD OF APPLIANCES FOR THE MACHINE SHOP.

FLATHER 30-INCH VERTICAL TURRET MACHINE.

The E. J. Flather Mfg. Co., Nashua, N. H., has recently completed and placed on the market the vertical turret machine shown herewith. As may be seen, it is of simple and attractive design, embodying a number of new features. One of the most noticeable of these features is the use of a cross-rail adjustable for height. In most machines of this size (30-inch swing) the cross-rail is solid with or bolted to the column, at a height that will clear the highest work on which it is expected to use a tool. Under these circumstances, for work close to the face of the chuck, the turret slide has to be extended to nearly the full limit of its travel, making it very difficult to take cuts up to the full capacity of the machine. Other special features of this mill that might be mentioned are a new design of work spindle and bearing, a quick-change gear feed mechanism, the making of the base and column in one casting, the provision for an unusually long cross-slide movement, and the use of a thread and nut feed for the turret slide in place of the usual rack and pinion movement.

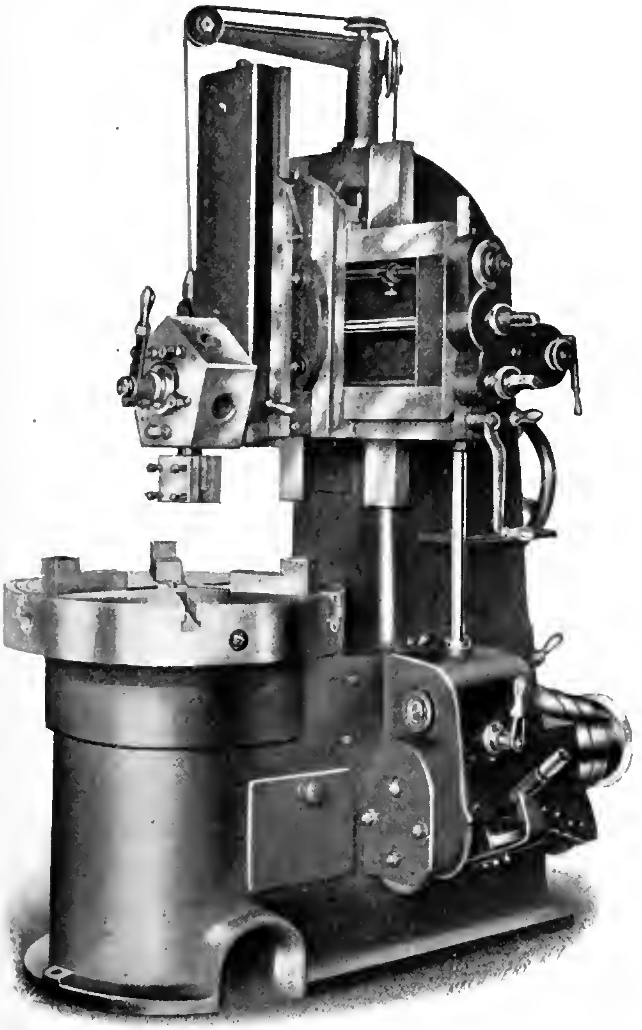


Fig. 1. The Flather 30-inch Vertical Turret Machine.

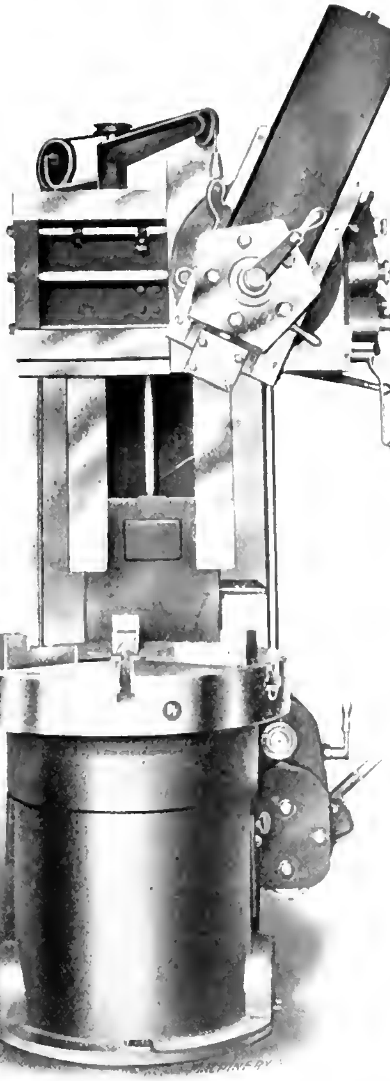

Fig. 2. Front View of Turret Machine.

The Table, the Spindle and the Drive.

In Fig. 3 at *A* is shown the cast iron spindle of the machine, made with thick walls and ribbed in its large diameter so as to be very stiff and strong. The journal for this spindle is formed in two parts. The thrust is taken on the upper beveled face of sleeve *B*, which is screwed and doweled to a machined seat in the solid base of the machine. This thrust bearing, it will be seen, is of large area, and is provided with ample means for lubrication. The side strain is taken by the long bearings of the shank of the spindle in bushing *C*, which fits closely into sleeve *B* on its outside diameter, and is provided with a taper internal bearing scraped to fit the taper journal of the spindle. To the lower end of bushing *C* is threaded the nut *D*, which is split and provided with a clamp screw, as indicated by the dotted lines. To the lower end of spindle *A* are threaded the lock nuts *E E*, which adjust washer *F* against the lower end of *C*. It will be seen that provision is thus made for taking up both the wear of the thrust and the side wear on the journal. By loosening *D*, nuts *E* may be screwed up to give the required tightness of fit for the journal, and then *D* may be screwed up to give the required amount of play for axial motion. The table is 30 inches in diameter, and has 16 changes of spindle speed, obtained by a combination of four-step cone, back gears, and two-speed countershaft. The table is driven by spur gear teeth cut in the periphery of the extended diameter of the spindle, where it is bolted to the table. These mesh with pinion *H* on a vertical shaft, connected by bevel gears *J* and *K* with the driving shaft.

Feed Mechanism and Automatic Stop.

Twelve changes of feed are provided by a quick-change gear device, shown at the base of the machine on the operator's side. The six changes obtained in this mechanism are doubled by a positive clutch, giving the following feeds in revolutions per inch: 7, 8, 9, 10, 11½, 12, 21, 24, 27, 30, 34½, and 36. It should be noted that provision is made for cutting threads of unusual pitches other than those given, by using other gears in place of those provided in the gear casing at the front of the feed box in Fig. 1. The feeds are reversible, and each

rate is the same for either the vertical movement of the turret slide or the horizontal movement of the saddle on the cross-rail.

Worm gearing has been entirely avoided in the feed mechanism. To make this possible in the case of the turret slide, the usual rack and pinion has been replaced with a screw *L* and nut *M*, as shown in Fig. 5. The connection with the splined shaft *O* in the cross-rail is made by bevel gears through short shaft *N*; the screw is stationary while the nut revolves, as shown. Both cross and vertical movements are provided with an automatic trip, controlled, in the case of the cross movement, by dogs adjustable lengthwise on a stop rod, which is seen above the splined feed rod in the cross rail in Fig. 1. This rod is also provided with fixed stops at the limits of its motion, making it impossible to over-run the saddle on the cross-slide and damage the feeding mechanism. The feed stop operates on the feed clutch at the rear of the cross-rail, as shown in Fig. 3, dropping it out of engagement when the stop strikes the dog. The movement of the turret slide is controlled by a stop acting on the same stop rod, through the medium of a train of gearing and the index dial, shown at the right end of the cross-rail above the splined feed rod shaft in Fig. 1. The vertical movement of the turret slide may be adjusted to stop after any desired amount of movement, by setting the adjustable dial to read for the desired amount. This mechanism acts on the stop rod to throw out the clutch in the same way as for the horizontal movement.

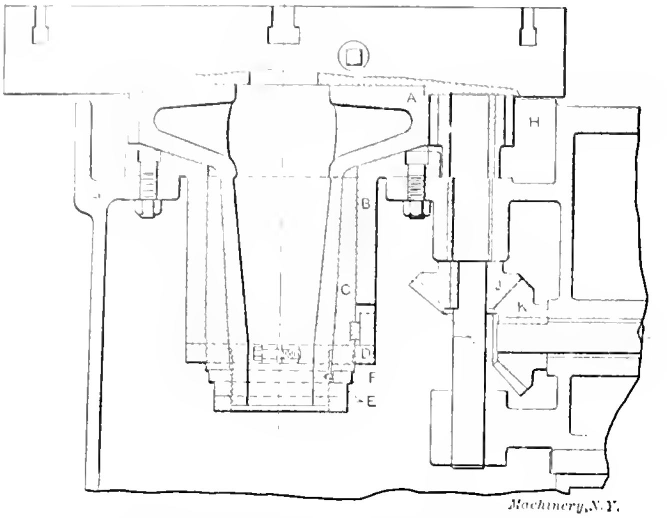

Fig. 3. Vertical Section of Spindle and Table Drive.

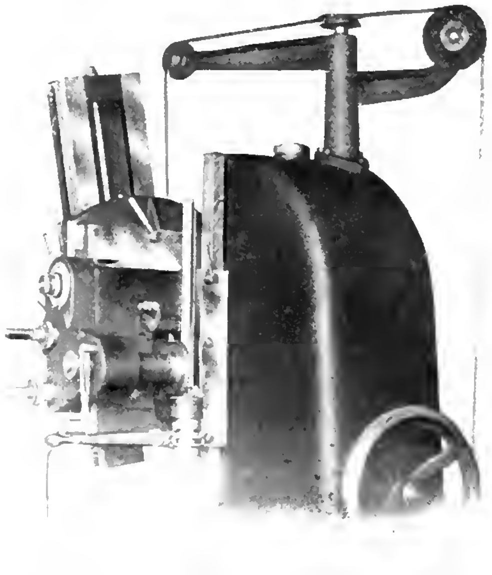

Fig 4. Arrangement of Cross-rail, Feed Mechanism, etc.

The Turret and Turret Slide.

The turret slide is, of course, set on a swivel saddle so that the movement may take place at any desired angle. The automatic stop operates at any angular setting of the saddle. The slide is counter-balanced by an arrangement which, it will be seen, is very simple as compared with that provided in many designs of this apparatus. It consists simply of a swinging crane arm carrying idler pulleys so located as to follow the movement of the slide freely. The turret is five-sided, and is 10 inches in diameter. The tools are clamped in place by hardened steel set-screws *P*, seated in bushed nuts *Q*. The lock bolt, of hardened steel, works in a hardened steel index ring.

Dimensions.

The principal dimensions of the machine are as follows: The extreme diameter of swing is 32 inches. The cross-rail may be adjusted by the hand wheel shown at the rear of the column in Fig. 4, to give from 8½ inches to 26 inches of height over the face of the chuck. The maximum distance under the turret head is 28½ inches, giving a total adjustment for the cross-rail of 17½ inches. The turret slide has a vertical feed of 17 inches, and is mounted on a cross-slide which has a travel of 23 inches, thus making it possible to turn reverse bevels on work of unusually large diameter. The machine stands 88 inches high, and occupies a floor space of about 68 x 47 inches. The approximate weight is 5,300 pounds.

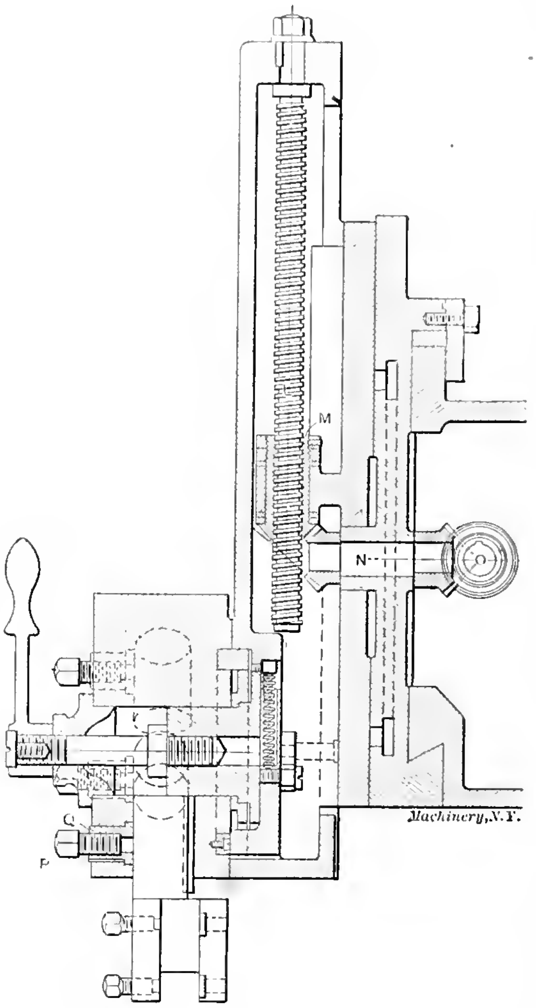

Fig. 5. Section through Turret Slide, showing Screw Feed.

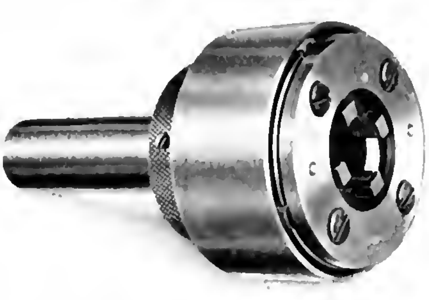
This machine is intended for the regular routine work of the boring mill, and for that reason it has not been encumbered with special features. It may be built at a cost that is reasonable in view of the cutting power and rigidity which the builders have aimed to obtain. The lines of the machine, as may be seen from the engravings, are simple but pleasing.

SOLID ADJUSTABLE THREADING DIE FOR USE ON TURRET LATHES, ETC.

The die-head shown herewith is designed to use a die formed of separate chasers and to so hold them as to give them an adjustment through a wide range of diameters. It is intended for use in machine operations where solid dies or adjustable round dies would otherwise be used.

The adjustment is made very easily, by loosening the front clamping plate and turning the outer hardened hood to the right or left as required, keeping the dies pressed against the inner bearing meanwhile. The seating of the outer edges of the dies against the tapered inner surface of the shell adjusts them simultaneously to a varying diameter as the hardened hood is turned. The chasers are tightened in place by locking the hood with a set-screw, and clamping the front plate up against them. The chasers (which are made of high grade tool steel or high speed steel, as required) are carefully tempered, and have a much longer life than one-piece threading dies, since they can be easily and quickly removed from the head and sharpened on an emery wheel or grindstone. They have a slight clearance in the threads which permits them to act freely with no drag. In addition to the advantages of a long life and the solid holding of the chasers, the feature of adjustability is very important, it being possible to use the same set of chasers for a wide range of diameters.



Die made by Adjustable Collet Co.

The heads are made of any suitable length to accommodate long threaded work. They may also be furnished with plain chasers and used as adjustable hollow mills. The material and workmanship of the tool is stated by the manufacturer, the Adjustable Collet Co., Cleveland, O., to be of exceedingly high grade, making the device an accurate and durable one.

FOX POLISHING MACHINE.

The accompanying illustrations show a polishing machine built by the Fox Machine Co., 815-825 N. Front St., Grand Rapids, Mich. This machine is of interest in itself, and makes possible, as well, a great improvement in the arrangement and general conditions of the polishing room beyond what is commonly met with in work of this kind. The machine is mounted on a substantial base, to the top of which is mounted a yoke which carries the arbor. This is best seen in Fig. 2. The lever shown at the front of the machine is attached to a shaft carrying an eccentric by which this yoke is raised or lowered. The lowering of the yoke and the contained arbor brings the pulley into contact with the belt, and starts the machine. To stop the machine, the lever is thrown back; this raises the pulley away from the belt, and brings the band brake, shown at the right of the pulley in Fig. 1, into operation, instantly stopping the spindle. The connecting-rod from the eccentric to the yoke is adjustable in length so that the belt may be brought down to exactly the right tension when the lever is thrown in, thus avoiding the necessity for treatment with resin or special preparations. The spindle or arbor is mounted in Hyatt roller bearings. The fit is a close one, but leaves enough freedom so that the spindle may be spun between the end of the thumb and finger. The use of these bearings in this machine has been very successful, and has led the builders to adopt them for their entire plant. In spindles running as fast as those used for polishing, a small amount of friction means a considerable amount of power, so that the matter of getting good bearings is an important one. The rollers and casings of the bearings are ground for high speeds, and are thoroughly protected against dust and grit.

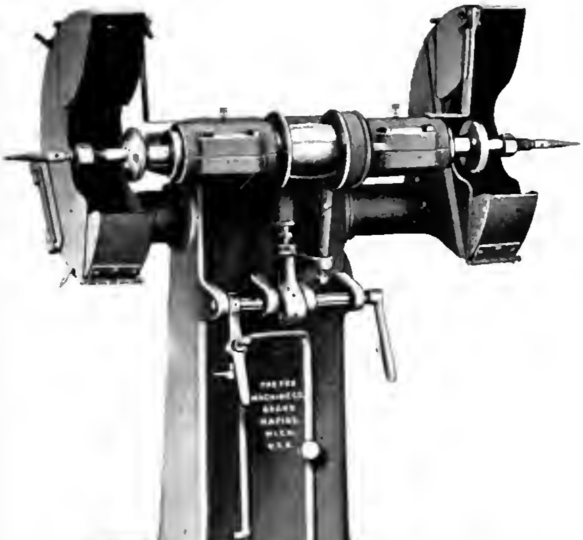


Fig. 1. Fox Polishing Machine with Exhaust into Base.

Each machine is provided with a pair of substantial steel dust hoods, attached to flanged brackets which are bolted to the column of the machine. The dust is exhausted from these hoods through brackets down into the column. From here it may be either led away through exhaust ducts in the floor, or through an opening at the rear of the base. The hoods are hinged so as to open up to permit the removal and insertion of polishing wheels.

Fig. 2. Side View of Base, showing Belt Tightener and Brake.

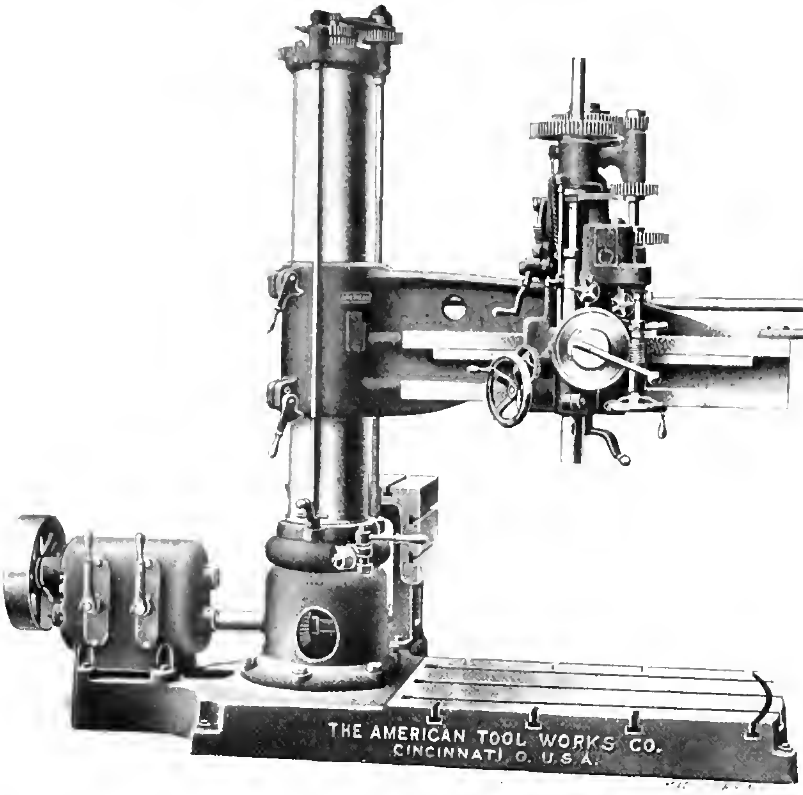
In designing the machine, it was the object of the manufacturers to produce a tool which would stand continuous service without requiring repairs. Really remarkable results have been obtained on this score. Ten machines of this type have been in constant use in the shops of the builders for about four years, most of them with two operators to a machine. It is stated that in that time the cost of repairs has not exceeded 25 cents; there has not been a single hot bearing, nor has one of the bearings ever been adjusted.

AMERICAN TOOL WORKS CO. HIGH-SPEED RADIAL DRILL.

The accompanying illustration shows one of a new line of radial drills designed and built by the American Tool Works Co., 300-350 Culvert St., Cincinnati, O., in order to take advantage of recent developments in high-speed drills, especially those of modified flat drill form like the "Celfor," "Norka," and other types which we have described from time to time. These drills have been developed until, with proper machinery for driving them, they will pierce a hole practically as quickly as it can be punched, in the case of work where punching is practicable. The radial drill has been steadily growing in favor for general work, owing to the convenience of its operation, and the facilities it offers for presenting to the tool, work of all shapes and sizes. The drive of the machine, however, has of necessity to be so long and complicated that in previous designs it has been impossible to bring from the driving pulley to the point of the tool, sufficient power to use these new high-speed drills to their full capacity. By strengthening the machine generally, improving the feed, and providing triple back gearing at the spindle head, the makers of this machine believe that they have provided a radial drill which obviates the defects of previous designs.

General Design.

The general design follows that of the 2-foot radial drill built by the same firm (see "New Machinery and Tools" in the July, 1908, issue of MACHINERY), and so will be only briefly described. The column is of the double tubular type with the outer sleeve revolving on conical roller bearings, hardened and ground. The inner member extends to the full height of the column, and has bearings at both top and bottom. This gives the equivalent of a double column and makes a very rigid support. The base is very heavy and is strongly ribbed, especially at the point of support. An extension of the base at the back is drilled to receive a plain box or a universal table, as ordered. The arm is of combined parabolic beam and tubular section, giving great resistance to bending and torsional strains. Its design leaves its lower edge parallel with the base, permitting work to be operated on in close proximity with the column without requiring the spindle to be unduly extended.



A Radial Drill, Especially Designed for using the New Forms of High-speed Tools.

The Drive.

The machine illustrated has a speed box drive, though it will be furnished with a cone pulley instead, if desired by the purchaser. This speed box, by the operation of the two levers shown, provides four speed changes, all controlled by friction clutches, which permit a change of speed without stopping the machine. From the speed box, power is transmitted in the usual way to the splined driving shaft shown extending along the back of the arm. The connection between this splined shaft and the driving shaft of the head is effected through a reversing mechanism operated by friction clutches, and controlled by the lever seen projecting forward toward the operator's position from beneath the cross-rail. The locating of the reversing arrangement here between the speed box and the triple back gears gives the clutches the advantage of a high speed even on slow, heavy work, thus providing them with ample power for the most severe conditions the machine will be called on to meet. This arrangement also facilitates the use of the reversing lever in combination with the back gear lever for tapping, giving a slow forward movement and a quick reverse. The triple back gears (a construction which, so far as our memory serves us for the moment, is a novelty in radial drill construction) are located in the head close to the spindle. The use of triple gears and the placing of them in this position is a prime factor in the matter of bringing a sufficient amount of power to the point of the drill, as it makes this possible without requiring transmission shafts of unwieldy size, and the transmission of high torque through sliding keys.

The drive just described provides for twelve changes of speed, the four in the speed box being tripled by the triple gears. This number is doubled by the use of a two-speed counter-shaft, giving 24 changes, which range in geometrical progression from 18 to 346 revolutions per minute, all immediately available without stopping the machine. This wide range of speeds, in conjunction with the high driving power, makes the machine as useful for the lighter work as for the heavy service for which it has been particularly designed. Particular attention should be called to the fact that the changes can be made without stopping the machine. The counter-shaft and speed box changes are effected by friction clutches which, of course, can be operated without shock at any practicable speed. The triple back gears are provided with a special feature which in combination with the rounding of the edges of the teeth of the gears, permits throwing them in at high speed with practically no shock to the parts. These arrangements make possible very rapid manipulation of the machine without any danger of breakage.

The Feeding Mechanism.

This machine is provided with eight rates of feed, covering a range in geometrical progression from 0.0066 inch to 0.0633 inch. These feeds are all obtained by the shifting of the knobs shown below the feed box. The dials with which these are provided indicate the rates of feed directly, making unnecessary any reference to index plates before making the change. These feeds are geared and positive, thus insuring a maximum productive capacity. The friction connec-

Note: C = carbon steel, H.S. = high-speed steel.

tion is provided, however, between the feed work and the feed pinion shaft. While this is strong enough to carry, without slipping, the heaviest feed the tools are capable of standing, it will serve as a safety device to prevent any damage to the feed mechanism. The spindle sleeve is provided with a depth gage and automatic trip acting on the worm clutch. The graduations being on the sleeve, the reading of depths is very simple; all depths can be read from zero. Two or more tripping dogs can be supplied, making it possible to counterbore a number of holes without reversing. The trip acts automatically at the extreme of the feed, preventing possible damage to the feed mechanism. The spindle is easily handled, being counter-balanced and provided with a quick advance and return lever, as well as with a fine hand adjustment, which may be used as well for hand feeding.

In the tables are given some examples of tests which indicate the power consumed under various severe conditions of service and illustrate as well, the capacity of the machine for transmitting this power. The driving of a 6-inch tap is an interesting illustration of the possibilities of the machine.

Unless otherwise specified, this radial drill is furnished with plain box table, counter-shaft and cone pulley drive. At extra expense it will be provided with the speed box as described, a universal table, and an electric motor drive. It is particularly adapted to the use of the latter, as it is only necessary to mount the motor on an extension of the base opposite the speed box, to which it is connected by chain or gearing.

STOCKBRIDGE GEAR-DRIVEN SHAPER.

The Stockbridge Machine Co., of Worcester, Mass., has recently designed a shaper with a drive in which all the changes of speed are effected by changes of gearing, thus adapting it either to be used as a constant speed pulley machine, or to be driven by a constant speed motor. The machine is designed new throughout, instead of following the plan sometimes adopted of taking a standard form of shaper and adding a gear box to it. Fig. 1 shows this machine as designed.

The Speed Change Gearing.

The construction of the gear box, which is, of course, the vital feature of the new design, is indicated in the vertical section in Fig. 2, which shows the pulley-driven arrangement. Power is received at pulley A, which is fastened to the driving shaft B. To the latter are keyed a series of five gears, C_1, C_2, etc. These engage corresponding gears D_1, D_2, etc., mounted on a stepped steel sleeve E, which is journaled in ring oiling bearings at F and F in the casing. In the bored interior of sleeve G (to which pinion D_1 is keyed) and on the interior periphery of each of the gears D_2, D_3, D_4 and D_5 is a series of cast iron expansion rings H_1, etc. These are expanded by the wedge-shaped plungers J_1, etc., whose lower ends are raised by suitable cam surfaces in rod K. The speed changes are "selective"– that is to say, any one of the changes can be obtained without going through the intermediate steps between it and the last previous change. In making a change knob L is rotated, revolving K to bring the proper cam surface into agreement with the proper plunger to operate the clutch desired, giving the speed indicated by a dial surrounding knob L on the hub of hand-wheel M. The plunger thus brought into alignment with the cam on K is then raised and the clutch tightened, by shifting K end-wise. This is done by a clutch fork operated by the horizontal handle shown above the hand-wheel in Fig. 1, engaging sliding collar N shown in Fig. 2. This shifting of K thus binds any desired one of gears D with sleeve E, which is thus driven at a corresponding speed from shaft B. On E are keyed pinions O and P, meshing with gears Q and R respectively, which run loosely on the crank-gear pinion shaft S. A clutch T operated by a lever at the rear of the change speed box engages either Q or R with S, this in effect being a back gear change. It will be seen that ten rates of speed are thus obtained.

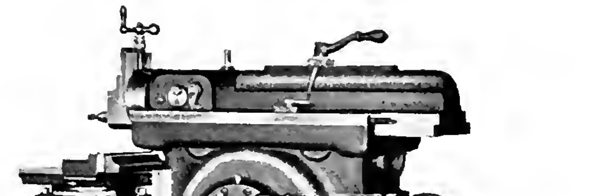

Fig. 1. Stockbridge Shaper, arranged for Motor Drive.

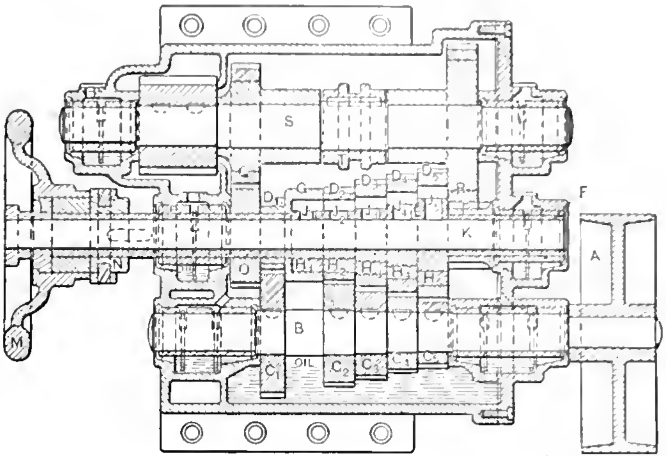

Fig. 2. Gear Box with Constant Speed Pulley Drive.

The details of this gear box have been carefully worked out. The gear teeth are all cut in steel, excepting in the case of the driving pinion of the crank gear. The friction rings H may be adjusted for wear by means of screws reached through a hand-hole at the back of the gear box. The gears run in oil and the boxes are all bronze bushed and provided with ring oiling facilities. The handwheel M will be found useful in moving the ram by hand for fine settings. The dial which shows to what position knob L has been turned, is marked with numbers giving strokes of ram per minute for each of the five gears D. Locating this gear box at the back of the shaper and bolting it direct to the column makes a stiffer, as well as a more compact construction than the more common one in which it is built out from the side of the shaper.

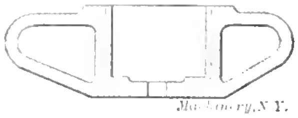
General Features of Design.

As was stated, the machine has been newly designed for this new gear drive to give it the necessary stiffness to make all the increased power of which it is capable, useful at the point of the cutting tool. A number of new features of the design may be mentioned. One of them is the construction of the rocker arm, of which a cross section is shown in Fig. 3. As may be seen it is provided with a cored U-shape rib on either side, giving as rigid a construction as could well be made for this part. The slot is of unusual depth and width, giving ample bearing surface for the crank-pin block. The rocker arm is held between two boxes at the bottom and is tied to the ram at the top, preventing the possibility of any tendency to come out of alignment.

The ram itself has been strengthened and stiffened over previous designs. On the working side the gib is solid with the column. On the other side it is made complete in one piece and bolted solidly to the column. Taper packing is provided for taking up wear and the whole construction adds considerable to the stiffness of the shaper.

The method followed of attaching the saddle to its slide on the face of the column is new in shaper construction, though it is exactly identical with that which has been followed for

a long time in the similar bearing on the column-and-knee type of milling machines. It is believed by the builders to give a much superior construction to that ordinarily followed for shapers as it gives one bearing surface cast solid with the saddle or cross-rail, and this, in combination with the method of tightening provided, prevents all possibility of the cross-rail's tilting away from the column when the gib on the opposite side is loosened. The adjusting gib is on the working side of the machine and is locked by the tightening of two binder screws, which serve to make the cross-rail practically a part of the column. This arrangement also makes it unnecessary for the operator to go around to the further side of the column to tighten the binder bolts, as is necessary when two loose gibs are used.



Machinery,N.Y.

Fig. 3. Cross-section of Crank.

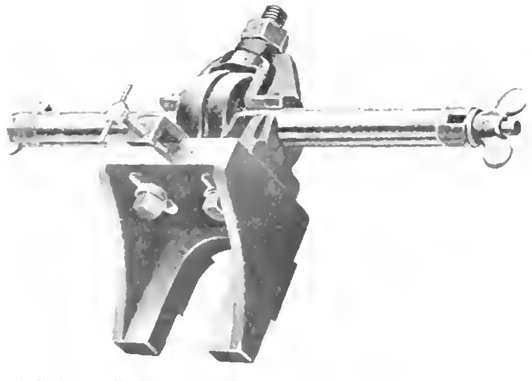
The regular distinctive features of the Stockbridge shaper are continued in this machine. Among them is the automatic down feed which was illustrated in the department of "New Machinery and Tools" in the November, 1907, issue of MACHINERY. The crank motion provided on this machine is well known. It gives a very even cutting speed for the entire length of the cut and a quick return of between three and four to one. This is obtained without jar to the machine, as the high speed is gradually brought to zero at either end, reversing the stroke easily and smoothly.

For the pulley drive machine, the construction shown in Fig. 1 is modified by using a regular base instead of the extension base there shown for supporting the motor. The driving shaft then has mounted on it a single diameter pulley, as shown in Fig. 2 instead of the geared connection for the motor used in Fig. 1.

KRIEGER BORING TOOL AND HOLDER.

The boring tool shown herewith is built by the Krieger Tool & Mfg. Co., 83 to 91 West Randolph St., Chicago. Its particular advantages are the firmness and convenience with which the boring tool may be held and adjusted, and the simplicity of its attachment to the lathe.

The bracket on which the tool is held may be slipped over the tool-post, and clamped by a square block passing through the tool-post slot and tightened down by the regular screw. The boring-bar holder proper is attached to the face of the bracket by bolts passing through the slots shown. This may be raised or lowered to bring the tool to the proper height, by means of the screw shown, which provides for very fine adjustment in a vertical direction. The holder is in the form of a V-block having a V-clamp supported by it, which is clamped down on the tool by the stud and nut shown. This is adapted for a wide range of boring-bars (from ¼ up to 1¼ inch) which it will hold so firmly as to prevent any possibility of turning.



A Universally-adjustable Boring Tool Holder used in the Regular Tool-post.

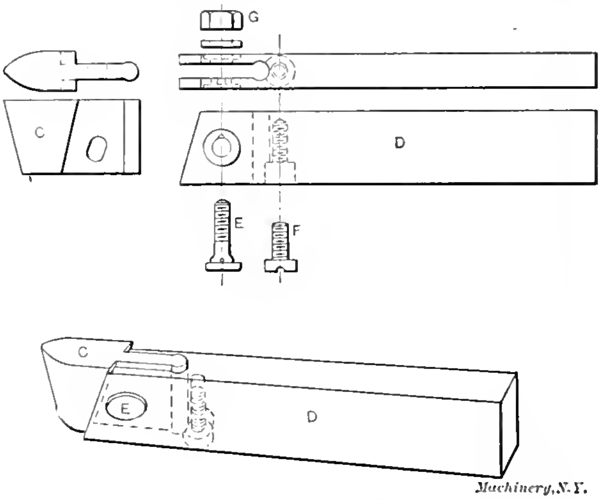
These boring-bars have been previously described (see "New Machinery and Tools") in the April, 1908, issue of MACHINERY. The blades, formed of simple pieces of square stock, may be set in either of two positions; they may be inclined, as would be necessary to recess the bottom of a blind hole, for instance, or set straight, as would be done in machining a cored hole large enough to admit the boring-bar. The blade is clamped in place by the thumb screw at the back end of the bar, there being no headless set-screw or other delicate contrivance of that kind at the business end of the tool.

With this holder the bar can, of course, be accurately lined with the center of the spindle, and extended to a distance just sufficient to reach the bottom of the hole which is being bored, thus giving the maximum degree of rigidity to the tool support.

TOOL-HOLDER FOR HIGH-SPEED STEEL.

The cutting tool shown in the accompanying engraving is the invention of Mr. F. E. Bocorselski, the superintendent of the Baush Machine Tool Co., of Springfield, Mass., who manufactures the device. It is made in two styles, of which the first, shown in Fig. 1, is adapted for more severe service. In each case the holder *D* is made of 20-point carbon steel, case-hardened, and the blade is drop forged from high-speed cutting steel. This makes a durable and effective tool.

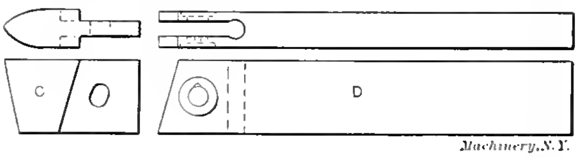
In the style shown in elevation and perspective, in Fig. 1, the drop forged blade *C* is provided with a tenon, as shown, entering a corresponding mortise in the holder *D*. The front end of the latter is cut off at an angle, as shown, and the tenon of the blade is beveled to fit this angle; the rear end of this tenon is provided with a bead fitting a hole drilled through the shank into which the slot is cut. The blade may thus be set into its seat from the top and tapped into place, when it will fit firmly on all its bearing surfaces in the shank. To hold it in position sideways bolt *E* is used, which clamps the thin sides of the holder firmly against the shank of the blade. One advantage of this construction is the large bearing area and intimate contact between the blade and the holder, which permit the rapid conduction of the heat. The two parts, it will be noticed, are of the same height and section, so that the full cross-section of the holder is available for this purpose. An ejector screw *F* is used for removing the blade for grinding or changing cutting edges. This, it will be seen, may be screwed up against the under side of the tenon of the blade, ejecting it from its wedge seat in the holder after bolt *E* has been removed. This screw may also be used to give a more firm support to the blade by screwing it up against the blade after clamping it in place.



Machinery,N.Y.

Fig. 1. Details of Tool-holder.

The other form of tool-holder, Fig. 2, is without the ejector screw and the bead on the tenon of the blade, the bolt and the bearing of the taper seat of the blade against the end of the holder being relied on to hold it in place. This



Machinery,N.Y.

Fig. 2. A Holder of Simpler Construction.

holder, which is doubtless intended for lighter service, is identical in other respects with that in Fig. 1. The blades, drop forged from high-speed steel, are made of various other forms, as well as in the shape shown in the engraving, for turning cast iron, thus fitting them for the full range of lathe work.

FERRACUTE DRAWING PRESS FOR METAL CASKETS.

The Ferracute Machine Co., of Bridgeton, N. J., has recently completed the remarkable double-action drawing press shown herewith. It was built for the Montross Metal Casket Co., of Philadelphia, and, as may be surmised from the firm name of the purchaser, is intended for blanking and forming the cover and body of seamless metal caskets. Examples of its work are shown on the floor around the base of the machine. The machine is, of course, as useful for producing similar work in other and less lugubrious lines, such as bath tubs, horse troughs, automobile bodies and miscellaneous large drawn work in steel or copper. The machine is interesting because of its large size (it weighs nearly 100 tons and is capable of exerting a pressure of 1,000 tons) and for the mechanical features of its construction as well.

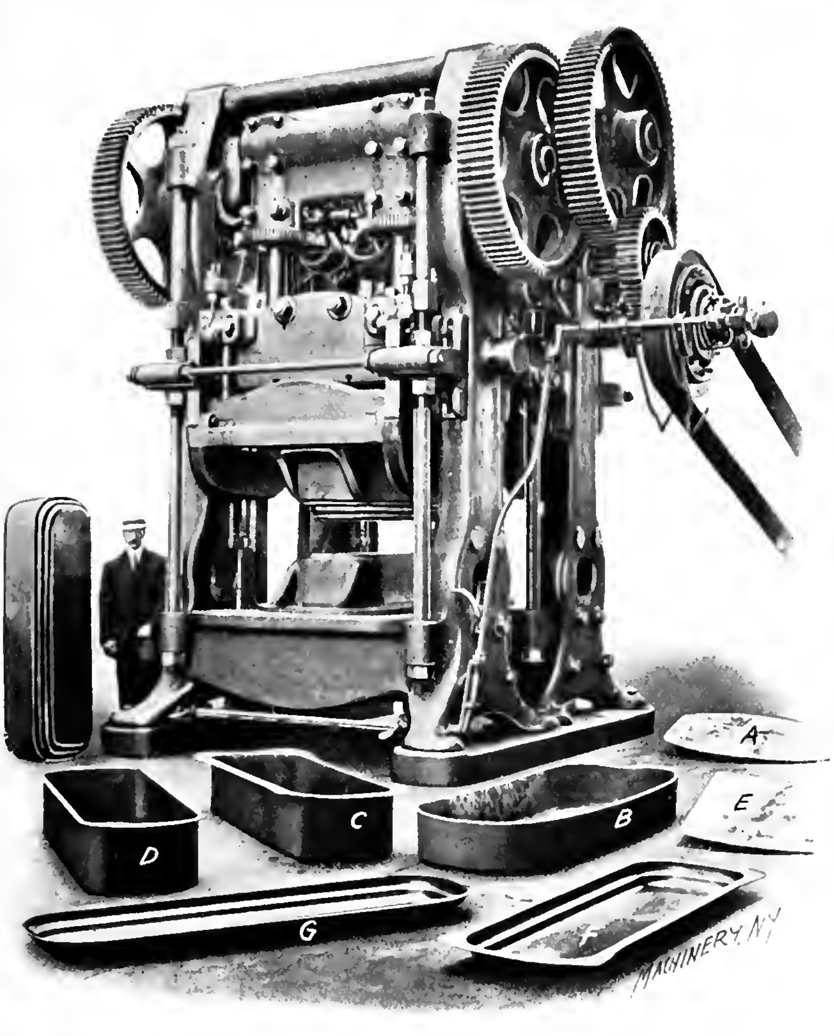


Fig. 1. A Press for Drawn Work of the Largest Size; Built up from Two Presses on the Same Base.

This press is virtually formed of two separate presses, mounted on an iron base. The frame is thus composed of four heavy cast iron columns, each of which is reinforced by two 4¾-inch steel rods, which add materially to the tensile strength of the columns. Besides being united at the base by the bed, these columns are connected at the top by stays, and by the necessary mechanical connections for the mechanism. The construction allows vertical pressure to be communicated to the table ram at four points, there being two crank-shafts, with double pitman rods for each. The adjusting gears of the four pitmans are connected by gearing, so that one hand-wheel moves them all; the adjustment is exceedingly delicate, as one turn of the hand-wheel gives only 0.001 inch of movement. A small electric motor, which may be seen in the interior of the machine between the two outer pitmans, is connected with this adjusting mechanism to enable adjustment to be made rapidly when the ram is to be raised or lowered any considerable amount.

The double-action mechanism is unusual and interesting. The outer slide or blank holder is hung from the inner ram by four heavy studs. It descends with the ram for about half of its stroke, when it is arrested by meeting the lower die and the work. At this point the continued descending of the inner die operates a toggle mechanism, forcing adjustable wedges in on top of the blank holder, transferring the pressure directly to the frame of the machine, this pressure not being borne by the main shaft as in ordinary cam presses. The four toggle levers which operate this wedge mechanism are connected with adjustable tie-rods by which the holding down pressure may be varied to suit the conditions of the work. This arrangement has been used by the builders for some time on smaller presses, but has never before been applied to large drawing presses. One advantage of the construction is that in this machine the whole outer ram or blank holder may be quickly removed by unscrewing the nuts from the top of the studs, allowing the outer ram to drop down through from the inner ram. By removing it in this way the machine may be made into a single-action press in which the full power of the ram is available. It is then especially adapted for working cutting dies, owing to the long and accurately adjustable gibbed slide bearings with which the machine is provided. This transformation of a double-action press into one of the single-action type is believed by the builders to be a new feature.

The machine is triple geared, with all the gearing cut from the solid. The five large gears are each 5 feet in diameter and 10 inches face. The ratio of the gearing is 200 to 1. The friction clutch used is of modern design, especially adapted for high speed and heavy service.

As stated, the weight of the press is nearly 100 tons, and it is capable of exercising a pressure of 1,000 tons. The stroke of the inner punch or ram is 28 inches. The outer ram may have, if desired, as much as 24 inches of movement, but with the presses adjusted as shown in the illustration, its stroke of 14 inches is capable of producing a shell of very nearly that depth. The crank-shafts are each 10 inches in diameter, forged from high carbon steel. The pinions are of phosphor bronze. An adjustable positive knock-out attachment is used in connec-

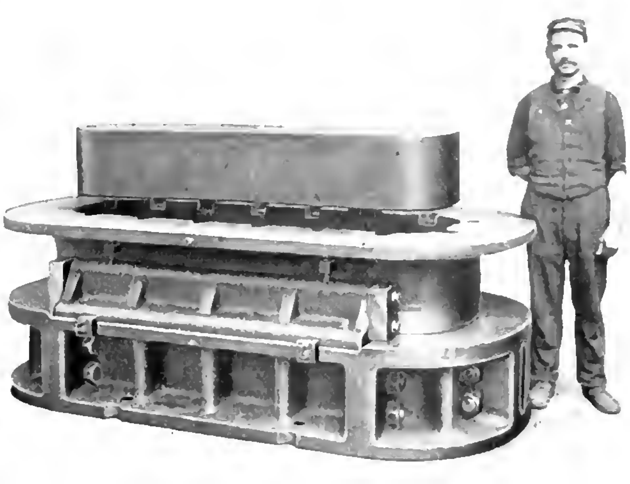

Fig. 2. One of the Drawing Dies used in the Press shown in Fig. 1

tion with the dies, two of the rods which connect the knockout with the ram are shown in the engraving.

The work shown about the base of the machine is 6 feet long, 20 inches wide, and 12 inches deep for the body of the casket, while the lid is 4 inches deep, giving a total height of 16 inches for the completed article. The parts are arranged in the order of the operations. At *A* is the blank for the body of the casket. This is first rough drawn, as shown at *B*, to a depth of 9½ inches. It is then, at *C*, redrawn to a full depth of 12 inches. The edges are next trimmed, and at *D* the edge is shown formed. The operations on the lid are similar; except that but one drawing operation is necessary, the blank being shown at *E*, the drawn shape at *F*, and a completed cover with trimmed and formed edge at *G*.

One of the drawing dies (that for the last drawing operation) is shown in Fig. 2. It is, of course, of large size, but it has been reduced to minimum dimensions by careful designing. The lower die is shown on the floor with the blank holder resting on it. The upper die, or punch, is shown suspended above that.

WALKER NO. 2½ SURFACE GRINDER.

In the "New Machinery and Tools" department of the February, 1908, issue of MACHINERY we illustrated and described the No. 3 surface grinder built by the Walker Grinder Co. of Worcester, Mass. This machine is now available in a smaller size, the No. 2½ shown herewith. This, besides being of smaller dimensions, incorporates a number of improvements as well, particularly in the feed mechanism.

The main features of this grinder are the same as in the original machine. The work table slides on ways directly on the bed of the casting, while the cross movement is effected by moving the wheel column in or out. The guiding surface of the wheel column is extended, by means of projecting horns, on ways which pass through openings in the rear of the base so that the wheel is supported practically under the working point at even the outermost extreme of adjustment. The table has an automatic reciprocating movement, controlled by the dogs shown which can be adjusted to any desired position in the slot on the front of the table. The cross feed is arranged to feed automatically in either direction at the will of the operator, at each end of the stroke, and is provided with a safety device which prevents the possibility of forcing this automatic movement beyond the limits of the cross travel.

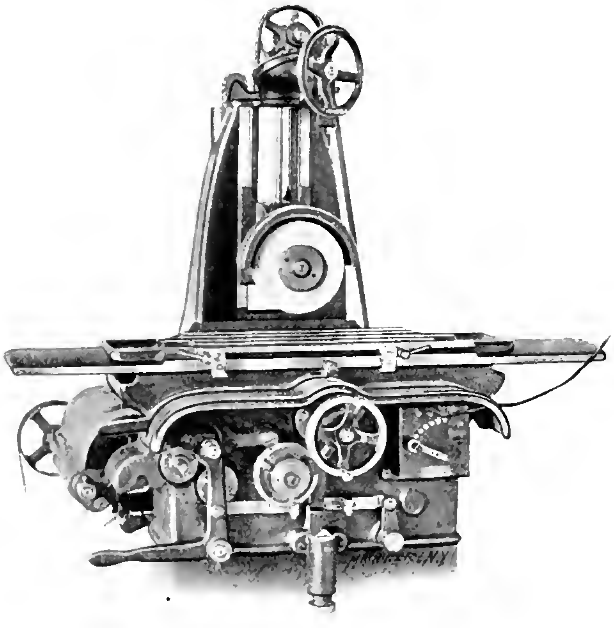

Fig. 1. Walker Surface Grinder with Friction Feed.

The improvement in the automatic cross feed consists in operating it from a friction device, similar to that provided for planers, instead of having it operated by the reversing lever for the table motion as in the previous construction. This gives a more strongly driven feed, and relieves the dogs of all work except that of shifting the positive clutch which controls the table feed.

The friction disk for operating the cross-feed is mounted below and just to the left of the cross-feed hand-wheel in Fig. 1. This disk plays between stops, which may be adjusted to any suitable position about the circumference of the carrier in which they are mounted, to give the desired amount of feed at each end of the stroke. The reversing plate, which is thus given a definitely limited movement at the end of the stroke, has pivoted to it a plunger having rack teeth cut in it, meshing with a pinion mounted loosely on the cross-feed screw. This plunger is confined in a holder which is also loosely pivoted about the same axis. The point of attachment to the cross-feed plate is such that it may be given a movement each side of the dead center, thus giving an out and in movement to the plunger at each end of the stroke. This out and in movement is transmitted to the pinion, which in turn carries an arm with a reversible pawl engaging a ratchet wheel on the cross-feed screw. By reversing this pawl, the direction of the feed is regulated.

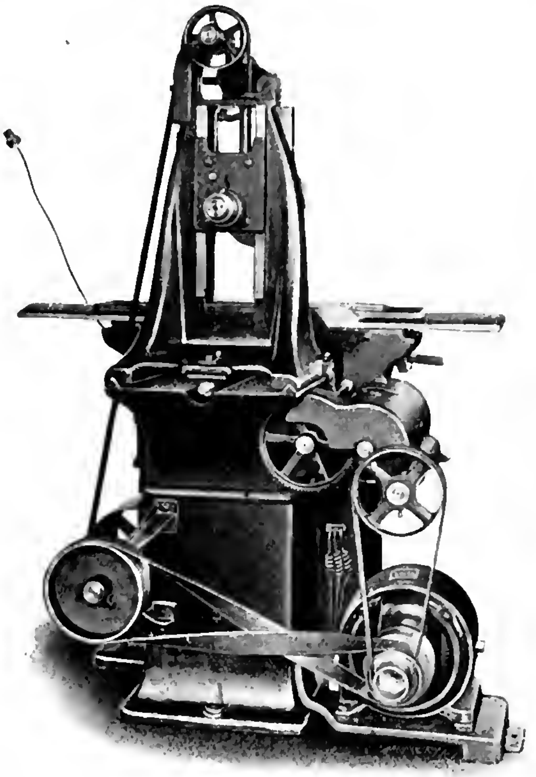

Fig. 2. Rear View of Grinder showing Wheel and Feed Driving Connections.

The machine we show is motor driven. The motor is mounted on a special base connected with the base of the machine, and fastened to the floor at its outer extremity. By this means, although one end of the motor base rests on the floor, the whole arrangement is still a self-contained unit. It will be noted that the motor is placed on the clean side of the grinder, the direction of rotation of the wheel throwing the dust and emery toward the opposite end. The motor shown is of the direct current type, but an alternating current motor will be furnished if desired. The starting box is in a convenient location at the right-hand side at the front of the machine, as shown in Fig. 1.

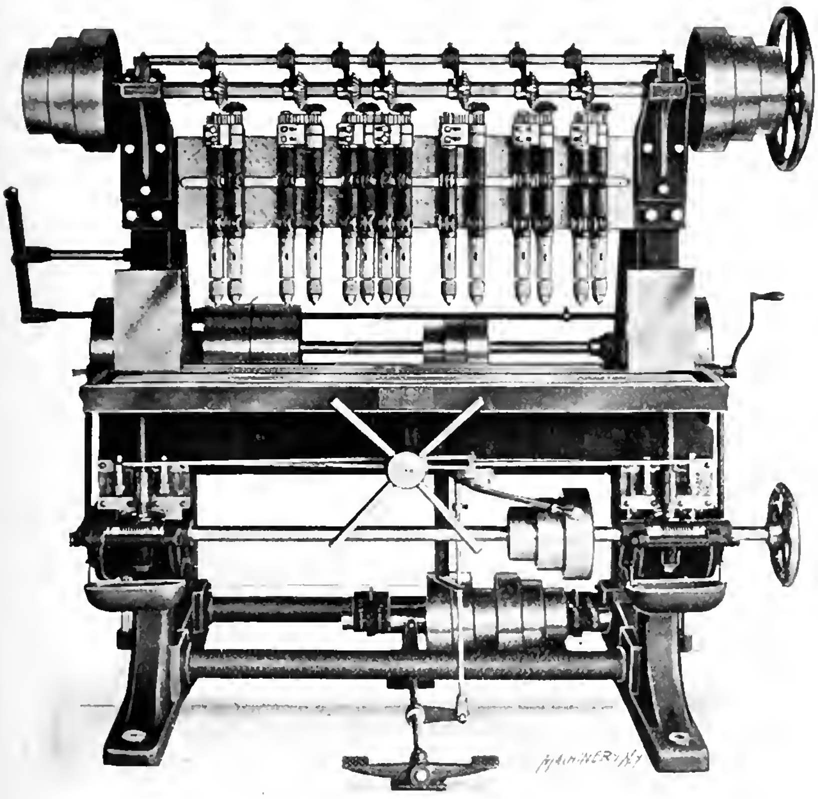
As may be seen in Fig. 2, the outer end of the armature shaft is provided with a three-step cone. Two of these steps are of considerable width for driving the emery wheel drum. The two speeds thus provided, allow for speeding up the spindle as the wheel wears to smaller diameter. The third step of the cone pulley on the armature shaft is connected with the table feed driving mechanism. A feed movement of somewhat different construction from the belt-driven type shown in our previous issue, is used with this motor-driven machine. No bevel gears are used in reversing by this movement. The shaft on which the feed driving pulley is mounted carries two pinions, one of which meshes directly with a mating gear on the reversing shaft, while the other one is connected with

a similar gear through an intermediate idler, the location of which may be understood by looking at the feed box at the left of Fig. 1. The clutch for connecting these two gears alternately with the reversing shaft on which they are loosely mounted, is of the positive instead of the friction type, as in the older design. The automatic movement in this new machine has also been improved, being so constructed that the workman can reverse the cross-feed and set the automatic stop for the return stroke without waiting for the stop to be released from the previous movement.

The machine as shown is arranged for dry grinding, but provision has been made in its design, and in the water guards and other attachments which will be furnished, to use water if desired by the purchaser. This machine will grind a length of 20 inches, a width of 8 inches, and a height of 10 inches with a full-sized wheel. The same motor arrangement shown can be applied to No. 3 machine, if desired.

IMPROVED SPINDLE ARRANGEMENT FOR ANDREW MULTIPLE DRILLING MACHINE.

We have described in this department in previous issues of MACHINERY (February, 1906, November, 1907, and April, 1908) various designs of the multiple drill built by M. L. Andrew & Co. of Cincinnati, Ohio. These drilling machines follow the general design shown in the engraving. The frame of the machine consists of two side housings connected by suitable distance pieces and a cross rail at the top, on the latter of which the spindle heads are adjustable. The work table is supported on a screw at each end for feeding the work up to the drills. These feed screws are operated simultaneously by worm gearing, which keeps the table always horizontal, at right angles to the axis of the drill spindle. The feed screws act on double split nuts, which are simultaneously closed or opened by a single lever, thus furnishing means for throwing the power feed in or out of action. A pilot wheel is provided for raising and lowering the table by hand. Three rates of feed are furnished, and three spindle speeds. The uses of the machine are obvious, it being possible to drill a number of holes at one setting, spaced through a great variety of layouts.



Andrew Drilling Machine with Double Spindle Drive allowing Close Spacing.

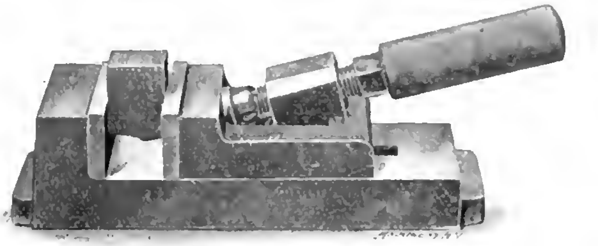
The improvement illustrated in the machine herewith shown relates to a provision for decreasing the minimum distance between two adjacent spindles. In the older design, this was limited by the driving mechanism, which consists, as may be seen, of a horizontal shaft at the top of the machine connected by bevel gears with the various spindles. These bevel gears have to be large enough to drive drills up to 1/2 inch in diameter, and they consequently limit the closeness with which any two adjacent heads can be spaced. The improvement consists, as shown, of driving two heads from one set of bevel gearing, by connecting the two heads with an idler gear, mounted with a swivel adjustment on the driving spindle, to correctly mesh with a spur gear on the driven spindle of the pair. As these driving spur gears take no room sidewise outside of their diameter, the spacing of the spindles is limited only by the requirements of the spindles and the heads. This improvement, in connection with the bracket arrangement for the side adjustment of the spindles for staggered holes (described in the February, 1906, issue) materially increases the range of usefulness of this machine.

ARMSTRONG QUICK-ACTION DRILL VISE.

The illustration shows a drill vise made by Armstrong Bros. Tool Co., 113 N. Francisco Avenue, Chicago, Ill. The special feature of this vise is the provision for rapidly sliding the jaws in or out to suit the work, without the necessity for using the slow screw movement for this purpose. When the jaw has been adjusted to position it may be tightened by turning the knurl handled screw shown. The vise is, of course, useful as well for many operations in the shaper or milling machine and it is provided with projecting lugs for strapping it to the table of the machine.

The movable jaw is held in alignment by a hinged clamp which fits a slot machined in it, and extends down through a similar central slot in the base. Through the upper member of this hinged clamp is threaded the tightening screw, with its knurled handle. The inner end of this tightening screw carries a ball jointed abutment (such as used for the heads of jack screws) which bears against an inclined surface on the rear of the jaw. When the screw is loose and the rear end of the handle is raised, the jaw and its contained clamp is free to slide to any desired position. The pressing down of the handle, by means of an eccentric surface formed by the upper part of the clamp, binds the latter firmly in position on the base. The turning of the screw against the jaw and the consequent tightening of the work in place, tends still further to throw the handle down and to bind the clamp still more firmly in place. It will be noticed that the screw points downward. This has the effect of pressing the sliding jaw downward and against the work instead of lifting it as is the case with vise jaws of the ordinary construction, operated by a screw in the base. By this means the work is held true and solid with one turn of the handle.

The sides of this vise are ground parallel and at right angles with the bottom so that work can be drilled from three different sides. The jaws are made of tool steel. The device is made in three sizes. No. 1 has a jaw 2 inches wide, 15/16 deep and opens 1 3/4 inch. The corresponding figures for the No. 2 vise are 2 3/4, 1 3/16, and 2 1/2 inches re-



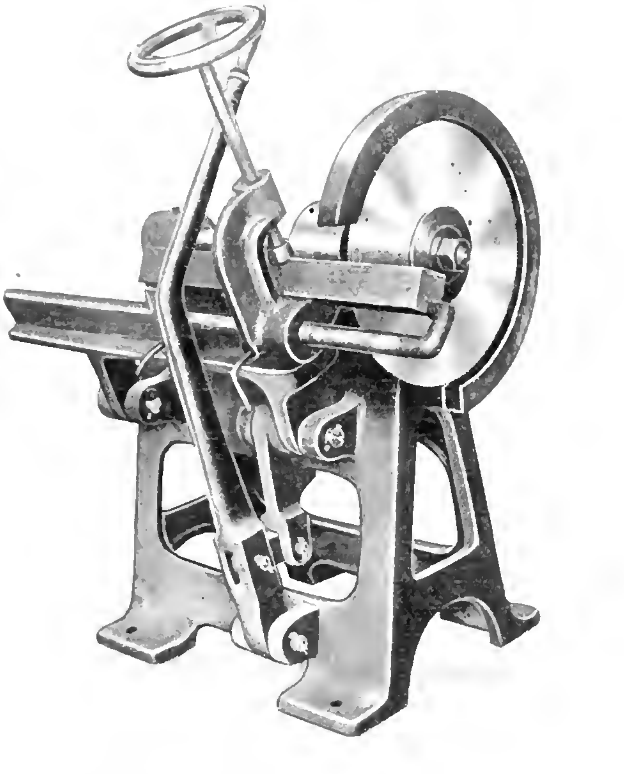
A Drill Vise that can be Rapidly Adjusted.

spectively, and for the No. 3 vise $3\frac{1}{2}$, $1\frac{7}{16}$ and 3 inches respectively. These vises weigh $4\frac{1}{4}$, $8\frac{1}{2}$ and 16 pounds respectively.

THE BILLINGS & SPENCER HOT SAW.

The cold saw shown herewith has been designed by the Billings & Spencer Co. of Hartford, Conn., and is especially adapted for the work of the drop forging plant. Used as a hot saw, it is employed for the rapid cutting off of bar stock and trimming the ends of such forgings as crank-shafts, spindles, axles, etc. While designed primarily for use as a hot saw, it is capable of cutting cold steck as well, in the smaller sizes.

The carriage is swung toward the saw about a pivot, by a compound lever movement, actuated by the long hand-lever shown. This gives a rapid-acting feed, and at the same time a very powerful one. The carriage is provided with a hand-wheel for clamping the work, and an adjustable stop for setting the work to length. The saw used is 20 inches in diameter and $\frac{1}{8}$ inch thick, and should run at 2,500 revolutions per minute. It is driven by a 4-inch belt. The capacity of the machine for hot sawing of steel of all kinds, is for work up to 3 inches in diameter. Cold iron or soft steel up to $1\frac{1}{2}$ inch in diameter can be handled.



Hot Saw Especially Adapted to the Requirements of Drop Forging Work.

LANG'S HEEL BLOCKS AND STUDS FOR SETTING UP AND HOLDING LARGE WORK.

In the September, 1905, issne of MACHINERY was pnblished an article entitled "Importance of Good Clamping Facilities in Machining Large Work," in which was described the surprising saving of time effected on such work in the shops of the Bullock Electric Mfg. Co. of Cincinnati, Ohio, by the use of special appliances for clamping on planers, boring mills, etc., and on the flcor plate for use with portable tools. One of these appliances was a form of T-bolt head made by the G. R. Lang Co. and used with plain studs threaded at each end. These were supplied for each machine, in a box, together with a variety of clamps; this provided from 1 to 2 dozen T-heads and 3 to 12 dozen studs, ranging from 3 to 36 inches in length, supplied with suitable nuts and washers. The use of these obviated a tremendous amount of lost time in the hunting up of suitable clamping arrangements. In addition, each machine was provided with turn-buckles having forked stub ends, to be used as drivers and braces, and with cast iron heel blocks also made in step form, so as to be adjustable for height. This latter appliance is now manufactured as a regular stock product by the G. R. Lang Co., of Meadville, Pa.

This device is shown in Fig. 1. As may be seen, the form of the blocks explains their use. They are made in two sizes, 4 and 6 inches high respectively, and can be stacked up to extend to any height from 1 inch to 3 feet if necessary. These steps are obtained in increments. The fractions of an inch can be taken care of by using small pieces of flat iron and washers between the steps and the ends of the clamp. These blocks are cast from accurately machined metal patterns which produce good flat surfaces, and thus give a solid bearing snpport to the clamp. In addition to their other conveniences, they have that of stability. It is not always possible to leave work from Saturday night to Monday morning without it becoming loosened, especially if wood blocking is used.

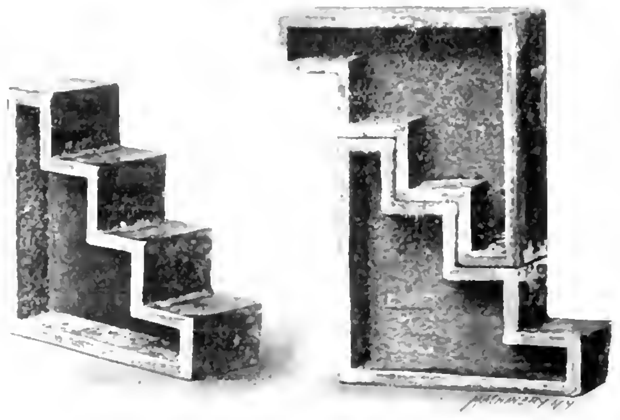


Fig. 1. Adjustable Cast Iron Stepped Blocking.

In Fig. 2 is shown a modification of the bolt head mentioned in the former article. These heads are made of a good qnality of steel, and are carefully machined to fit the slots they are to be used in. They are especially adapted to places where the maker's T-bolt heads would interfere with the work—in such cases, for instance, as bolting chuck jaws to a boring mill table, and other similar short work. They may also be used on old machines where T-slots have been badly broken out by the use of poorly fitting bolts, and where a good machine fit is required to hold. Standard sizes are kept in stock, but special sizes will be furnished when the dimensions of the T-slots they are to fit are given by the customer. The use of the studs with these, in place of the ordinary T-bolts, gives the same advantages as with the builder's previous form of bolt head. It is not only cheaper to fit the machine with these than with forged bolts, but it costs less to keep them in shape. The stnds are made of steel and hardened, and will greatly ontwear the ordinary bolt, which wears out on the upper threads and becomes useless for the greater part of its length. The square head shown in Fig. 2 is not tapped entirely through. It is thus possible to make them into permanent bolts by simply screwing studs down tightly into them, where they will stay until removed with a wrench.

Fig. 2. Machined Steel Tee-head.

CINCINNATI TWO-SPEED PLANER DRIVE.

What seems to be the limit of simplicity in the construction and operation of a two-speed planer drive, has been designed by the Cincinnati Planer Co. of Cincinnati, Ohio. This arrangement is shown applied to a standard planer in Fig. 1. The only change in the construction of the machine is the addition of a second tight pulley on the driving shaft, and a provision for a second speed in the counter-shaft, as shown in Fig. 2. This gives two forward speeds with constant reverse at high speed, without manipulation of the counter-

shaft belt shifters, the only change being the shifting of a plug in one of the belt forks in the reversing.

Fig. 2 shows the arrangement of the pulleys on the counter-shaft and on the driving shaft of the machine. With the exception of loose pulleys *A* and *B*, the arrangement of this counter-shaft is unchanged. The regular driving pulley *C* has a speed, as will be noticed, of 400 revolutions per minute, for a cutting speed of 50 feet per minute. This pulley is keyed to the shaft and drives the usual forward driving pulley *D* and the reversing pulley *E*, the latter of which, it will be noticed, has a heavy balance rim. On the driving shaft of the machine the forward belt is shifted from loose pulley *F* to pulley *G* for the cutting stroke, being returned to *F* for the reverse, which is effected by shifting the backing belt from loose pulley *H* to driving pulley *G*. This is, of course, the usual arrangement. In addition to the belt from the main line to the loose pulley *K* on the counter-shaft, there is a second one running at half the speed which drives loose pulley *B* on its left-hand side, at 200 revolutions per minute. By a change in the reversing mechanism of the planer, the forward motion belt instead of playing between *G* and *F* and being driven by a pulley *D*, may be shifted to play between tight pulley *J* and loose pulley *F*, and be driven at a reduced speed by pulley *B*, giving a forward cutting speed of 25 feet per minute.

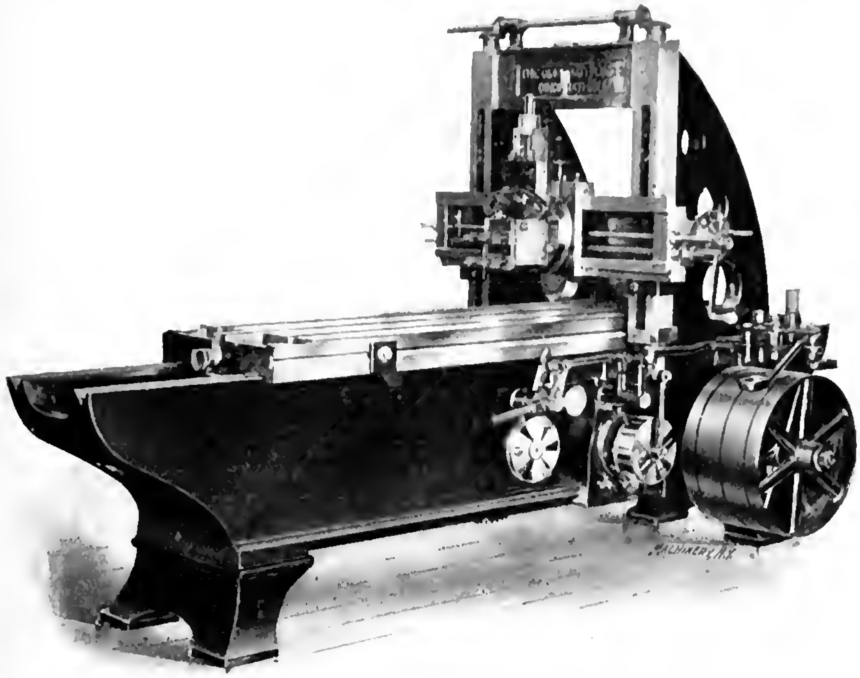

Fig. 1. Cincinnati Planer with Modified Belt-shifting and Driving Pulley Arrangement for Two-speed Drive.

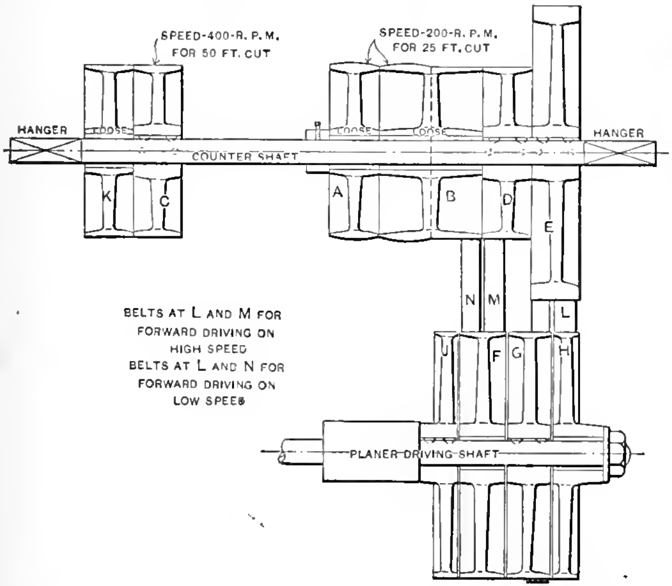
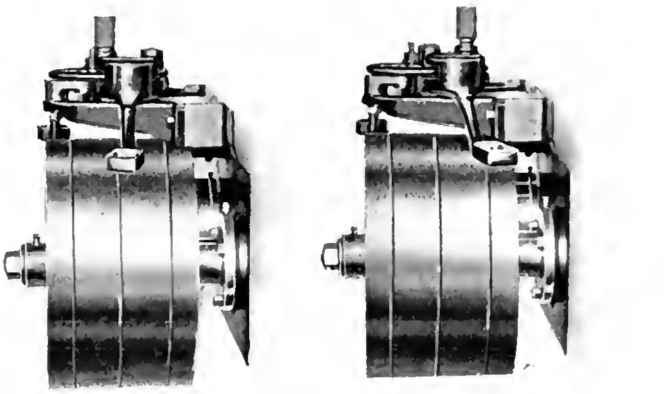


Machinery,N.Y.

Fig. 2. Arrangement of Pulleys on Counter-shaft and Driving Shaft.

This change in the position and direction of shifting of the forward cutting belt, is effected by changing the connection between the reversing cam and the forward belt shifter. Figs. 3 and 4 show the two positions of this apparatus. In Fig. 3 the knurl handled plug shown, passes down through its seat in the belt lever into the slot in the reversing cam, which thus actuates the belts in the usual way. By shifting this plug to the position shown in Fig. 4, on the opposite side of the fulcrum of the shifting lever, the direction of movement of the shifting is reversed, and the position of the belt is changed so that it operates on pulley *B* in Fig. 2 instead of on pulley *D*, giving the reduced cutting speeds.

Only one belt shifter is required for the counter-shaft, as this provides for simultaneously shifting the belt onto and from loose pulleys *A* and *K*, so that no more movements are required for the counter-shaft operation than with the usual simple arrangement. It will be noticed that the loose, slow-cutting pulley *B* revolves on the shaft only the difference in speed of the two drivers *B* and *C*, so that the service is not severe. The loose pulleys on the counter-shaft are arranged with special bronze bushings which allow room for a large reservoir of oil in the center. Slots on opposite sides lead from this central reservoir to the shaft and are so disposed as to cover practically the entire bearing surface. These slots are filled with felt which gradually draws the oil by capillary attraction to the journal. These pulleys, arranged in this way, need oiling only two or three times a year.



Figs. 3 and 4. Position of the Driving Belt Shifter Plug for Fast and Slow Drive.

The machine to which this drive is shown attached in Fig. 1, is one of the builder's regular 24 x 24-inch planers. It will be seen that very little change has been made in its design, the alterations being confined to the reversing mechanism, and the addition of an extra driving pulley.

PEERLESS HIGH-SPEED REAMERS.

The Cleveland Twist Drill Co., Cleveland, Ohio, is making a new form of reamer with high-speed steel cutting edges and carbon steel bodies and shanks, united into a solid, inseparable unit. The high-speed blades only are hardened, so that while the tools have all the hardness and cutting qualities of solid high-speed tools, they are at the same time less brittle than reamers made entirely of carbon steel. This special construction allows these tools to be marketed at a price very much below that of ordinary high-speed reamers. The process of fitting the high-speed steel blades into and solidly joining them to soft steel bodies, is done by a process termed "brazo-hardening," which has been developed and patented by the builders.

These tools are made in a number of styles, of which three are shown in the accompanying engravings. Fig. 1 shows a solid reamer of the kind largely used in screw machine work. The inserted high-speed blades are plainly seen in the engraving. Fig. 2 is a tapered shank expansion chucking reamer, in which the variation of size is obtained by screwing in or out a taper plug seated in a taper hole in the end of the reamer. The end of the reamer is split to allow the blades to spread or contract as the plug is screwed out and in. Shell reamers also are made on this expansion plan, as shown in Fig. 3, though in this case the threaded and tapered member which spreads the split ends of the reamer, is a bushing instead of a plug. This bushing is turned for adjustment by means of a keyed plug inserted in it, with a head flatted for a wrench. The advantage of the expansion reamer of this form is that it may be kept up to size at the point where it is most subject to wear. Besides this, the amount of longitudinal clearance is varied according to the material to be cut, so that jamming in the hole is prevented. This results from the fact that it is necessary to expand a reamer more to get a given size in soft metals than in hard metals, and this greater expansion gives the greater longitudinal clearance required. Owing to the process of using a soft body, and a hard cutting edge, the Peerless expansion reamers will stand much more expansion than the carbon steel reamers of similar design, and the builders state that they are the only expansion reamers which have as many cutting edges as the corresponding size of the solid type. Their price is about the same as that of the ordinary solid high-speed reamer.

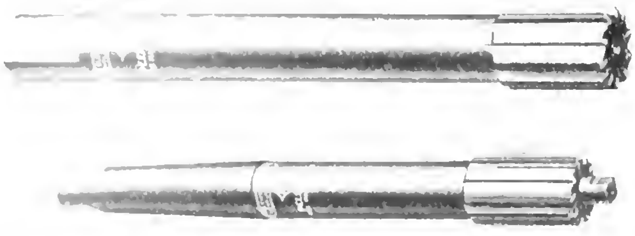


Fig. 1. Solid Roughing Reamer with Brazed Blades of High-speed Steel.
Fig. 2. Expansible Reamer with Blades similar to Fig. 1.

Fig. 3. Expansion Shell Reamer with Brazed-in Blades of High-speed Steel.

COMBINATION REVOLVING OIL-STONE AND GRINDER FOR GENERAL EDGE TOOL SHARPENING.

We have described in previous issues of MACHINERY (see New Machinery and Tools for June, 1907, and April, 1908) two forms of the edge tool sharpening machine built by Mummert, Wolf & Dixon Co., Hanover, Pa., in which the sharpening is done by a revolving oil-stone wheel in place of an emery wheel or grindstone. It is stated that tools may be ground in this way with the same effectiveness as by hand on the oil-stone, but in a great deal shorter time. The latest development in this idea is shown in the accompanying engraving, which represents a machine made by the same builders, and provided with all the various wheels necessary for keeping wood-working and patternshop tools up to a high degree of efficiency.

As may be seen, two wheel spindles are provided, of which the upper one, running at a high-speed, is provided with an ordinary emery wheel, a leather stropping wheel, and an emery cone. The lower one carries two oil-stones, one of fine grain and the other of coarser texture. The machine is driven from the upper high-speed spindle by a 2-inch belt on the 3-inch diameter driving pulley shown. This spindle is connected to enclosed spur and spiral gearing which reduces the speed of the grinding shaft (which should be about 1,800 revolutions per minute) down to 260 revolutions per minute for the oil-stones' spindle. These stones run in a dished tray, which is provided for catching the kerosene oil with which they are supplied. After the stones have once been filled with this oil, but a small amount is required daily to keep them in condition. The oil is provided by the closed oil pot shown above the cone wheel, mounted on hinges so that it may be moved out of the way when working on the upper spindle. The use of kerosene keeps the wheels clean and sharp, and prevents glazing. The wheels readily absorb the oil, and when not running appear to be dry. As soon as they are rotated at the proper speed, the oil is brought to the surface by centrifugal force. The adhesion of the oil to the stone prevents it from falling off, though oil guards are provided to keep it from flying in the case there is any loose oil in the pan below the wheel.

The outfit of wheels provided, as mentioned, covers practically the full range of tools used in the wood-working shop or pattern-shop. The grinding cone is useful for sharpening pattern-maker's gouges having inside bevels. It is conveniently placed where it can be used without interference between the tools and the oil-stones. The leather wheel, which is mounted on the large diameter of the cone, is for stropping the tools after grinding. The edge of the leather on one side of the wheel projects outward, making it possible to strop inside bevels. The periphery of the wheel is used for flat tools such as chisels, plane bits, etc. The regular grinding wheel at the back of the spindle may be conveniently used with a narrow wheel 8 or 10 inches in diameter for gumming saws, grinding molding bits, etc.

A New Design of the Mummert, Wolf & Dixon Oil-stone Tool Sharpener.

Two grades of oil-stones are provided, as described, one of comparatively coarse grain for rapidly bringing the grinding edge into shape, while the other has a very fine grain and puts on a keen, smooth edge. If the workman desires he may make use of the tool holding attachment shown, for grinding plane bits, chisels and other tools having straight edges. It may be swung up into position and set for any desired angle

of cutting edge. The blade is clamped in the holder and shifted back and forth across the face of the wheel. When not in use, it is left hanging downward where it is out of the way of the operator.

The machine is shown arranged for counter-shaft drive. The counter-shaft may be placed either on the ceiling or beneath the floor, the position of the pulley making this possible. For motor drive a different form of pedestal is provided, to which the motor is attached. This is belted direct to the pulley on the upper arbor, making a very compact arrangement.

LINDHOLM ROTARY CENTER TEST INDICATOR.

The centering of prick-punch marks, jig buttons and similar reference points in fine machining, tool-making, etc., has always been a painstaking and time consuming operation. When doing this work on the face-plate of a lathe, the operation is much simpler as it is possible to apply a test indicator to the prick-punch mark or button, and center the work easily and quickly. So far as we know, the notion of making a test indicator which would do this when the work is stationary and the spindle revolves, has not occurred to anyone before the invention of the device we show herewith. If it has occurred, the arrangement has at least never been put on the market.

Fig. 1. The Lindholm Rotary Center Test Indicator.

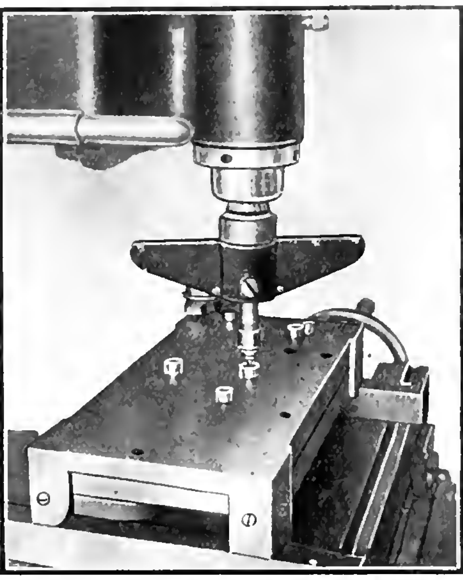

Fig. 2. Indicating the Concentricity of a Jig Button with the Spindle.

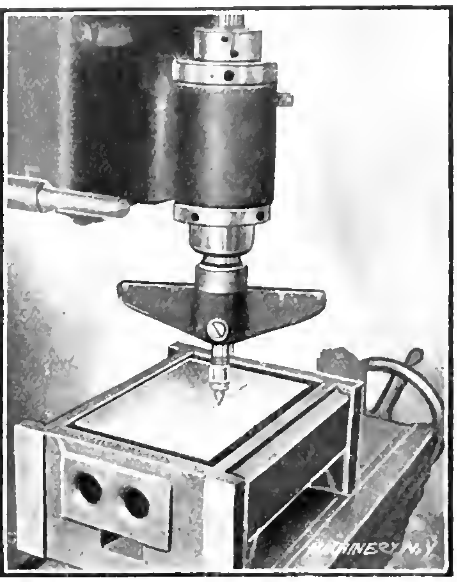

Fig. 3 Centering a Prick Punch Mark with the Spindle.

Description of the Instrument.

The indicator for this purpose here described, is made by Lindholm & Dennis, New Haven, Conn. Fig. 1 shows an exterior view of the device, while the construction is more plainly seen in the line drawing, Fig. 4. The instrument is mounted on a shank *B*, of any suitable form to be held in the spindle of the milling machine, drill press, or other machine in which the work is to be done. This has firmly screwed to it a body or frame *A*, which carries the indicating point and the multiplying mechanism. The indicating point *E* is mounted on a stem *C*, which is supported in turn in a ball joint formed in the body *A* by its spherical end, and the spherical seats in the two set screws shown. When the work is set so that the point of *E* enters the prick-punch mark or the center hole of the jig button and is pressed lightly in place by the spring supporting it, the revolving of the machine spindle in which the instrument is set, causes the stem *C* to "wobble" with reference to the body of the instrument if the axis of rotation of the spindle is not in alignment with the reference point in the work. If it is in line with the axis of rotation, the stem runs as true with the instrument as if it were solid with the body *A*. The "wobble" which takes place if the work is not lined up with the spindle, is transmitted through arm *J* (which is fast to stem *C*) through levers *K* and *L*, to the fine wire attached to the long end of the latter. This wire passes through a hole in the shank of stem *C*, where it is attached to the end of a stirrup *G*. This stirrup passes through slots in the sides of the stem, and engages thimble *D* sliding on the outside surface of *C* where it moves up and down under the influence of the stem itself, as the spindle is revolved, this movement being multiplied by the levers just described. Spring *H* keeps the stirrup and thimble normally at their lowest position, and furnishes the resistance against which the movement of the stem is transmitted through the lever mechanism.

The movement of the thimble on the shank is read by a series of graduations in the periphery of the latter. These graduations, which are 1/32 inch apart, represent thousandths of an inch of eccentricity. Of course, the advantage of having the indicating done by this thimble instead of by a pointer moving over a dial, is that the readings can be taken while the instrument is rotating. This would not be the case with a dial, as the workman would have to take readings in different positions of the spindle, stopping the latter and following it around to the indicating point for each reading. As will be shown later, it is very important that readings be taken while the spindle is revolving.

While the uses of this instrument would seem so obvious as to need scarcely any description, a number of interesting results have been observed in practical use. The device was invented a number of years ago, and has been used in at least two large establishments where the finest kind of tool-making is done, and the makers state that in these plants it has revolutionized methods in jig making, and has proved to be a great time saver and cost reducer in the tool-making department.

Uses in Tool-making and other Fine Machine Work.

In tool-making it is well known that the greater part of the time on a job is consumed in getting ready and setting up; this is noticeable, for instance, in setting a jig or fixture on a face-plate or lathe, by indicating a prick-punch mark or button centrally with the spindle. It is not necessary to explain the maneuvers gone through in strapping and clamping the work properly, balancing the face-plate, and then knocking the work back and forth to get the button or prick-punch mark central. The time required for all this on fine work runs up into the hours on even simple fixtures. The use of master plate or micrometer methods does not effect a saving of time when used in connection with the lathe, as the same preliminaries must be gone through. In handling work of such dimensions and shapes that it would be impractical to use the lathe, the milling machine is used, but this does not reduce the time expended, no matter what the method used. Accuracy is difficult, also, when using the method of locating the points by the graduations on screws, or by trying to split thousandths of an inch in vernier readings. To overcome this uncertainty, obtain accurate results,

and reduce the time employed to the minimum, this rotary indicator was designed.

The instrument is inserted in the spindle of the machine used, the pointer of the indicator is placed in the prick-punch mark or button on the work, and the exact location of the center of the button or prick-punch mark with reference to the axis of rotation of the spindle is seen at once on starting the machine. Adjusting the work so that it becomes central requires but a fraction of a minute. Releasing the indicator and inserting the boring tool requires but a short time more, and the machining operation is at once commenced.

It has been found by the use of this instrument that the same speed should be used when indicating the work as is employed when boring the hole, thereby insuring the same conditions of the machine in relation to the work when boring as when indicating. An instrument was tried on a vertical milling machine to determine the accuracy of the spindle and the table in relation to each other when the machine had been running for a certain length of time in one case, and when allowed to stand for an hour in the second case. After the machine had been running for some time it was stopped and a jig with a button placed on the table and the pointer of the indicator placed in the button, which was then indicated centrally with the spindle. The machine was next stopped for an hour, the indicator remaining in place in the button. The machine again being started, the spindle was shown to be out of center with the work by 0.0005 inch. Allowing the machine to run brought the spindle back to its former position. The time required for this was about ten minutes. This experiment was tried a number of times, and proved that the condition of the spindle in relation to the work should be taken into consideration when doing accurate work. [This was doubtless due in part to temperature changes, but perhaps more to the distribution of the oil over the surface of the journal, which is different in running conditions than when the spindle is standing still.—EDITOR.]

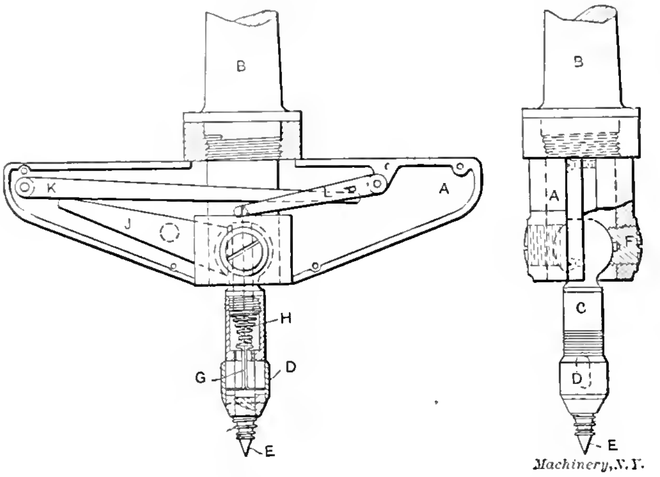

Fig. 4. Details of the Construction of the Instrument.

Another experiment was tried to determine what effect a light blow would have on the table. A lead hammer was used, striking very light blows. This was found to alter the setting from 0.0025 to 0.0005 inch, showing that a slight jar would have a tendency to change conditions. All clamps and stops were securely fastened during this test.

In Fig. 2 is shown a jig with the buttons in place, located on the table of the milling machine. The point of the rotary indicator is placed in the button and the machine started. The indicator revolves with the spindle, and the thimble moves up and down showing just how much the button is out of center with the spindle. The table is then adjusted until the thimble is at a stand-still. The time required need not be more than 20 seconds. The instrument is removed and a boring tool inserted, the same speed being used as when indicating. In Fig. 3 the same vertical milling machine is shown, but instead of using a button, a small prick-punch mark has been made at the intersection of two lines, and the point is placed directly in this. The time required to indicate is about the same as for the button, and the accuracy of the operation depends entirely on the question of the accuracy of the tool-maker in placing the prick-punch mark. The indicator will locate the latter exactly in line with the spindle. Fig. 5 shows the rotary indicator in place in the horizontal milling machine. Here the instrument revolves about the horizontal axis and the thimble oscillates to and fro.

The device can, of course, be used on other tools—on the drill press, for instance, with the indicator in the spindle and the pointer in a prick-punch mark. In this case the work is done under somewhat the same difficulties as in the lathe—that is, a hammer or mallet must be used to bring the work central. The indicator can be used in the lathe tail-stock as well as in the spindle. It will be noted that any form of shank convenient can be used for this instrument. Figs. 2, 3, and 5 show a straight shank screwed into the body of the instrument, which is held by a collet in the spindle of the machine; Figs. 1 and 4 show a taper shank.

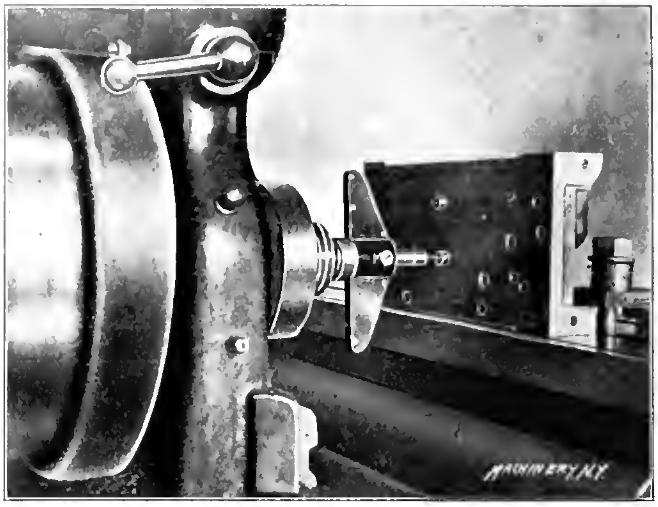

Fig. 5. Use of the Indicator in the Horizontal Milling Machine.

HIGH-FRAME WHITNEY POLISHING JACK.

In the department of "New Machinery and Tools" of the March, 1907, issue of MACHINERY, was illustrated the Whitney polishing jack, built by the New Britain Machine Co., of New Britain, Conn. The essential feature of this jack was that it was designed to be belted from below, the belt passing through the frame and through the floor, to the line shafting on the ceiling of the floor below. No counter-shaft was required, the machine being arranged for starting and stopping by raising and lowering the spindle, and thus tightening or releasing the belt. This arrangement makes a machine which may be handled by even female help with ease and safety. So far as the operation of the machine is concerned, there is also a great advantage in belting downward, as the pressure is taken against a solid bearing instead of upward against a box cap. This gives a steady running spindle.

Fig. 1. Whitney High-frame Polishing Jack, made by New Britain Machine Co.

The new Whitney "high" polishing jack shown herewith, may be used with the operator standing, or seated on a high stool. The starting and stopping of the spindle is done by means of the toggle lever shown at the front; raising it lowers the hinged plate on which the spindle boxes are mounted, and thus loosens the belt, at the same time bringing the pulley down against a brake block and stopping it at once. This

relaxes the belt as well, greatly lengthening its life. By the use of this brake, a heavy emery wheel 14 inches in diameter by 2 inches wide can be stopped from full speed in three seconds. The pressing down of the lever raises the arbor again and tightens the belt into working tension. The lever and the attached link passes by the dead center enough to lock it in position. There is no possibility (as there is with a shifter) of having the belt run off and of being obliged to start slowly on this account. There is, in fact, very little to accelerate on this machine, so that the starting is done in a very short space of time. An ordinary leather-covered wooden polishing wheel, of course, requires less time. Where frequent changes of wheels are to be made, as is quite necessary in the general run of polishing work, this question of quick stopping is an important one.

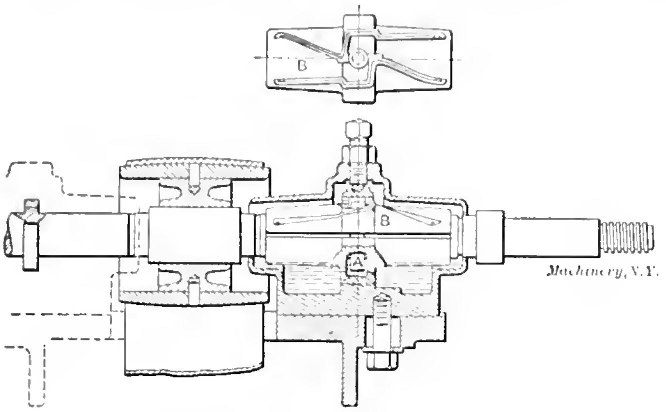

Fig. 2. Design of Spindle and Bearings.

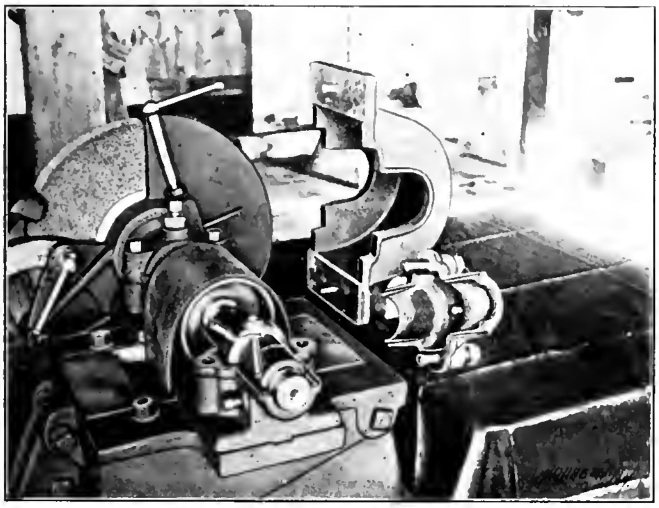

Fig. 3. Belt-cover, Bearing Cap, and Upper Half of Box removed.

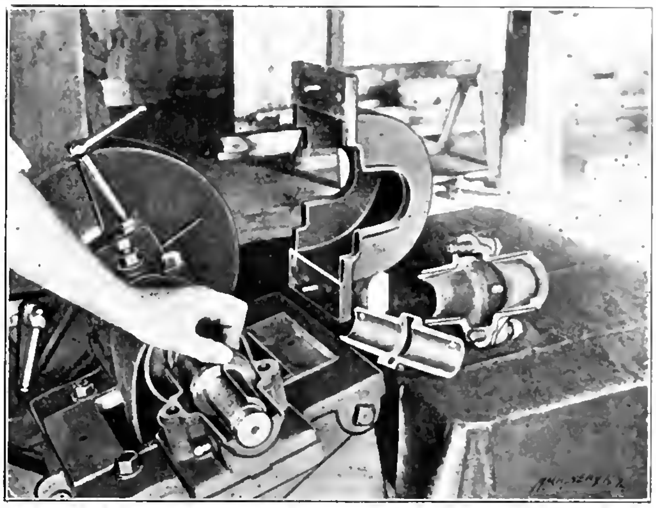

Fig. 4. Removing the Lower Half of Box.

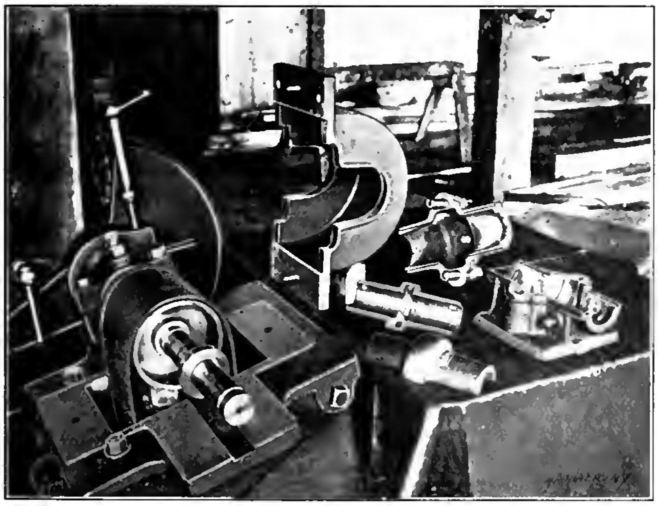

Fig. 5. Removing the Outer Bearing.

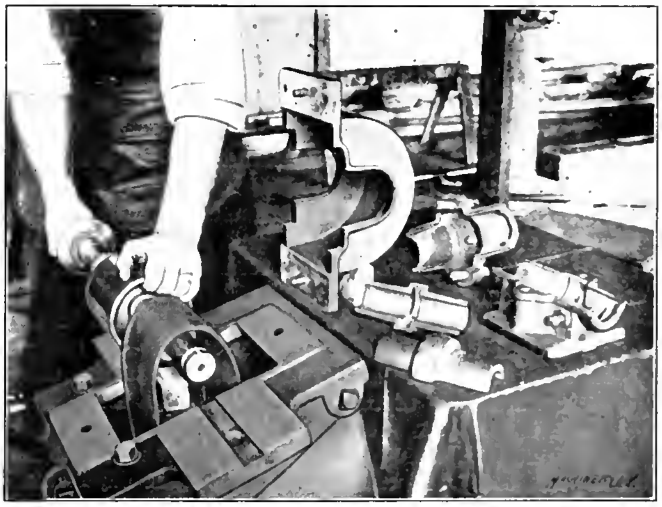

Fig 6. Removing the Spindle.

The line drawing, Fig. 2, and the views in Figs. 3 to 6, which show the dismantling of the head, illustrate the oiling arrangements. The bearings are made in halves, as shown, with a central recess in which is confined a collar A solid with the shaft. These collars take up the end thrust. They run in a reservoir of oil which is conveyed to the top of the upper box *B*, where it escapes through the horizontal openings at one side or the other, depending on which side of the shoulder is receiving the thrust. From whichever side of the collar the oil is delivered it is led by ducts, as shown, to oil holes at each end of the bearing. By cutting open the casing of the bearing, it has been found that the oil ways and oil holes are entirely full immediately on the starting of the spindle, and the flow continues without intermission as long as the spindle runs. No more than the proper amount of oil can be gotten into the reservoir, as the self-sealing oil covers are situated at the proper height to receive and hold a definite amount. The end thrust collars being located inside the box, have their oil throwing tendency thus put to good instead of evil uses. The spindle may be run in either direction, the only change necessary being to turn the tops of the boxes around so that the arrows cast thereon will point in the direction of the desired rotation. The shafts are ground and the boxes are made of gray iron. This, with the copious lubrication provided, gives a glazed bearing of a kind that is very durable. The bearing, as may be seen plainly in Fig. 2, is self-aligning, and accommodates itself to any possible spring or vibration at the high speeds prevalent in polishing practice.

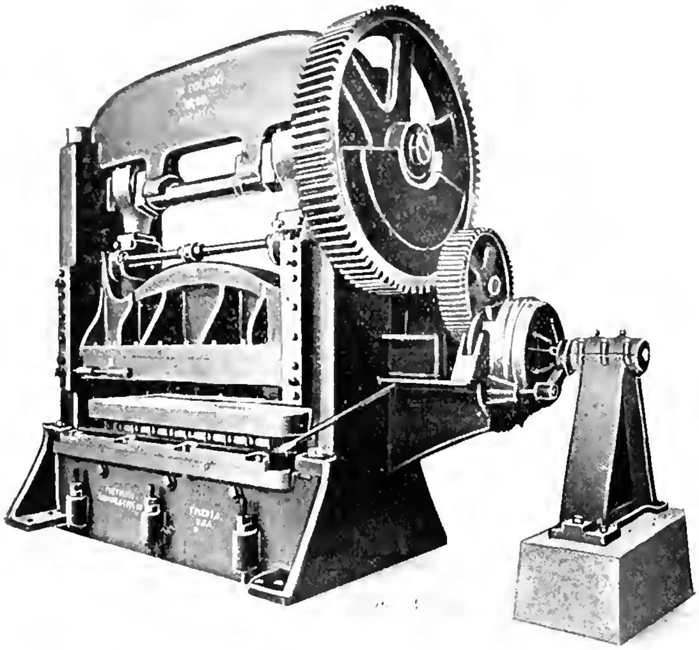
Figs. 3 to 6, which show the successive operations in dismantling the head, give a good idea of its construction. The removal of two bolts in the cap, as shown in Fig. 3, permits the latter to be removed and allows the upper half of the box to be picked off from the shaft. The lower half of the box may be tipped around and pulled out from the under side, as shown in Fig. 4. The bearing pedestal may now be slid out endwise on one side (see Fig. 5), and the whole spindle, bearing box, and wheel frame removed from the other

side. All this is done as may be seen in Fig. 6, without removing the belt, which is then enough slackened to permit relacing.

It might be mentioned in connection with this design of frame that the insurance requirements are fully met, as in the case of fire there is nothing to burn and there is really no communication between the floors through the belt holes, as the joint between the base and the floor prevents the water from passing downward, or fire from working upward. It is not necessary to have the line shaft on the floor below, as a low platform may be built to contain it and the form of hanger used that allows the driving pulley to revolve partly in the frame of the machine. This will call for but little rise above the general floor level.

TOLEDO HEAVY SINGLE-ACTION DRAWING PRESS.

The press shown herewith, built by the Toledo Machine and Tool Co., Toledo, O., is designed for very heavy drawing, on work of comparatively shallow form, having been originally designed for making seamless casket covers. It is applicable, of course, to any work of a similar nature. The operation consists in first placing a plain flat piece in position on the dies. The press is started by the friction clutch shown, and the descending of the ram, at a single stroke, clamps the work and draws it to the desired form. The resulting blanks are practically free from wrinkles and buckles.



Single-action Press for Large, Heavy, Shallow Drawing.

The pressure ring shown in the illustration rests on studs or pins around the exterior of the lower die. On this ring the flat sheet is placed. As the ram comes down and strikes the work laid on top of the pressure ring, the latter is carried down against the pressure of the studs or pins, which are supported by a heavy spring arrangement in the interior of the press bed. The tension on this ring is adjustable by means of six studs mounted on the outside of the base, three of which show in the illustration. These serve to adjust the spring pressure from the outside, it being thus unnecessary for the operator to get down under the press bed. A special foundation has to be provided for the machine, so constructed as to provide a pit under the press for the attachments, and for that portion of the bed which projects below the floor line.

Two men only are required to operate the machine—one operator and a helper. It is stated that the placing of the work in the press, the forming of the shape, and the removal of the finished work can be completed in ten seconds. A desirable feature of this die is the fact that it is made adjustable for a number of lengths of covers or tops, without removing either the upper or lower members from the machine. This is particularly advantageous on work of this kind, owing to the enormous size and weight of the parts.

The complete weight of the press is about 85,000 pounds. It takes in 102 inches between uprights and has a table 52 inches wide from front to back. The stroke is 12 inches. With stroke and adjustment up, the distance from the bed to the bottom of the slide is 27 inches.

NORTHERN TYPE "S" VARIABLE SPEED MOTOR.

The direct driving of machine tools by electric motors has developed in the past few years to such an extent as to result in a radical development in motor design, to meet the requirements of this work. Prominent among these requirements is that of variable speed, which is advisable to avoid complicated mechanical construction, and which is also used in connection with the mechanical changes for giving finer gradations of speed. There are well-known difficulties met in connection with the attempt to build a variable speed motor, even with the design in which the variation is obtained by inserting resistance in a shunt field circuit. The chief difficulty is the sparking met with at the extremes of the speed changes, particularly at the highest speed, when the field has been weakened. This sparking is due to the distortion of the magnetic field by the armature reaction, which increases the voltage between the adjacent bars of the commutator as they pass under the brush. The particular point of improvement in this new type "S" motor is the construction of the magnet core, which greatly reduces this distortion of the field, permitting a wide variation without any trouble at the commutator.

Fig. 1 shows the motor as a whole, while Fig. 2 shows the peculiar construction of the field. Each pole, it will be seen, is made in two parts with an air gap between. The whole field itself is built up of punchings of the shape shown. When the field is weakened and the effect of the armature reaction is therefore at its greatest, there is very little shifting of the field, owing to the reluctance of the air gap between the two sides of the pole pieces, which effectually prevents one stream of magnetic force lines from passing over into the path of the other. The lines thus travel nearly straight to the pole faces, at an even density, where the small inwardly projecting tips permit them to expand and distribute themselves fully over the entire air gap. The magnetic circuit from pole to pole is shown in Fig. 2. It should be particularly noticed that while the pole pieces are in halves, the magnetic circuit in each quarter is complete, without joints, as each one includes in itself a north and south pole.

This arrangement of the magnetic circuit lends itself readily to effective and simple mechanical construction, as it is possible to construct the entire magnetic circuit of the motor from soft sheet steel stampings. This increases the magnetic efficiency, as all joints are eliminated, and the possibilities of blow-holes and other defects are avoided. For this reason, therefore, less section is required, with a consequent reduction in weight, while the material used is of the kind

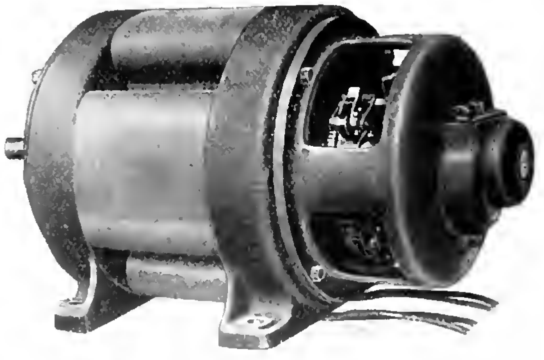


Fig. 1. New Variable Speed Motor made by Northern Electrical Mfg. Co.

best adapted to respond quickly to changes in full strength, owing to its low hysteresis. The laminated construction also prevents any eddy currents from being set up in the pole faces. All of these points are especially desirable in a motor for use in variable speed work. The construction, in addition, lends itself readily to special ratings, as the length of the machine can be so increased as to span the gap in ratings between successive frames, as it is simply necessary to stack up the proper width of armature and field punchings to give a motor of the size required. Before being finally secured together, the whole mass is placed under hydraulic pressure and compressed, where it is held rigid while the retaining rivets are set. The end flanges are machined and tapped for the bearing frames.

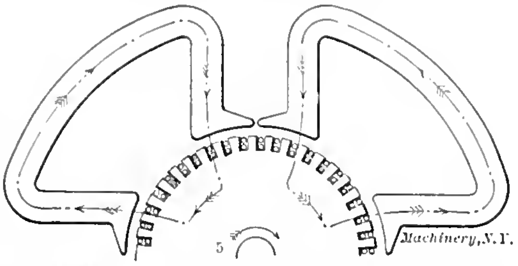

Fig. 2. Diagram showing Split Field Magnet Core which prevents Field Distortion.

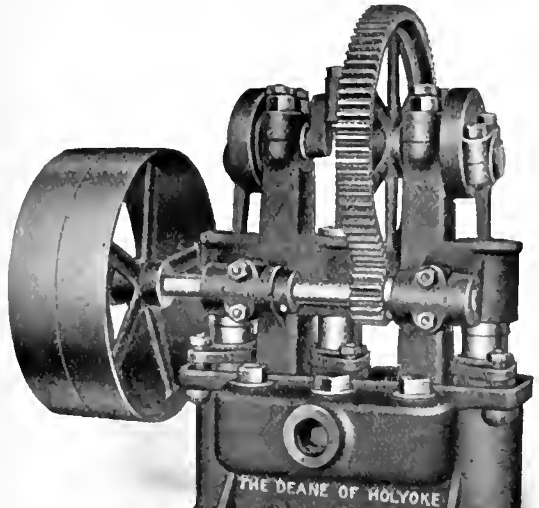
The armature is of the characteristic type made by this firm. It is wound with machine formed coils and has a commutator of hard drawn copper bars. A box type brush holder is used, with easy means of adjusting the tension on the brush and for removing it for inspection. The bearings are of the self-aligning type. The motor will be furnished in the enclosed form when desired. It is especially efficient under these conditions, as the laminated construction reduces the eddy-current heating to a minimum, and the nature and extent of the exposed surface are such as to greatly assist in the dissipation of the heat generated by the internal resistance.

These motors are built by the Northern Electrical Mfg. Co., Madison, Wis. They are made in sizes up to 50 horse-power, under constant speed, with a wide range of adjustable speed ratings up to 6 to 1 in regular designs, and with even larger ratios under special conditions.

DEANE TRIPLEX POWER PUMP.

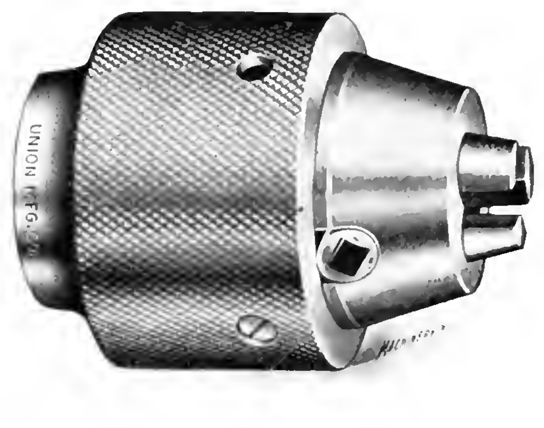
The accompanying illustration shows a power triplex pump put on the market by the Deane Steam Pump Co., of Holyoke, Mass. Special pains have been taken in the design of this machine to make it simple, compact and rigid, and particularly to make it entirely accessible for inspection and adjustment in all its parts. The crank and pinion shaft bearings and the connecting-rod bearings are adjustable for wear. The crank-shaft and connecting-rods are drop forged. The stuffing boxes, which are unusually deep, are of the stud gland type. The design of the frame is such as to afford an unusual amount of room for repacking the plungers, which, it will be seen, is done from the outside. Each valve is separately accessible through a quickly-removed hand-hole cover. The valves are of rubber or bronze, depending on the service for which the pump is required. A drip flange is carried all around the pump at the top of the water cylinders to catch leakage from the plungers, and any oil which may run down over the frames from the working parts. The machine is supplied regularly with tight and loose pulleys, as shown, but may be fitted with double gearing and a special base for direct connection to a motor, at a slight additional cost.



Deane Triplex Power Pump.

UNION GEARED DRILL CHUCK.

The accompanying engraving shows a geared drill chuck which has just been placed on the market by the Union Manufacturing Co. of New Britain, Conn. It is called the "Union geared drill chuck." In its general construction it is the same as the "Czar drill chuck," made by the same builders for many years. The parts are of steel, and the standard of workmanship followed in the old chuck is carried out in this new one. The improvement in construction is the provision of a pinion meshing with a circular rack for rotating the knurled sleeve with a key, instead of by grasping it by hand, as was necessary in the former construction. This has the well-known advantages of tighter gripping possibilities, and of making it unnecessary to hold the spindle with one hand while the tightening is done with the other. The particular construction followed in incorporating this improvement gives a pinion enclosed within the body of the chuck, which the builders believe is superior to the construction in which the gearing is outside, or in which the pinion is part of the wrench, as it insures perfect alignment of the pinion with the rack, and also avoids unnecessary wear of those parts.



Geared Drill Chuck with Enclosed Pinion.

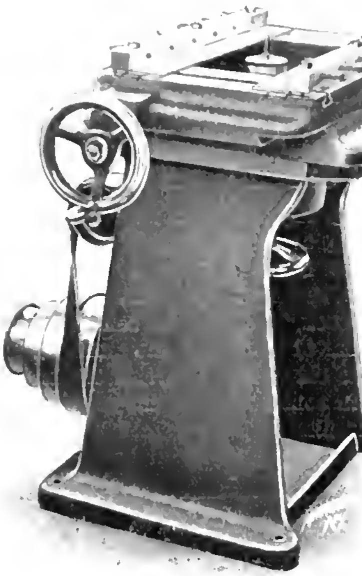
BILLINGS & SPENCER MILLING MACHINE FOR DIE CUTTING.

The Billings & Spencer Co. of Hartford, Conn., is building the specialized form of milling machine shown herewith for making trimming and punching dies. It was developed originally for the making of these dies, in the shops of the builders, especially for drop forging work, but it is, of course, as useful for making the trimming and punching dies used in sheet metal work.

The salient feature of the machine is the inverted spindle, in combination with a work table provided with screw and hand-wheel movement in two directions. With this construction, by using a mill tapered to give the amount of draft desired for the die, the latter may be clamped in the chuck jaws shown on the table, and be worked out to fit the outlines scribed upon it, in such a way that the operator can follow the action of the cutter along the line with nothing to interfere with his vision. This is more convenient for this particular work than the ordinary vertical spindle milling machine, in which the cutting through has to be done blindly with the design on the lower side of the work, or has to be

done by the expedient of employing a mill having a reverse taper—that is, a larger diameter at the end than at the shank. Even when using such a mill, however, the cutter spindle obstructs the vision of the operator more or less.

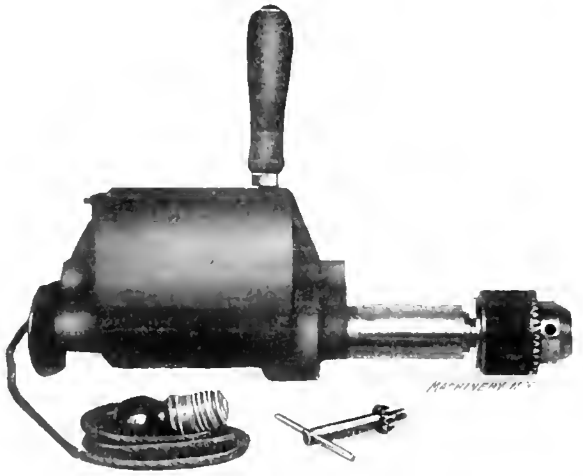
With this machine, the operator stands at the front, where he can control the movement of the work by the two cross-slide hand wheels, one on his right and the other on his left. The inverted spindle holding the cutter is placed in the opening of the heavy universal carriage. The construction of the spindle is such as to hold the cutter very rigidly, at the same time allowing it to be easily removed or replaced by the operation of the hand-wheel located at the base of the spindle, and partially seen in the engraving. In removing the cutter, the turning of the hand-wheel releases it and at the same time forces the collet outward, acting as a positive ejector. The spindle is provided with an efficient oiling system, insuring perfect lubrication to all the bearings. Four collets (⅜, ½, ⅝, and ¾ inch diameter) are furnished with the machine.



An Inverted Milling Machine for Die Work.

WILLEY PORTABLE ELECTRIC BREAST DRILL.

The drill shown herewith is made by the Willey Machine Co. of Jeffersonville, Ind. The main feature of the design is the simplicity of its construction; this is a matter which has to be carefully considered in making a machine which will be durable under the rough usage to which tools of this kind are often subjected in service. But two gears are used, both cut from solid bar steel. The drill spindle has two long bearings, with removable bushings of high grade phosphor bronze, in place of the single short bearing often met with in drills of this type. Owing to the low speed of the motor, the wear on the commutator, bushings, gears and bearings is comparatively slight. By simply removing two nuts the entire machine can be taken apart by any ordinary mechanic for inspection of the enclosed mechanism, no electrical knowledge being necessary. All these points tend toward increasing the durability of the tool, and facilitate inspection and maintenance.



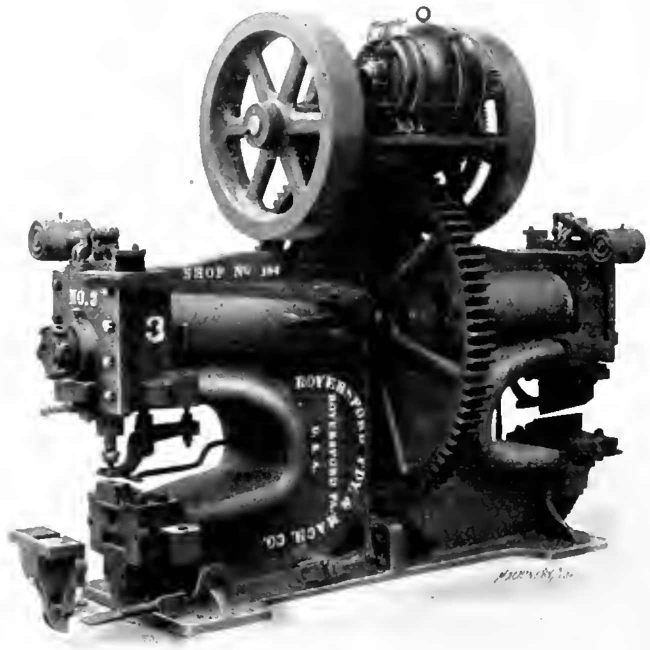
An Electrical Breast Drill of Simple Design.

All the electrical connections are attached to the main casing of the machine, and are not disturbed when it is taken apart for any purpose. A snap switch is located on the side of the frame, convenient for starting and stopping the drill. Special attention has been given to ventilation, insuring cool running and high efficiency of the motor. A system of air ducts has been provided in the armature for this purpose similar to those found in larger electrical apparatus.

The tool is made in four sizes, having a maximum capacity of ¼, ⅜, ½, and ¾ inch respectively in steel, the largest of these having two speeds. The motors are wound for either direct or alternating current and for any voltage up to 250. The side handle shown can be quickly attached or removed as required by the work in hand.

ROYERSFORD COMBINED PUNCHING AND SHEARING MACHINE.

Royersford Foundry and Machine Co., Royersford, Pa., has recently gone into a heavier line of punching and shearing machines than it has built for some years past. Having found a constant call for heavier work, the builders have designed the No. 3 punch and shear shown herewith, which is made with either 26- or 32-inch throats on both sides, with the added provision of a 4-inch extension on the punch side, which gives a depth of 30 or 36 inches at this point.



Combined Punch and Shear for General Work.

These machines are suitable for general structural work, railroad shop, machine shop and boiler works purposes. They are of compact design and of simple construction, requiring very little floor space. Each side is independent of each other, but both sides can be operated together. The removable lower jaw on the punch side makes the machine very convenient for punching I-beams and channels.

The shearing capacity of the tool is for work up to 10 inches wide by 1 inch thick on flat stock, and 2 inches diameter for round stock. The capacity of the punch is for holes up to 1½ inch in diameter in 1-inch plate. The machine with a 26-inch throat weighs 18,000 pounds, and with the 32-inch throat 21,500 pounds.

UNIVERSAL HACK-SAW FRAME.

The adjustable hack-saw frame built by the West Haven Mfg. Co. of West Haven, Conn., has recently been improved, resulting in the design shown in the accompanying illustra-

tion. This form the builders call their "1908 universal hack-saw frame."

This frame has been designed to meet the demands for increased length and lightness. It is made of a high quality of crucible steel 3/4 x 3/16 inch in section, highly nickled and polished. The small parts are case-hardened. The special feature of the design is the provision for adjusting the length of the frame for different sizes of blades. An improvement in this new model is the accurate graduations provided for setting the frame for these adjustments. The spaces are all marked for different lengths so that the proper position may be obtained at once. Another special feature is the fact that the blade is held in place by a knurled nut, so that it is impossible for it to fall off the pins when the strain is relieved for the purposes of adjustment. The blade is arranged to cut in four different positions without removing it from the frame.

Adjustable Graduated Hack-saw Frame

The distance from the bottom of the frame to the cutting edge of the saw is 3⅛ inches. The handle is 1⅜ inch in diameter, and 4⅛ inches long. The list price is $1.00.

CUTLER-HAMMER MACHINE TOOL CONTROLLER.

We show herewith, in Figs. 1 and 2, a drum type machine tool controller which has recently been brought out by the Cutler-Hammer Mfg. Co., Milwaukee, Wis. The most noticeable feature of this controller is the fact that it is mounted in the same case with both the armature and field resistances, making unnecessary any special provisions for these pieces of apparatus, with the complicated connections which would otherwise be required, and which would have to be made after the apparatus is installed.

Fig. 1. Front View showing Armature Resistance.

Fig. 2. Rear View showing Field Resistance.

Fig. 1 is a front view of this new type of controller, and shows the removable resistance units mounted in the lower half of the frame with insulated wires running from each unit to metal contact fingers in the upper part of the device. These units constitute the armature resistance, and are employed for starting duty only. Fig. 2 is a rear view of the same controller, and shows another type of resistance unit, also removable, mounted in the back. The four units shown herewith constitute the field regulating resistance. They are each divided into five steps, giving twenty contact points in all, providing a range of variation in speed of from 2 to 1 to 3 to 1.

These controllers are made for both reversible and non-reversible motors, ranging from 1 to 7½ horse-power, and are designed for use on either 110 or 220 volt direct current circuits.

Garvin Machine Co., Spring and Varick Streets, New York. Milling machine with extra long feed, designed for work requiring long cuts; in other particulars similar to the No. 15 plain milling machine built by the same firm.

Henry Koch & Son, Nyack, N. Y. Test indicator suitable for general use in centering work in the chuck, lining parts in erecting machinery, testing workmanship, and other similar operations.

Williamson Vise Co., Bradford, Pa. Tilting drill press table for use in connection with any standard form of drill press. The square platen of this vise can be tilted at any angle from the vertical to the horizontal to permit the drilling of holes at any angle required.

H. A. Stocker Machinery Co., Chicago, Ill. The Rearwin emery wheel dresser having wheels with cutting blades arranged in spiral form so that they over-lap each other and make a continuous cut on the wheel. The teeth are said to be self-sharpening.

H. O. Costello, 87 Oakland Avenue, Providence, R. I. Quick adjusting micrometer in which, by means of a ratchet arrangement, the barrel is adjusted rapidly for position without requiring the thread to be screwed the whole length of the adjustment.

American Gas Furnace Co., 24 John Street, New York. Heating machine intended especially for tempering and coloring steel parts. It is made in the form of a tumbling barrel, uniformly heated, and provided with gas and air valves and a thermometer so that the temperature can be controlled accurately.

William P. Stein & Co., Rochester, N. Y. Surface grinding machine of the type in which the work to be ground is moved by hand over a flat table beneath the wheel; it is especially adapted to the sharpening of dies. The table is provided with grooves for catching loose emery.

New Departure Mfg. Co., Bristol, Conn. New Departure "Two-in-One" annular ball bearing. This bearing gets its name from the fact that it is designed to sustain both radial and thrust loads. In the compact type of double bearing, the balls are spaced by a sheet metal separator which preserves the relative position on all the balls in both races.

Baird Machine Co., Oakville, Conn. A tilted revolving barrel for drying small parts of wire or sheet metal in hot sawdust after being subjected to a wet tumbling or plating process. This barrel has double walls and is steam heated, the operation of emptying it being accomplished in the same way as with the builders' tilting tumbling barrel.

Higley Machine Co., 91 Liberty St., New York City. Revolving table type cold-saw, which may be set at any angle for cutting structural shapes, etc. It is provided with a friction feed which is so regulated as to automatically proportion the power of the cut to the resistance offered, thus saving the saw from being injured by a forced feed.

Rockford Tool Co., Rockford, Ill. Twentieth century balance tester for balancing pulleys, armatures and other rotating parts, in place of using parallel straight edges. The shaft is supported by four knife edge disks of large diameter, rotating on ball bearing pivots. The frames are adjustable to suit work of different lengths.

John B. Morris Foundry Co., 933 Harriet St., Cincinnati, Ohio. The Schellenbach lathe which we have previously il-

lustrated as the complete geared head type in our June, 1908, issue, but with the cone head and plain change gear mechanism substituted for the original geared changes. Otherwise, it has the same special features of taper attachment, improved carriage construction, etc.

Massey Vise Co., 176-178 S. Clinton St., Chicago, Ill. Parallel bar vise in which the parallel bars are fast to the removable jaw, and pass through widely spaced bearings in the stationary jaws, being connected by a yoke at the rear which slides on ways on a fixed guide attached to the movable jaw. This gives a support for the full length of the sliding jaw at all times.

Kinsler-Bennett Co., Hartford, Conn. Two new types of universal joints; one of these is a form of the regular double fork and central block type, provided, however, with a shell which covers and protects the joint. In the other the construction has been modified, the fork of one member having a closed end, encircling the block, while the other member is in itself a shell which serves to cover the mechanism.

Morrow Mfg Co., Elmira, N. Y. A ball bearing drill chuck. The jaws are forced down on the work by being pressed outward through a taper sleeve. The thrust of the tightening is taken by a ball joint, making it possible to get a very strong grip with comparatively little twisting action, as the work lost in friction is minimized by this construction.

E. W. Bliss Co., 5 Adams St., Brooklyn, N. Y. Large presses for making side seams in cylindrical work. This is a modification of the horn type of press; in this case, however, the horn is placed parallel with the crank-shaft of the double frame press, the work being inserted through an opening in the side of the press. It will press seams in work up to 30 inches in diameter and 40 inches in length.

F. E. Reed Co., Worcester, Mass. A special lathe for manual training and pattern work, driven by a motor mounted in the cabinet base. The motor has a 3-step cone mounted in the armature shaft which is bolted directly to the spindle cone, the bed being of such form as to make this possible. These lathes are furnished with a complete outfit of accessories necessary for manual training and pattern work.

Messrs. Edward Brown & Son, 311 Walnut Street, Philadelphia, Pa. A portable pyrometer of the type in which a thermocouple is applied at the point where the temperature is to be measured, and the leads are connected with a sensitive volt meter to indicate the temperatures. For low temperatures a couple of heavy nickel allow or tungsten is used. This has a fusing point of 2,700 degrees Fahr. At higher temperatures a platinum-rhodium couple is used.

Armstrong-Blum Mfg. Co., 113 N. Francisco Ave., Chicago, Ill. Marvel draw-cut hack-saw. Its characteristic features are the use of the draw-cut principle, and the provision of a spring tension appliance to bring pressure on the blade during its cutting stroke, which is relieved on the return. An automatic trip is provided for stopping the mechanism when the cut is finished. The machine has a strongly built frame and has a capacity for cutting stock up to 4 inches by 4 inches.

C. S. Bonney, Irvington, N. J. Automatic reversible taper for use in tapping small holes up to 5/16 or 3/8 inch. The device is used in connection with a drill press or lathe, and is operated in the same way as a friction-driven reversing tapping machine. The main spindle runs constantly in one direction, the reverse being provided for in gearing within the attachment itself. The stopping and reversing of the tap are automatically effected at any desired depth by the setting of the stop provided.

Western Tool & Mfg. Co., Springfield, Ohio. Champion combination tool holder. This holder is provided with blades and attachment which allow it to be used as a straight turning tool, side turning tool, boring tool, key-seating tool and in other combinations. The shank is a steel drop forging, case-hardened, as are the various other parts of the device. It is furnished complete for all the combinations of which it is capable, or with a selection of parts to make up any possible combinations desired.

Oesterlein Machine Co., Cincinnati, Ohio. Vertical milling attachment designed for use with the builder's No. 30 universal or No. 34 plain milling machines. It is designed to take as heavy a cut on the vertical spindle as can be taken on the main spindle, without chattering or other signs of distress. The attachment, which is adjustable to any angular position about the axis of the spindle of the machine, is strongly attached to the frame, being clamped both to the face of the column and to the overhanging arm.

Olney Machine Works, Philadelphia, Pa. An automatic cutter grinder for the grinding of either straight or spiral toothed end mills, cutters, etc. The machine incorporates provisions for automatically reciprocating the table and the work mounted on it, and for indexing the latter. The spiral attachment is very simple and easily adjusted, being made somewhat on the plan of the taper attachment for the lathe. The emery wheel may be set at any angle to suit the requirements of the tooth being ground.

John Steptoe Shaper Co., Cincinnati, Ohio. A motor-driven shaper of very compact arrangement, in which the working parts do not extend out beyond the space occupied by the ordinary cone-driven shaper. The machine was originally designed for use on a United States revenue cutter. A variable speed General Electric motor is used which is connected with the crank-shaft by a gearing which gives two changes, the range of strokes per minute being thus obtained partly by mechanical and partly by electrical means.

Potter & Johnston, Pawtucket, R. I. Line of screw shaving and turning machines made in three sizes, the largest of which takes 3 inches in diameter through the spindle quill. The collet is operated by a pilot wheel, making it possible for the operator to perform all the movements necessary without leaving his position, even on a machine as large as this. The carriage carries a cross slide on which are mounted two tool slides. Both cross slides and tool slides are operated by levers, and all the movements provided with stops. The carriage is adjustable on the bed by means of a hand-wheel and screw to suit work of different lengths.

Rockford Drilling Machine Co., Rockford, Ill. Portable engine lathe mounted on trucks and especially designed for fitting and erecting, or for any operation where it is most convenient to take the lathe to the work. A counter-shaft and electric motor are mounted beneath the bed of the lathe. A two-speed change is provided in the head-stock, giving a slow speed for turning and a higher one for filing and polishing. This in combination with the five-step cone pulley in the counter-shaft gives ten speeds. A turret tool post is provided on the carriage so that any one of four tools is instantly available for use.

Bullard Machine Tool Co., Bridgeport, Conn. Boring and reaming bar for finishing cored holes and special grinder for keeping the cutters in condition. This boring bar has two openings at right angles to each other, one of square stock for the single pointed cutters, and the other for the floating double-ended boring blades. As shown used, the first cutter is a chamfering tool which cuts the scale away to permit the following tools to cut true and even without being thrown out and dulled by the rough scale. Roughing and truing blades follow in succession, and then a sizing cutter of the double-ended type which floats in a slot in the bar is used for bringing the hole almost to the size of the finishing cutter, which acts as a reamer. This finishing cutter is provided with a slot and a taper hole by means of which its size may be adjusted as it wears. The grinding machine provides for grinding cutting edges of the proper angles for all of these cutters.

ANNUAL CONVENTION OF THE NATIONAL MACHINE TOOL BUILDERS' ASSOCIATION.

The seventh annual convention of the National Machine Tool Builders' Association was held at the Hotel Imperial, New York, October 20 and 21. The association now has ninety-five members, four new concerns having been admitted since the June meeting. These are: C. H. Allen & Co., Barre, Mass.; Powell Planer Co., Worcester, Mass.; Barnes Drill Co., Rockford, Ill.; and W. E. Gang Co., Cincinnati, Ohio.

The matters of general interest to people outside the association, brought before the meeting were the papers: "A Review of the Department of Commerce and Labor's Report on the Conditions of the Machine Tool Industry in Continental Europe," by Captain G. L. Carden; "Different Plans of Paying Employes with the Advantages and Disadvantages of Each Plan to Employer and Employe," by Mr. Harrington Emerson; and "The Commercial Side of the Machine Tool Industry in Europe and a Review of European Conditions," by Mr. J. W. Carrel.

Captain Carden made a tour of European manufacturing plants during the past year, acting as special United States agent to investigate the conditions as regards foreign market for American machine tools. His paper was a general review of the situation and briefly summarized the articles published in the *Daily Consular Reports*, issued by the Department of Commerce and Labor, Bureau of Manufacturers, Washington, D. C. These reports will be prepared in monograph form later for general distribution. Captain Carden spoke of the strong competition rapidly developing in Germany, and emphasized that in his opinion Germany would be America's chief competitor in the manufacture of machinery and machine tools in the future. From being an importer of machine tools in large quantities, Germany has rapidly risen to the position where in 1907 it exported over 52,000 machine tools to twenty-three countries, reaching practically every country on the globe. He spoke enthusiastically of the great educational effect of the military training imparted in the German army service, and the resultant effect on industrial conditions. He earnestly advised the members of the association to take action with the view of providing for further stimulation of our foreign trade in machinery in every legitimate manner, and suggested that the policy of exporting men with the machines was one that should be followed more than it has been in the past. At the conclusion of this paper Mr. Doan, of the American Tool Works Co., Cincinnati, Ohio, made a motion to have a committee of twelve machine tool builders appointed to visit Washington and confer with department officials on the matter. This motion was carried.

Mr. Emerson's paper was the subject of warm discussion, there being the usual differences of opinion among specialists who have studied the production problem and reward for labor from the side of the manufacturers, devising ways and means by which workmen can be induced to produce more for a living wage. The sentiment was that the great difficulty confronting any scheme for fixing wages is the practical impossibility of determining what is a maximum day's production. The changes and improvements constantly developing in machine shop practice and machine tools makes a constantly changing state as regards labor and labor reward. For example, the introduction of high-speed steels in many cases reduced the time required for certain work to half or even a quarter the time required for the same operations using carbon steel.

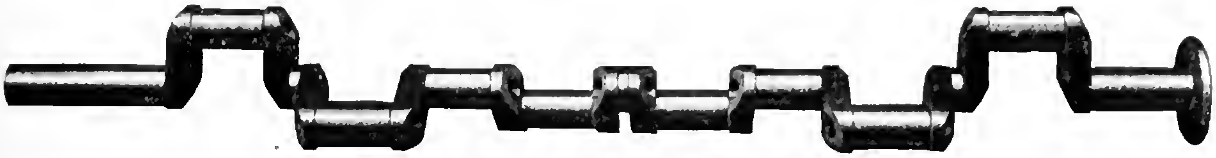
Mr. Carrel's paper was also a review of European conditions as seen by him on a tour of investigation in machine tool shops. The consensus of these reports, and of those furnished by Mr. Oskar Kylin in MACHINERY, seems to be that which practically all fore-sighted manufacturers had already seen, that is, European builders would eventually reorganize and equip their shops along American lines. So well has our example been imitated in certain cases that American competition already is almost hopeless when our high tariff, high wages, and ocean freights are considered.

All the officers were re-elected, being as follows: President, Fred L. Eberhardt, Gould & Eberhardt, Newark, N. J.; first vice-president, C. A. Johnson, Gisholt Machine Co., Madison, Wis.; second vice-president, E. P. Bullard, Jr., Bullard Machine Tool Co., Bridgeport, Conn.; secretary, P. E. Montanus, Springfield Machine Tool Co., Springfield, Ohio; treasurer, W. P. Davis, W. P. Davis Machine Co., Rochester, N. Y.

* * *

A NOTABLE CRANK-SHAFT JOB.

The illustration shows a six-throw crank-shaft, forged and finished complete at the Chester Works of A. P. Witteman & Co., Philadelphia, Pa. It was made for the Chadwick Engineering Works, and was installed by this concern in the racing launch built for Mr. Herbert Austin, of Boston, Mass.



Six-throw Chrome-nickel Crank-shaft forged with Bearing between each Pair of Crank-webs.

The forging was made from a 10-inch square chrome-nickel steel billet, the stock being thoroughly hammered and refined and then annealed for machining. The parts between the throws were then cut out and the forging twisted between each pair of crank webs, after which it was again annealed to relieve all the strains incident to the twisting operation. The shaft was then rough machined throughout and oil treated, following which it was finished and ground, all bearing surfaces being ground to limits of 0.0010 inch; that is, 0.005 inch above or below the given dimensions. The over-all dimension of the crank-shaft is 71¾ inches. The crank-pins are 2½ inches diameter, 4½ inches long, and the shaft bearings between the cranks are 2½ inches diameter and 4 inches long. The size of the crank webs is 6¼ × 2¾ × 1½ inch. The longitudinal holes through the crank-pins and bearings are 1⅛ inch diameter.

The crank-shaft was made for a six-cylinder engine, the cylinders being 8 inches stroke by 7 inches diameter, and developing 150 horse-power at 850 revolutions per minute. The weight of the engine complete with all attachments is only 1,400 pounds. Anyone familiar with the manufacture of multiple throw crank-shafts can readily see from the illustration that the design is something quite different from the usual form of six-throw crank-shafts. It will be noticed that instead of combining the two crank-pin bearings in the one throw, each crank-pin bearing has a separate pair of crank webs. This, of course, increases the difficulty of manufacture. It will be noticed that the space between the cheeks in the case of the two end throws is very narrow, being only ⅝ inch. A twist had to be accomplished within this narrow space. It is evident from this fact that the material is of great toughness and strength.

The boat for which the crank-shaft was built is 37 feet long over-all with a beam of 4 feet 6 inches. The reversing gear propeller shaft was also built for the Chadwick Engineering Works by the Chester Works of A. P. Witteman & Co., and particular attention is called to the fact that the total weight of the reversing gear and shaft was only 222 pounds. A test piece taken from the shaft showed the following physical properties due to the heat treatment:

Tensile strength, 143,500 pounds per square inch;
Elastic limit, 110,000 pounds per square inch;
Elongation, 18 per cent in two inches.

* * *

A lot of people think that they are climbing the ladder of success when they catch hold of the other fellow's coat tails.—*The Silent Partner.*

MACHINERY'S SIXTH ANNUAL OUTING.

On October 22, following the convention of the National Machine Tool Builders' Association, MACHINERY gave its annual outing to five hundred machine tool builders, mechanical engineers, machinery dealers and others interested in the machine tool business and kindred lines.

The outing this year differed materially from preceding ones, the chief feature being athletic sports, and the contestants, members of the trade; in the games requiring team play the East was pitted against the West. The steamer *Sagamore* took the party to Point View Island, on the Sound, which had been hired for the day, and on which was a large pavilion and athletic field well suited for the sports. Music was furnished by the Eighth Regiment Band, and luncheon was served in the pavilion, which had been appropriately decorated for the occasion.

The sports which followed the luncheon comprised a potato race, a baseball game between the East and West, a sack race, a three-legged race, and a push-ball game, the contesting teams being chosen from Eastern and Western territory.

There were fourteen entries in the potato race, as follows: Charles H. Besly, F. C. Billings, F. B. Doe, W. S. Gorton, R. B. Jacobs, E. A. Johnson, T. G. Meachem, C. H. Peirson, L. D. Rockwell, E. C. Smith, A. K. Spencer, Charles A. Strelinger, W. W. Totman and E. H. Waring. Referee, Charles F. Chase. After an exciting and laughable contest Mr. Peirson was declared the winner of the prize, which was a sterling silver berry spoon.

The ball game, which was confined to one hour and won by the Western team, was remarkably good considering that none of the players had any previous practice together, the score being 8 to 7. The captains were C. A. Johnson of the Gisholt Machine Co., Madison, Wis., for the West, and D. B. Bullard of the Bullard Machine Tool Co., Bridgeport, Conn., for the East, and the players were as follows:

EAST.		WEST.
D. B. Bullard	Pitcher	W. L. Schellenbach
F. E. Bocorselski	Catcher	David Hunt, Jr.
P. B. Gale	1st base	R. T. Lane
W. H. Taylor	2nd base	R. K. LeBlond
P. M. Brotherhood	3rd base	A. M. Watcher
A. R. Stedfast	Shortstop	C. A. Johnson
H. C. Warren	Right field	Rufus King
D. M. Wright	Left field	H. W. Kreuzburg
U. Eberhardt	Center field	G. H. Feltes
Frank L. Cogill	Umpire	Winthrop Ingersoll

The prizes were emblems similar to those worn on watch fobs, but attached to ribbons in the form of a badge marked with the position played by each of the winning team.

There were twelve entries to the sack race, as follows: C. L. Goodrich, A. W. Graham, D. Halstead, C. E. Holgate, R. B. Jacobs, J. Judd, D. R. McIntosh, C. A. Mackintosh, S. Robertson, C. T. Schmitt, E. Von Campe and N. G. Williams. Mr. Goodrich was the winner of the prize, which was a decorated stein.

Fourteen entered the three-legged race, as follows: W. C. Buell and A. W. Graham; A. E. Carpenter and A. T. Doud; E. Von Campe and C. E. Chapple; C. E. Watrous and H. A. Pratt; C. T. Schmitt and C. L. Goodrich; W. H. Miller and R. B. Jacobs; J. Judd and J. B. Anderson. Messrs. Carpenter and Doud won the prizes—twin flower vases of green glass decorated with gold.

The game of push-ball is played by eleven men on each side, on a rectangular field 50 yards wide and 120 yards long, with goal posts at the ends, 20 feet apart. The ball used in the game is 6 feet in diameter, the object being to push the ball over the bar between the goal posts, and the rules are much the same as in foot ball. The push-ball game proved to be the most popular game of the day, and after a hard-fought battle, in which every inch of ground was contested and neither side was able to make a goal, the East won out by a few feet. The game was limited to two ten-minute periods, with a resting interval of five minutes between. Someone remarked that if all the people on the ground pushed as hard for business, there would soon be a boom in the machinery trade.

We were unfortunately unable to obtain a complete list of the Western team, as some changes were made just prior to the game, and after it everybody left for the steamer. An accurate list will be given with the views of the games which we are now having reproduced.

EASTERN ELEVEN.
J. W. Bray,
D. B. Bullard,
E. Cramer,
Robert L. Crane,
James Coulter.
Oscar M. Flather,
L. P. Goodspeed,
R. B. Jacobs,
C. H. Kingsbury,
Marshall Prentiss,
Geo. J. Thompson.

WESTERN ELEVEN.
C. H. Besly,
——— Booth,
W. A. Greaves,
Oliver Henn,
D. Hunt, Jr.,
Winthrop Ingersoll,
G. E. Merryweather,
C. A. Strelinger.

Referee: Robert B. Luchars.

The push-ball prizes were similar to those for the baseball—one for each player—the ribbons being of a different color and the inscriptions appropriate.

The Push-ball Game—"Up in the Air."

The 1908 outing was generally considered to be the most successful of all those given by MACHINERY. In spite of the late date the weather was perfect, and all the events went off without a hitch. At the first outing, which was given six years ago, only twenty guests were present; while for 1908 nearly seven hundred acceptances and requests for invitations were received, although accommodations were provided for only five hundred, as a larger number would have caused overcrowding and discomfort to those who attended.

* * *

A paper presented by Mr. Thomas D. West, Sharpsville, Pa., before the American Foundrymen's Association was an appeal for the prevention of accidents in the foundry. While brief, the paper contained some valuable suggestions, which, if followed, would go a long way toward preventing the distressing accidents that are of frequent occurrence in foundries. He mentions indolence, smoking, drink, forwardness, stupidity, rashness, deliberate carelessness, independence of orders, callousness regarding the safety of others, and perhaps deliberate trickery or spite as causes, mostly on the part of operatives. Next in order are mismanagement, disorder, tyranny, particularly in the overseers, and absence of safety devices and intelligent control of the works on the part of the management. A point that prevents men in charge from exercising all possible precautions for safety, is the lack of credit they get for taking precautions from those higher up. It is desirable that foremen and sub-foremen should be encouraged to see that nothing but a good bolt, or sound and annealed chain is used for handling flasks and ladles; that the temper of sand is watched, and the ramming, venting, coring, clamping and other operations incident to the foundry are carefully attended to; to notice that the ladles are dry, and that no one sticks wet rods into the metal or spills water over the gangways and around the cupola. These matters may appear small and trivial, but they are important factors in causing foundry accidents.

COOPERATIVE IDEA OF JOHN DALY, TRIMMER BOSS.

Only one remains of the five coal dump piers of the Delaware, Lackawanna and Western Railroad, which reared their high and grimy fronts over the North River on the Hoboken side in the days when John Daly, the trimmer boss, used to ride down from the heights to his work in his carriage every morning. Less coal is brought by the road now to this port, and machines like the floating grain elevators lift it from the cars on flat piers.

One alone of the six black skeleton structures survives—one was built since the time of John Daly—and only there can a few old timers be found who remember the story of this man, a story full of suggestion to students of remedies for the woes of the workingman.

Away back in the '70s John Daly used to leave his little apartment in an old fashioned Hoboken tenement house, dinner can in hand, at a quarter of 7 every morning except Sunday, and hurry to the coal docks. Then when the whistle blew he would crawl on his back, shovel in hand, from the hatch of a coal barge, well back under the deck, and begin to push and pile up the coal beyond his head until it touched the deck. So, laboring hard in a strained position, he and some ninety-nine others worked in an eighteen-inch or two-foot space most of the time, for that is the way the coal trimmers work.

For this work they got 22 cents an hour while actually engaged in shoveling. Their pay did not run when boats were not in, but often they worked late into the night, and at the end of the month they sometimes had $75 each to bring home. And they brought it home, for they were not tipplers or drunkards. So it went, winter and summer, for years.

John Daly was a shrewd man—an ambitious man. He saw clearly that it would be hard to fill the places of himself and his fellows if they should decide to go on a strike. He talked to the others about it when they were waiting for boats, until he had persuaded them all to join him in a cooperative bid for the contract, which would terminate with the outgoing of the then superintendent.

The new superintendent came and the trimmer boss made his offer for the contract, to last during the incumbency of this superintendent, at the old rate. John Daly stepped up and said:

"If you give this man the contract he will not be able to carry it out, for we will not work for him and he cannot fill our places. Give us the contract jointly and we'll stay and do the work. We don't need him at all to boss us; we know our business."

The new superintendent thought the matter over, and in a few days agreed to John Daly's proposal, for, indeed, there was nothing else for him to do. John Daly was elected boss trimmer.

Thereafter the pay of each man was sometimes as high as $140 a month, and the trimmers are now princes among laboring men. Then old Matt Casey died.

The men held a meeting to decide what to do about a man for his place. Would it be right to admit a new comer at once to the sharing which they had slaved for years to attain and had taken the risk of discharge to secure? Surely not, they agreed.

"Hire him at 22 cents an hour," they told John Daly, "and after a time, when we see fit, we'll put him on an equal footing with ourselves."

A man was hired at 22 cents an hour.

Many more of the cooperative trimmers died as the years rolled around, some retired because of old age, some had to retire because John Daly gave them heart breaking, impossible tasks, to drive them away, as they believed, and some John Daly discharged for one offense or another, until of all the hundred cooperative trimmers not one was left but John Daly, now sole contractor, and he had working for him a hundred men at 22 cents an hour.

John Daly was known on many an occasion to spend only $5 for the trimming of a boat for which he got $145. These were the days in which he used to come down from the heights to his work in his own carriage. He owned real estate in Jersey City and Hoboken. He was believed to be rich.

A new superintendent, a Mr. Varian, came about 1883, and a new contract had to be made with him. History repeated itself. The men demanded a contract as a cooperative body and the utter elimination of John Daly.

Mr. Varian would not deal with them as a cooperative body. They struck then for 25 cents an hour, and a settlement was made by which there should be no contract, but all the money which a contract would bring them would be divided among them fairly by Mr. Varian himself.

Again did the tenements rejoice in $145 as a month's pay instead of $90, and this condition lasted all through the superintendency of Mr. Varian. He was succeeded a few years ago by a Mr. Johnson, who, thinking that a couple of honest contractors would treat the men fairly, while relieving his office of a burden of care that did not rightly belong to it, gave the contract to Thomas Connelly, who used to be weighmaster in the old days, and a man named Miller, one of the old-timers who worked for Daly. They are the bosses there to-day, employing about ninety men, the new machinery making up the difference, and the pay of the men is 22, 25 or 30 cents an hour, according to the valuation the bosses put on their work. The pay averages about $45 every two weeks.

But what of John Daly? He went West, with plenty of money to enjoy himself, and he died about ten years ago, far from home and friends, and they say, on the lone, high black pier, without a penny to his name.

So did the selfishness inborn in humankind battle and win against the altruism necessary to the success of cooperation, and so did its triumph spell the ruin of the winner at last.—*New York Sun.*

MISCELLANEOUS FOREIGN NOTES.

German Machine Exports.—The exports of machine tools from Germany have been on the increase during the first five months of 1908, in spite of the business depression. The exports during 1908 amounted to 19,486 metric tons, as compared with 13,798 metric tons for the first five months in 1907.

Extensions of the Krupp Works.—Some time ago it was announced that the Krupp firm, of Essen, Germany, was about to establish a branch in Roumania in order to supply the army with ordnance, and it was expected that the arsenal would be handed over to the firm for a period of years, and also that the firm would obtain a monopoly of governmental orders for iron and steel. The proposition, however, met with public disapproval, and has therefore been dropped for the present.

German Motor Car Industry.—It appears that at the present time greater attention than ever is given in Germany by the automobile manufacturers to small motor cars, many simply intended for a single passenger. In spite of the depression in the automobile business there is, even at the present time, a great demand for small and inexpensive cars, and many German firms are confident that they will be able to maintain the industrial stability of the motor trade by attending more to the production of vehicles for popular and business uses.

British Machine Tool Trade.—Reports from England indicate that the machine tool trade in the London district is comparatively good, considering the general depression in various other branches of engineering trades. As an indication of the fact that the depression in the machine tool trade in Great Britain is not so acute or general as in the United States, it may be mentioned that the firm of Henry Pels & Co. has enough work on hand to keep double shifts busy for several months, and is contemplating considerable extensions. This firm is building heavy tools in particular.

Iron and Steel Industries in Germany.—At a recent meeting of the National Association of German manufacturers of iron and steel, it was stated, according to report by Consul H. J. Dunlap, of Cologne, that the industry has been unusually prosperous during the past year, and that the output has been materially increased, caused, principally by the home demand. The financial panic in the United States, however, had an unfavorable effect on all industrial undertakings in the country, and caused a hesitancy in placing orders. However, the iron and steel industry in Germany is as yet fully employed.

One difficulty experienced has been that of shortage of railroad cars, an experience not altogether unknown also in the United States.

The Development of Russian Industries.—The South Russian iron and steel works are giving a great deal of attention to the production of the finer qualities of iron and steel. These works have not been in the habit of turning out higher grades of tool steel, but of late they have commenced with this manufacture, and some works turn out various qualities of high grade steel at a moderate cost. It is stated that Russia may become independent of foreign industries for the supply of high-class metals, and that Russia in general, is forging ahead industriously. It is noteworthy of the progress of Russia along industrial lines that several Russian works have been competing with considerable success with other European engineering firms for contracts for the Roumanian state railways. Thus, a large consignment of rails, locomotives and freight cars have been supplied by Russian works for Roumania.

PERSONAL.

L. B. Marks, New York, and J. E. Woodwell, Washington, D. C., have opened a consulting office in the Terminal Building, 41st Street and Park Avenue, New York.

J. G. Matthews, until lately with the Cleveland Twist Drill Co., Cleveland, Ohio, is now instructor in the mechanical drawing department of the Cleveland Technical High School.

H. P. James, formerly electrical engineer of the Bryant Electric Co., is now sales manager for the new line of push button specialties recently placed on the market by the Cutler-Hammer Mfg. Co., Milwaukee, Wis.

G. K. McMullen, for over ten years past sales manager of the Fox Machine Co., Grand Rapids, Mich., will sever his connection with that company November 15 to engage in business for himself. Announcement of the nature of the new venture will be made later.

Stanley H. Hodgkin of the Pulsometer Engineering Co., Ltd., Reading, England, is in the United States to make contracts with concerns desiring to manufacture patented machines in Great Britain in order to conform with the requirements of the new British patent law.

* * *

OBITUARY.

Bennett H. Brough, a well-known British metallurgist and secretary of the Iron and Steel Institute, died at Newcastle-on-Tyne, England, October 3.

S. R. Stokvis, managing director and chairman of R. S. Stokvis & Sons, Rotterdam, died after a short illness, September 14. Mr. Stokvis was the son of the founder of the house, R. S. Stokvis, and was in his eighty-first year. A brief account of the activities of the company was published in the May, 1908, issue.

William Keuffel, president of the Keuffel & Esser Co., New York, died at his home in Hoboken, N. J., October 1. Mr. Keuffel was born at Walbeck, Germany, 1838, and was educated in the public and private schools of his birth-place. At the age of fifteen he left school and became an apprentice in a general merchandise store where he remained four years, receiving a severe but thorough mercantile and business training which fitted him for his successful career of later years. He then entered a large hardware house in Hanover, Germany, and several years later went to Birmingham, England. In 1866 he emigrated to the United States, where in 1867 he founded, together with his friend Hermann Esser, the firm of Keuffel & Esser. Drafting at that time was in its infancy in this country, but Mr. Keuffel appreciated its coming importance, accompanying the development of American manufacturing and engineering enterprise. To supply all the requirements in office and field of the surveyor, engineer, architect and draftsman was the purpose of the new concern, and Mr. Keuffel can well be called the pioneer in this line, because at the time of the founding of his business, drafting supplies had not been carried exclusively by any house in the United States. The company now has a large factory in Hoboken, covering about five and one-half acres of floor space, and employing about 1,000 people. The new plant was opened July 20, 1907, forty years after the inception of the business. (See Machinery, August, 1907.) Mr. Keuffel is survived by a widow and four children, of whom Mr. W. G. Keuffel is the vice-president of the company.

William Keuffel.

* * *

COMING EVENTS.

November 10.—The November meeting of The American Society of Mechanical Engineers will be held in the Engineering Societies Building, 29 West 39th St. Mr. Franklin Phillips, president of the Hewes & Phillips Iron Works, Newark, N. J., will make an address: "The High Powered Rifle and Its Ammunition—Instruments of Precision," Illustrated by lantern slides. Mr. Phillips is an expert marksman, and in 1903 won the position as first alternate on the International Rifle Team to England. He was, for many years, chairman of the committee on Rifle and Pistol Practice in the National Guard of New Jersey and is now Ordnance Officer of the Second Infantry of that state. Tests of rifles and ammunition at Sea Girt, N. J., by men connected with the N. J. National Guard have led to marked improvement in arms and ammunition and to an entire change in the powder used by the government, thereby greatly increasing the accuracy of the shot. The improvement has been extended to large guns and instead of 2 per cent hits which were made at Santiago, 80 per cent is now the average in some ships. Mr. Phillips has actively participated in this work and as he is primarily a mechanical engineer, as well as a marksman, he will explain to his audience the practical bearing of his investigations upon the construction of arms and the elements entering into ammunition.

November 19-21.—Annual meeting of the National Society for the Promotion of Industrial Education, Atlanta, Ga. James P. Haney, 546 Fifth Ave., New York, secretary.

December 1-4.—Annual convention of the American Society of Mechanical Engineers, Engineering Societies Building, 29 West 39th St., New York City. C. W. Rice, 29 W. 39th St., New York, secretary.

December 10.—Mr. M. A. Loeb, secretary and treasurer of the Rock Island Battery Co., Rock Island, Ill., has issued a call to the manufacturers and dealers of gas and gasoline engines, and dealers and manufacturers of accessories thereto, to attend a preliminary meeting at the Auditorium Hotel, Chicago, December 9, 1908, with a view of discussing and formulating plans for the formation of an association. Officers are to be elected and a committee appointed for the purpose of arranging for a national convention to be held at some time and place decided upon by the executive committee.

December 31-January 7.—Ninth annual show of the American Motor Car Manufacturers' Association at Grand Central Palace, New York City.

January 16-23.—Ninth annual show of the Association of Licensed Automobile Manufacturers at Madison Square Garden, New York.

NEW BOOKS AND PAMPHLETS.

Annual Report of the State Geologist of the Geological Survey of New Jersey. 192 pages, 5½ x 9 inches. Published by the state geologist, Henry B. Kümmel, Trenton, N. J.

Modification of Illinois Coal by Low Temperature Distillation. By S. W. Carr and C. K. Francis. 48 pages, 6 x 9 inches. Published by the University of Illinois, Engineering Experiment Station, Urbana, Ill.

Reports of Committees, 16th Annual Convention of the Traveling Engineers' Association, Detroit, Mich., August 25, 1908. 84 pages, 6 x 9 inches. Secretary, W. O. Thompson, New York Central and H. R. R., East Buffalo, N. Y.

How to Build Up Furnace Efficiency. By Jos. W. Hayes. 47 pages, 3½ x 6¼ inches. Published by Jos W. Hayes, 601 Hartford Bldg., Chicago. Price 50 cents.

The pamphlet is a dissertation on furnace efficiency, and the facts that are to be learned by analyses of flue gases. It is of interest to all concerned with economical power production and smoke prevention.

Lighting Country Homes by Private Electric Plants. By T. H. Amrine. 35 pages, 6 x 9 inches. Published by the University of Illinois, Urbana, Ill.

This is Bulletin No. 25, issued by the University of Illinois. There are special sections of the bulletin devoted to selection of fixtures and planning of lighting, the design of plant, estimated cost of plant, operation and care of apparatus, and cost of operation.

MACHINERY.

December, 1908.

THE HINDLEY WORM AND GEAR.

JOHN EDGAR.*

THIS article, on the subject of the Hindley worm and gear, was prompted by an editorial (February, 1908) asking for data, and by certain hazy ideas that seem to prevail regarding the nature of contact between the thread and teeth.

This type of worm gear was first used in Hindley's dividing engine, and was by him considered superior to the ordinary type, in wearing quality. Investigation has practically settled that the nature of contact between the worm thread and the teeth of the ordinary worm-wheel is that of line contact, extending across the tooth on the pitch line. It has also been fairly well proved in practical examples that the contact is of a broader nature on account of the elasticity of the materials used in the construction. The convex surfaces of contact are flattened considerably under pressure and thus for practical purposes make actual surface contact. The contact in the ordinary worm and worm-wheel type is limited to two teeth of the wheel and worm-thread at most.

Comparison of Ordinary and Hindley Worm Gearing.

The conditions are much different in the case of the Hindley worm, and it is the intention in this article to show wherein the difference lies. As this style of gearing is uncommon to most of us, a few words regarding its construction will not be out of place. Fig. 1 is a sketch of the Hindley worm, showing the theoretical form. This worm is not of cylindrical shape, but is formed somewhat like an hour-glass, after which it is sometimes named. The worm blank being made smaller in diameter in the middle than at either end, conforms to the circumference of the wheel with which it meshes. The worm thread is cut by a tool which has motion in a circular path about a center identical with the axis of the wheel with which it is to mesh, and in the plane in which the axis of the worm lies. The process is similar to ordinary thread cutting in the engine lathe, except for the difference in the path of the tool, the tool having a circular instead of a straight path.

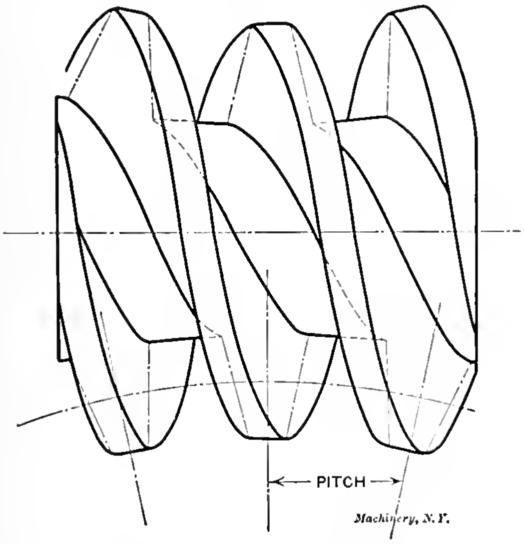

Fig. 1. The Typical Hindley Worm.

It is evident that the worm shape is dependent on the particular wheel with which it is to run, and Hindley worms are not interchangeable with any other but an exact duplicate. That is, a worm cut for a Hindley gear of 50 teeth cannot be used successfully with a wheel of 70 teeth, although the pitch of the tooth is exactly the same. In the ordinary type of worm gearing, one worm may be made to run with any number of diameters of wheels of the same pitch, and hobbed with the same hob.

In action the two styles of worm gear differ greatly and both diverge widely in action from the case of a plain nut and screw, which may be taken to represent a worm and worm gear, the latter of infinite diameter and with an angle of embrace of 360 degrees. In studying the action between the thread and teeth of the ordinary type of worm gear, we must comprehend odontics, rolling contacts and the theory of tooth gearing, in general, in order to understand the action of the ordinary worm gear. But, in studying the action of the Hindley type, we are concerned with no such theories, as the action is purely sliding and devoid of rolling contact. In the ordinary worm we have an axial pitch which is constant from top to root of the thread, while in the Hindley worm we have a section in which the pitch of the thread varies from top to bottom.

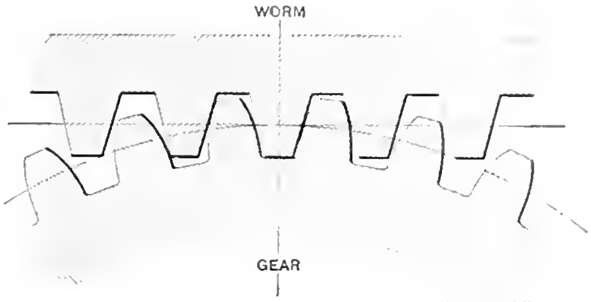

Fig. 2. Section of Common Worm and Worm-wheel on Middle Plane.

Interference as found in the ordinary type of worm gear is absent from the Hindley, and the consequent undercutting and weakening of the teeth, therefore, is a feature with which the designer of the Hindley worm gearing does not have to contend. For this reason we are not limited in the length of teeth, by interference, as in the ordinary case. This fact permits the wide latitude in the choice of tooth shape and proportions. In most examples we will find that the depth of thread is much greater in proportion to the thickness than in the ordinary worm gear in which the height is limited by reason of the interference at the top and root of the teeth.

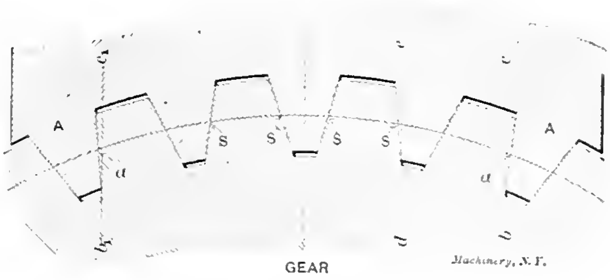

Fig. 3. Section of Hindley Worm and Gear on Middle Plane.

Nature of Contact of Hindley Worm Gearing.

The general idea of the Hindley worm gearing is that there is surface contact between the worm and gear, and that the contact is generally over the whole number of teeth in mesh. If such were the actual conditions, the Hindley type would surely be an ideal mechanism for high velocity ratios, but that such is not the fact is the purpose of this article to point out. That the contact is of a superior nature we will not deny, nor that it is much nearer a surface contact than exists in the ordinary worm gear. As a means of comparison,

---

* Address: 7 Webster St., Hyde Park, Mass.

Figs. 2 and 3 are shown. Fig. 2 shows an axial section taken through the worm and gear of the ordinary type, while Fig. 3 shows a similar section through the Hindley worm and gear. The "airy" appearance of Fig. 2 as compared with Fig. 3, indicates a vast difference in the nature of contact, and gives the advantage to the Hindley type, wherein is the origin of certain false ideas in favor of the latter. These illustrations also show peculiar differences in the action of the two types. The absence of rolling action in Fig. 3 is the most prominent, and it shows the similarity between this type of gear and a screw and nut.

From an inspection of Fig. 3 we may feel sure that the contact on the axial plane is as shown, but as to the nature of contact in a plane either side of the middle plane we are in the dark so far as the drawing illustrates. Mr. George P. Grant has this to say concerning the contact of the Hindley worm and gear: "It is commonly but erroneously stated that the worm (Hindley) fits and fills its gear on the axial section. . . . It has even been stated that the contact is between surfaces, the worm filling the whole gear tooth. . . . It is also certain that it (the contact) is on the normal and not on the axial section, and that the Hindley hob will not cut a tooth that will fill any section of it. The contact may be linear on some line of no great length, but it is probably a point contact on the normal section."

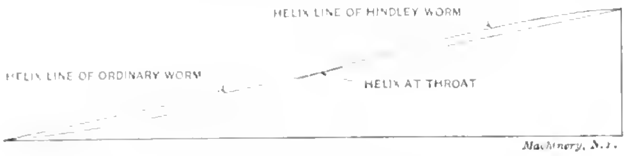

Fig. 4. Development of Ordinary Worm and Hindley Worm Spirals on a Plane.

It is not clear what reason Mr. Grant had for saying that the contact is normal instead of axial; but there is every reason to believe that the contact is on the axial section since it is on this section that the teeth of the hob have a common pitch. The teeth have not a common pitch on any section at an angle with the axial section. For what reason would one expect to find contact on the normal section in this case any more than in the case of the ordinary worm? Since both styles of worm-wheels are hobbed with a revolving hob which lies in a plane perpendicular to the axis of the worm-wheel, the contact could hardly be on a normal section.

Prof. MacCord states that he considers the contact to be line contact on the axial section, and he gives directions for obtaining the exact nature of the contact and also the thread and tooth sections. These directions, on account of the complicated nature of the method, are hard to follow. Much, however, can be found out by simple methods. In what follows, describing these simpler methods, the results, of course, are of an approximate order, but they nevertheless give a means of comparison and a material basis for the line of argument.

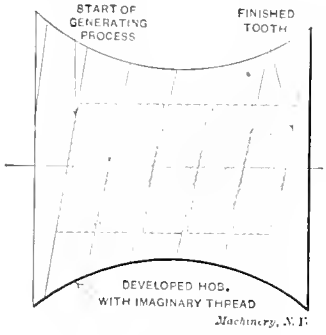

Fig. 5. Successive Steps in Shaping Hindley Worm.

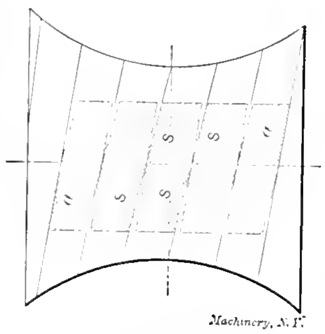

Fig. 6. Surfaces of Contact of Hindley Worm.

The Ideal Case Considered.

It is assumed that we are examining an ideal Hindley gear in which the worm and wheel are theoretically correct in shape and that the surfaces are perfectly smooth and inelastic. From the nature of the worm, the helix angle varies from mid-section to the ends, decreasing as the thread approaches the ends of the worm. The thread is spiral as well as helical. This change in the thread angle is caused by the increase in diameter at the ends of the worm and by the fact that the axial pitch of the thread decreases as it reaches the ends. The decrease in axial pitch is due, of course, to the circular path of the threading tool. If we take a development on a flat surface of a line scribed in the spiral path on the worm blank, as shown in Fig. 4, the change in the angle becomes noticeable.

In the operation of forming the teeth of the gear, the blank is rotated, each portion of the hob working the tooth into shape so that it will pass the corresponding portion of the worm thread without interference, permitting a smooth transmission of motion. If each portion has a different shape or is placed in a different relation, the shape of a gear tooth will be a compromise between the extremes, and this is what is actually the result, as we shall see later.

The progressive steps of the process are shown in Fig. 5; the successive positions of one tooth are shown, beginning at the left and ending at the right-hand position where each tooth is given its final shape. The nature of the process is shown in Fig. 6, the shaded portions representing the gear teeth. Here we have a representation of the contact of the thread and teeth; it shows that surface contact is impossible on any but the heavily shaded portions of the teeth, it being confined to the mid-section and the extreme end sections of the worm. Line contact is obtained throughout the length of the worm on the axial plane. This figure also shows that no advantage is gained in surface contact by making the worm of greater length. The location of the contacts are shown in Fig. 6 at *a*, *s*, *s*, *s*, *s*, *a*, but it must be remembered that they lie on opposite sides of the cutting plane. From this it is apparent that the worm does not entirely fill the space between the teeth of the gear and that the contact is not wholly a surface contact.

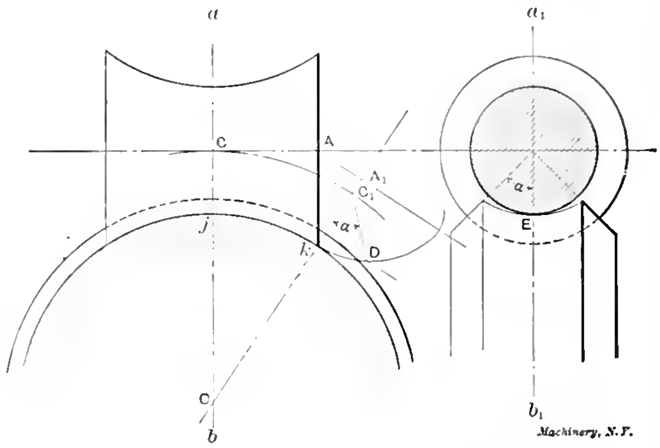

Fig. 7. Effect of Hour-glass Shape on Worm-wheel Contact.

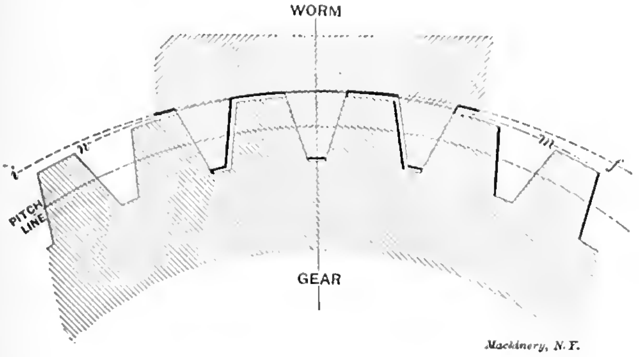
Let us investigate still further and see whether the conditions are not modified by other irregularities: Fig. 7 is drawn to represent a worm and gear of the Hindley type, in mesh, the teeth of which have no depth. As before mentioned, the peculiarity of this type of worm is its hour-glass shape. The hob and worm may be treated as identical in form. In the process of generation, the tooth has a pitch line curvature that changes with corresponding positions in relation to the thread portion acting upon it. The tooth must necessarily be modified from what it should be for any particular location in its contact with the worm thread. It is quite clearly shown that if the tooth is to fill the worm thread or *vice versa*, it must be formed in strict accordance with the thread at that particular point. Thus if at *j* the tooth fills the thread, that tooth must be formed by the thread at that point, while the tooth at *k* must be formed by the thread at *k*. Now, since each tooth must pass from *k* to *j*, its form must be such that it will do so without interference. It is evident that the radial section of the gear at *k* must be the same as at *j*. Since the worm is largest in diameter at *k*, the curvature of the tooth on the radial section is dependent on the thread at that point. The curvature of the tooth at *k* evidently is that of an ellipse whose major axis is $A\,A_1$. Now, since the thread is made with angular sides, the hob could

hardly act on the teeth of the gear the same at all points from k to j except on the axial plane where the relative shape of the hob thread is the same for any position along the line of action (see Fig. 3). This is evident from Fig. 7 at E, which point only touches at the mid-section of the worm. Therefore we still have the line contact from top to bottom of teeth on the axial plane, but the construction, Fig. 7, shows that the surface contact s, s, s, s, Figs. 3 and 6, does not actually exist, but that the surface contact at the ends of the worm remains undisturbed.

From the above we may safely conclude that the hob at j has but little effect on the actual shape of the tooth, and that its influence increases until k is reached. Fig. 7 also shows a good reason why the contact may be considered axial instead of normal, by the mere fact of the differences in curvature of worm and wheel at any point other than k. In practice the contact may appear to be surface contact, but this, no doubt, is due to the influence of the lubricating oil and the fact that materials of construction are distorted to some extent in form when subjected to pressure. This distortion permits the worm thread to imbed itself into the worm-wheel teeth, somewhat broadening the contact for the time being. The conditions as stated in the above discussion, would be met in the case of a hardened worm and gear with surfaces finished by lapping. In practice the worm and gear are ground together, sand and water being used as the abrasive. This grinding wears down the roughness of the surfaces and tends to correct irregularities in form that develop in the hobbing process.



Machinery, N.Y.

Fig. 8. Effect of the "Second Cut" on Contact.

Objections to the Hindley Gear.

The objections to the Hindley type of worm gear are many and are widely known. It must be set up accurately, the alignment being made perfect. End play is a feature that must be avoided, as any longitudinal displacement of the worm will cause the gear to cut. These peculiarities are the greatest drawbacks to the use of this gear and because of them I feel that it will not come into common use, at least not so common as the worm drive of the ordinary type. This feeling is strengthened by the fact that we have become so much more familiar with the latter type as to be able to design and construct drives that work satisfactorily in every respect.

Modifications of Hindley Worm Gear Practice.

Some modifications have been made in the process of manufacturing the Hindley worm gear. One that is probably of first importance is that known as the "second cut," this practice being generally credited to Mr. Albro of Philadelphia, but the credit for it is in dispute. The effect of the second cut is indicated in Fig. 8. From this sketch one would be likely to say that the part of the second cut was to remove the points of contact. Whether this is the reason or not, it is a fact that it does remove considerable of the contact from all but the mid-section of the worm. This second cut is made by enlarging the diameter of the circle in which the threading tool travels when cutting the worm. It is said to have advantages that add to the wearing quality of the drive, but just what these advantages are is not apparent, and since the process is considered more or less a trade secret, it is difficult to obtain authentic reasons for its use. The second cut is mentioned here in the hope that someone knowing the reason for its use may respond with a full account. This he may be sure will be appreciated generally by the readers of MACHINERY.

The limiting length of the worm is dependent on the shape of the thread. In Fig. 8 the worm is shown with three sections in mesh, while Fig. 3 shows five. Fig. 3 shows a case that would be impossible in practice on account of the undercut sections A which lock the worm in mesh. The side of the thread must fall inside the line bc to permit the worm and gear to be assembled. Following are the conclusions which I derived from my investigation regarding the Hindley type of gear:

1. The contact is purely sliding contact.
2. The nature of the contact is linear, closely resembling surface contact.
3. Linear contact extends from the top to the root of the tooth.
4. The contact is on the axial section.
5. The thread section fills the tooth space on the axial section only.
6. The mid-portion of the hob has little or no effect in shaping the teeth of the gear.
7. Surface contact exists on opposite sides of the axial plane at the end of the worm thread and is intermittent in nature, because the end of the thread passes out of contact with the tooth in the revolving of the worm. This contact is on a plane normal with the thread angle.

In practice it is usual to allow considerable back-lash between the thread and the tooth of the worm and gear. This play tends to counteract bad workmanship, either in construction or erection.

[The foregoing article is, we think, a sound and unprejudiced exposition of the theoretical Hindley worm gear, but should be regarded as not applying strictly to this type of worm gearing as actually manufactured. The commercial Hindley gear differs considerably from the ideal form, as intimated by Mr. Edgar in the part where he speaks of the "second cut" process, but this difference is not all. The shape produced in the manufactured gear so differs from the theoretical type that comparison really is unfair. The "grinding in" of the worm and gear with sand and water or powdered glass and water, has much more significance than is ordinarily given it by those unfamiliar with the process. It is more than a mere smoothing process, it being claimed that it actually shapes the worm teeth to a form that cannot be duplicated with a cutting tool by any known process. It appears also that there is a misconception about the rigid requirements of location of the worm and its gear. Hindley worm gears have been made, and are in successful use, in which considerable longitudinal motion of the worm was provided for on account of the need for such motion; and from an investigation of the manufacture, we are inclined to believe that the matter of location in other planes is not much more important than with the ordinary worm gear type, notwithstanding a previously expressed opinion to the contrary.—EDITOR.]

* * *

Various writers on the work of wood seasoning have called attention to the merits of lumber sawed from logs long submerged. They do this by speaking of the distinct advantages gained by soaking the logs or the sawed lumber in water as a preliminary step to the air seasoning. It is pointed out that in Japan logs are kept in brackish ponds for several years before being worked up. To this treatment is ascribed the peculiar freedom from warping found in woodwork from Japan, and especially in the wood carvings which are common in that country. The warping of woodwork is due to a change in dimension caused by the wood adjusting itself to the moisture condition of the surrounding air. In damp air wood swells, but shrinks as the air becomes drier. This property of wood can not be overcome entirely, but the search continues for methods of reducing it and retarding it so as to lessen its damage. Soaking does decrease the tendency to warp, but by no means overcomes it entirely. The effect of soaking as a remedy for warping, however, is less than can reasonably be expected from some methods of steaming. As a commercial practice the soaking of logs or lumber to remedy warping of the finished product is not to be recommended, except when it can be done during storage or transportation, because of the time required to produce results that fall far short of what is usually claimed.

AEROPLANE-TYPE FLYING MACHINES.

A REVIEW OF WHAT HAS BEEN ACCOMPLISHED TOWARD HUMAN FLIGHT.

HARRY WILKIN PERRY *

Nineteen-hundred-and-eight will undoubtedly go down in history as the year of the actual accomplishment of human flight. Many successful flights were made by experimenters before this year, and the Wright brothers really flew for thirty-eight minutes in one trial near their home in Dayton, Ohio, as long ago as October, 1905, but the fall of the present year appears to have been the culminating period for the public demonstration of man's mastery of the unstable atmosphere. The skeptical world is convinced at last that the dawn of a new era in transportation has arrived and that it is only a question of manufacturing activity and practice under competent instruction, for the time to come when many men will be doing all that a very few are doing to-day—and more. Even as this is written, lessons in operation of the aeroplane are being given to army officers and others in France by Wilbur Wright, and the pupils unanimously assert that the operation is extremely simple and can be learned in a few lessons. Contracts have been signed for the sale of the French patents held by Wilbur and Orville Wright, and for the manufacture of fifty machines on the same model as the ones that have been so successfully demonstrated at Le Mans in France and at Fort Myer in Virginia. So it appears that the long era of experimentation is finally drawing to a close and the commercial period of actual manufacture and use of flying machines is about to begin.

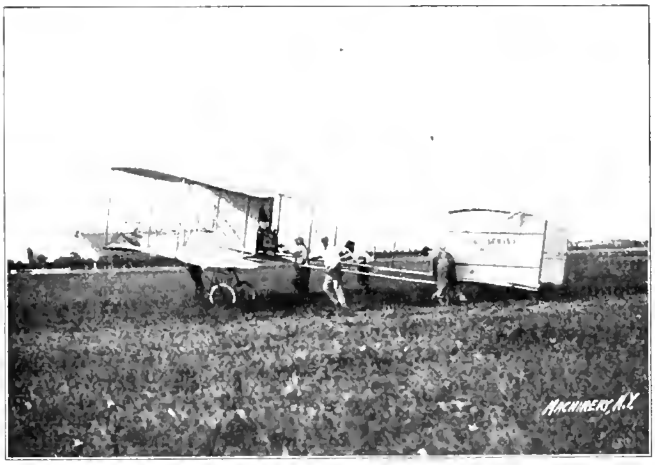

Fig. 3. Henry Farman's Aeroplane at Brighton Beach Race Track, Coney Island, N. Y., August, 1908.

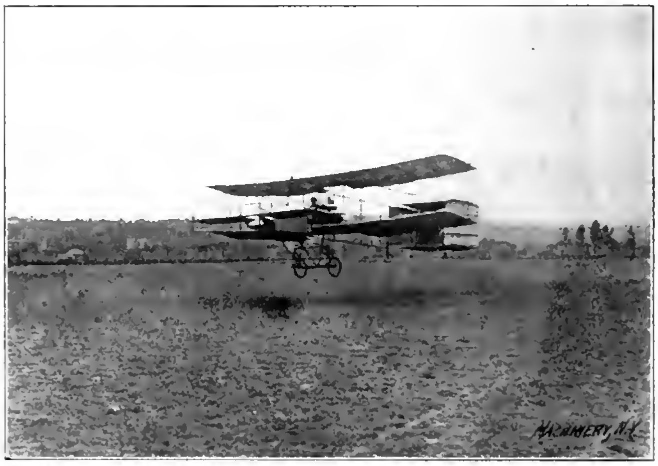

Fig. 4. Farman's Aeroplane in Flight at Issy-les-Moulineaux, France.

While all credit must be freely given to the Wright brothers for their success, and particularly for the improvements they have devised for controlling the movements of their aeroplanes, the fact is not to be lost sight of that in principle, form and construction their machines follow closely the gliding machines used experimentally many years ago by Octave Chanute and A. M. Herring, and that many of the laws of aerostatics and aviation were worked out by Prof. S. P. Langley through a long series of experiments, and by Lilienthal, Pilcher and Maxim. The only types of heavier-than-air machines that have been developed to a stage where they can be called successful are those that follow closely the forms originated by these pioneer investigators. These are the so-called biplanes, having fixed wings arranged in two parallel planes one above the other, or monoplanes, having a series of supporting surfaces disposed in approximately the same horizontal plane. Because they have given only slight promise of success, it is possible to eliminate from consideration the machines that come within the classification of helicopters (from the Greek words meaning spiral and wing), in which the weight is lifted by two or more propellers revolving in a nearly horizontal plane; and also those known as ornithopters (meaning bird wing), which are designed to fly by reason of a mechanical simulation of the motion of birds' wings. We can also pass by the tetrahedral and a variety of other curious forms with which experiments have been made.

It is needless here to recount the long series of successful flights by Wilbur Wright in France and his brother Orville at Fort Myer during August, September and October of this year. These are common knowledge, and the deplorable accident at Fort Myer on September 17, which resulted in the death of Lieut. Thomas E. Selfridge and the serious injury of Orville Wright, from which he only recovered sufficiently to leave the hospital on October 31, in nowise detracts from the convincing demonstrations that have been given. Only four days after the accident to his brother, Wilbur Wright broke all records by a flight of 1 hour 31 minutes 20 seconds, during which he covered a distance of 60.85 miles, flying in an elliptical course over the military grounds at Auvours, his elevation varying at will from 25 to 80 feet. He was awarded the gold medal offered as a prize by the Aero Club of France for the flight of longest duration made before October 1, 1908. Subsequently he again broke all records by flying for 1 hour 4 minutes 26 1-5 seconds with one

---

* Address: 25 West 42d St., New York.

passenger aboard, on October 6, thus fulfilling the conditions of the $100,000 contract entered into with Lazarre Weiller for the French patent rights, and proving his ability to meet the requirements of the United States government contract to fly for one hour with a passenger. He has flown in winds up to eighteen miles an hour and remained aloft for more than an hour in gusty and uncertain winds, part of the time after dark. Remarkable mastery of the machine has been shown in turning, in ascending and descending, in righting the machine after a sudden gust of wind, in meeting unexpected emergencies and in alighting without perceptible jar.

The general appearance and construction of the Wright biplane are well shown in Figs. 1 and 2. The "wings" or main supporting surfaces measure 40 feet from end to end by 6½ feet wide, affording nearly 520 square feet. They are made of muslin cut on the bias and stretched over wood ribs that give a concave form to the under side of the "planes"—a form that hundreds of experiments have shown to give the best lifting effect and greatest stability. A pair of long, stout spruce runners carry the weight when resting on the ground and serve to alight upon when the aeroplane comes to earth. These runners project forward and curve upwardly to provide support for the front horizontal rudder which is of biplane form and hinged along a longitudinal axis. The front edges of the main planes are made stiff and rigid, the 40-foot wood strips being spaced apart by 6-foot vertical wood bars and stayed by piano wires stretched taut diagonally from corner to corner in both directions, in cantilever manner. But unlike other biplanes, the rear edges and corners of the wings are purposely left flexible. The vertical bars are connected by flexible joints with longitudinal strips placed to the rear of the center line, and to the upper and lower rear corners are attached small steel cables that pass diagonally downward and upward to pulleys secured to the rigid part of the frame and thence to one of the operating levers in front of the aviator's seat.

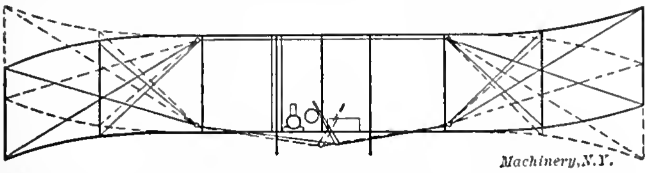

Fig. 5. Diagram Illustrating Method of Twisting the Wings of the Wright Aeroplane. Dotted Lines Indicate Alternating Positions of Wing Ends, and Operating Wires.

This construction, it should be noted, is of first importance in the manipulation of the aeroplane and forms the subject of all claims in the patents issued in the United States and France to the Wrights on May 22, 1903, and January 27, 1908, respectively. In the words of the patent, the object is "to provide means for maintaining or restoring the equilibrium or lateral balance of the apparatus." The four rear corners, Fig. 5, are so connected together and to the control lever that a sidewise movement of the lever draws downward the two rear corners of the wings or planes on one side and raises the corresponding corners on the opposite side to the same degree. This gives a helicoidal twist to the planes, causing them to present varying angles of incidence to the air, and tending to elevate the side of the machine on which the wings are twisted upward. The degree of twisting can be regulated to a nicety by the operator, enabling him exactly to counteract the effect of all air movements. In order to secure the desired effect, however, it was necessary to arrange a vertical rudder to act in conjunction with the wings and hold the machine to its course; otherwise it was found that instead of rising as intended, the wing presenting the greater angle of incidence would be retarded and would drop, while the opposite wing, presenting diminished resistance, would shoot ahead and rise, the machine being swung sharply out of its path. This, in fact, is what occurs when the aviator wishes to make a turn. Before reaching the turning point, he moves the lever to deflect the corners and rear edges of the planes, so that the ends of the wings on the inside of the turn drop, and those on the outside rise, canting the whole machine at a decided angle before the vertical rudder is moved to make the turn. Thus, the aeroplane has a bank of air against which to make its turning movement and does not slide sidewise, just as an automobile does not skid at high speed on the turn of a sufficiently banked track.

The Wright aeroplanes and their success have dispelled some illusions that have been held almost universally up to the present time. The most important of these is the belief that the weight of the machine and that of the engine must be cut down almost to the irreducible minimum and the power increased to the maximum. Beside the admirable workmanship of the best foreign aeroplanes and aeronautical engines, the Wright productions seem crude and unworkmanlike. The framing of the machines is heavy and almost roughly finished, and the engine looks more like an ordinary marine motor than one designed and built solely for use on a flight machine for navigating so light and unstable an element as the atmosphere. The whole aeroplane weighs 800 pounds without operator aboard, which, it is true, is some 200 pounds less than the Delagrange and Farman machines weigh with their wheeled attachment for starting and alighting, but Wilbur Wright has flown for periods of four and seven minutes with passengers aboard weighing 200 pounds and more, and he has attained speeds of forty to forty-three miles an hour, all with a slow-running engine of his own design and construction, weighing 170 pounds and developing only 25 to 30 horse-power, whereas the engines used in the Voisin Fréres aeroplanes as built for Delagrange and Farman develop 50 horse-power. The cylinders of the Wright engine are cast separately and bolted onto a broad, flat base that forms the crank chamber. They are water cooled and have a bore of 4 inches and stroke of 4½ inches. Turning at its normal speed of 1,100 revolutions a minute, the engine should develop 30 horse-power. The Wrights, as is well known, do not depend upon the motor for starting, but utilize the energy of a weight of 1,700 pounds that is raised to the top of a steel derrick and, in descending, "launches" the aeroplane from a single wooden rail placed on the ground. By the time the machine reaches the end of the rail it has attained a velocity sufficient to enable it to rise, and the propellers take up the work of keeping it in the air.

Two propellers are used, placed one-third the distance from center to the ends of the wings on either side, and with shafts slightly above the horizontal center. Each propeller has two peculiarly-shaped blades made of wood, and is driven by a bicycle chain running over sprocket wheels. To prevent lashing, long chain cases of bicyble tubing are made for the chains to run in. The engine is mounted to the right of the longitudinal center to balance the weight of the operator, who sits on the left; consequently, one of the driving chains is longer than the other. In order that the two propellers may turn in opposite directions and so balance each other when in action, the longer chain is crossed, reversing the direction of rotation of the propeller. A longer set of propellers, providing greater thrust, is fitted when an extra passenger is to be carried than when the aviator flies alone. These have a diameter of 7½ feet and are geared to the crank-shaft in a ratio of 10 to 33, by the use of large sprockets, so that the propellers revolve about four hundred times a minute. No clutch or change speed gearing is interposed between the engine shaft and the propellers, and the engine is started by turning the propellers over by hand.

No carbureter is fitted to the engine, the fuel being forced directly into the intake to each cylinder, by a geared pump, at a predetermined rate that cannot be altered when in the air. Consequently, the engine runs at constant speed and the operator pays no further attention to it after getting started. When it is desired to bring the machine to the ground, the ignition is cut out simply by touching a string that short circuits the current from the high-tension magneto, causing the engine to stop at once.

The Farman and Delagrange machines, Figs. 3, 4 and 6, built by the Voisin Fréres, are constructed after the same model. In actual performances, they are second only to the Wright machines. Up to the end of October, 1908, Henry Farman was the only aeroplanist who had flown straight across country instead of merely circling over open military grounds. On October 30 he flew direct from the grounds in Mourmelon to Rheims, a distance of sixteen miles, rising to

heights varying from 120 to 300 feet, passing over the tops of trees and across fields and streams. A rather strong wind blew from behind, but did not interfere with the steering. The time of the flight was about twenty minutes. Delagrange, on September 17, broke the European record by remaining in the air for a few seconds less than half an hour, though Orville Wright had flown for more than one hour at Fort Myer only the day before, and four days later Wilbur Wright stayed up more than an hour and a half.

The wings of the Farman and Delagrange aeroplanes are rigid along both front and rear edges; and there is no arrangement for restoring lateral equilibrium. The center of gravity is brought very low, however, by the weight of the wheeled attachment which hangs below the lower plane. The "wings" are 40 feet from end to end and 6 feet wide. They are spaced 6½ feet apart and are set at an angle of 15 degrees from the horizontal when the machine is at rest on the ground. A single-plane horizontal front rudder is used, 16½ feet from end to end, and 39 inches wide. Its angle of inclination is controlled by a rod that extends directly back to a connection by universal joint with the shaft of a steering wheel like that of an automobile.

To give increased longitudinal stability, a large "tail" is attached at the ends of four rearwardly-extending rods. It is cellular, having canvas sides as well as upper and lower planes. The planes have the same form as the main planes and are 6 feet broad by 10½ feet from end to end at the rear edge and 8 feet at the front. A vertical rudder is mounted in the center of this tail and its movements are controlled by wires connected with the steering wheel.

A 50-horse-power Antoinette special aeronautical engine, Fig. 7, weighing with attachments 250 pounds, drives a single two-bladed propeller that is attached directly to the crankshaft. This turns at the same rate as the engine—1,200 revolutions per minute. The eight cylinders of the engine are arranged in two lengthwise rows set at an angle of 90 degrees to each other. They are water cooled and have a bore and stroke of 5½ inches. Direct injection of the fuel is employed in this as in the Wright engines, the gasoline being pumped to a distributor in the head of each cylinder, where it remains until the suction stroke. This engine is mounted on wooden bars almost in the geometrical center of the biplane, directly back of the operator's seat.

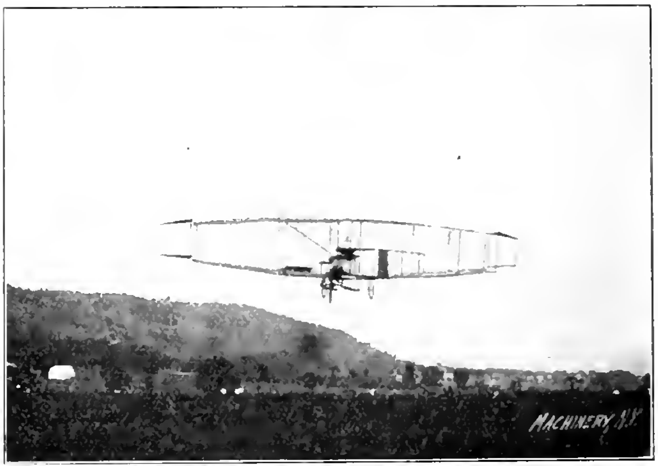
Fig 8. Power Plant and Operating Mechanism of Curtiss' "June Bug."



Copyright, 1908, by Edwin Levick, N. Y.

Fig. 9. The "June Bug" in Flight at Hammondsport, N. Y.

Of numerous other aeroplanes of the biplane type that have flown short distances, the one of most interest to Americans should be the "June Bug," built and flown at Hammondsport, N. Y., where it won the international trophy last July. This machine is very light, weighing but 430 pounds, including the tricycle upon which it runs on the ground. The framing is of tough woods and bamboo, and the covering of the wings is silk, varnished. The wings, which are tapered and curved toward each other at the ends, present a supporting surface of 408 square feet, so that with the operator at his post, each square foot has to lift only about 1½ pound, whereas the Wright machines have lifted 2½ to 3 pounds per square foot. A Curtiss air-cooled engine of 30 horse-power is used. It has eight cylinders of 3⅝ by 3¼ inches bore and stroke, with normal R.P.M. rate of 1,800, and is, like the Antoinette, of V type. The engine is bolted to a pair of parallel wood bars directly behind the head of the operator and almost in the exact center between the two superposed supporting planes of the machine. The power plant and operating mechanism are supported on a tricycle having bicycle wheels, which has been driven on the road, with the aeroplane wings and tail removed, at a speed of forty-five miles an hour simply by the thrust of the propeller blades in the air. Going to the other extreme from the designers of the engines previously described, Curtiss fitted a carbureter to each of the eight cylinders.

Movements of the "June Bug," Figs. 8 and 9, in the air are controlled by means of a single-plane horizontal rudder in front, a single vertical rudder in the rear, and by a system of movable tips on the ends of the wings. The rudders are manipulated by a wooden steering wheel having an outer peripheral groove in which lie a pair of small cables that extend to little pulleys on the framework at either side and

thence backwardly to the rear rudder. To elevate or depress the front rudder, it is required merely to push or pull on the wheels whose shaft is connected with levers that move the rudder. The wing tips are moved almost involuntarily by the operator in his instinctive leaning of the body away from the side of the machine that begins to restore lateral equilibrium: Wires connected with the tips pass through small pulleys and are attached at their ends to a light cradle made of steel tubing which fits around the shoulders of the aviator when seated. Thus, movement of the trunk of the body to one side elevates one set of tips and decreases the resistance on that side, and depresses the tips on the opposite side to the same degree, increasing the air resistance.

Of the many monoplanes that have been built on the principles evolved by Professor Langley, those of Louis Bleriot, Santos-Dumont and Messrs. Gastambide and Mangin have given the most promising results. As a class, the single plane machines seem to lack the stability and structural strength of the biplane. A number of accidents have occurred through the collapse of the wings, the plunging of the machines to the ground, and their complete capsize. In many respects the monoplane of Santos-Dumont (who has built and tried about a score of flying machines and airships) is most worthy of attention. It is the only one that up to this time of writing has flown more than 100 yards and alighted safely. Bleriot on June 29, 1908, flew 300 feet with his new monoplane driven by a 50-horse-power engine and having a wing spread of 36 feet and a total length fore and aft in excess of this; but on November 18, 1907, Santos-Dumont drove his monoplane, in Paris, 450 feet at a height of about 20 feet from the ground. The machine is very small, having a pair of wings with a spread of only 16¾ feet and a width of 6 feet, giving a supporting area of 107 square feet. The wings are mounted, together with the engine, on a tricycle, the complete apparatus weighing only 123½ pounds. It is driven by a two-cylinder opposed air-cooled engine of 17 to 20 horse-power, weighing 48½ pounds and mounted at the extreme front above the operator's head, where it drives a two-bladed propeller. Movements of the monoplane when in the air are governed by combined horizontal and vertical rudders attached by universal joint at the end of a 20-foot bamboo pole stayed by wires, and also by a horizontal rudder in front and a pair of kite-shaped vertical rudders secured to the sides of the tricycle under the wings. All of these rudders are controlled by a single operating handle.

While it is unsafe to prognosticate with regard to the development of so new a form of invention, one cannot but feel that the practical flight machine of the future will tend toward much smaller horizontal dimensions than those of most present aeroplanes, have a larger factor of safety, and positive means of maintaining lateral and longitudinal equilibrium that will enable any person with due caution to avoid absolutely a sudden dash to earth. At first we may expect that they will be built small and light for individual use, but later increase in capacity to two or four persons as the public grows accustomed to their use. They will be less expensive than automobiles and will be extensively used for private pleasure and for racing, as well as for scouting and other military purposes.

* * *

The Association of Licensed Automobile Manufacturers has tentatively adopted a design of quick detachable rim for automobile pneumatic tires. It is the desire of the mechanical branch of the association to settle on a standard design which will meet general approval, and which will do justice to all concerns that have developed detachable rims. The tentative adoption of one style was for bringing about conformity of action, and is in no sense a final adoption. The final adoption is contingent upon other than mechanical questions. This is the substance of a statement made by Mr. Albert L. Pope, chairman of the tire committee. The importance of a quickly detachable rim in the automobile trade is so great that it seemed necessary to take a decisive step that would lead to uniformity of design. It is probable that the detachable rim will become almost universally used because of the convenience and quickness of repair of punctured tires, made possible by this construction.

THE LAWRENCE INDUSTRIAL SCHOOL.[*]

The Lawrence Industrial School opened October 19 with a registration of over 900 students, and resumes its classes with the most brilliant prospect of another year of success. This school is the only independent industrial school in Massachusetts, with independent buildings, and with an independent board of five trustees. It was established under the industrial school act, and opened last year with evening and day classes for those already engaged in the trades. This school represents a new phase of education; namely, a practical education by which the industrial worker may meet his daily needs. Industrial superiority depends upon industrial training and education, and this training and education can be accomplished best, not by the necessarily rude methods of the mill and shop, but with those methods supplemented by industrial education. It was such a school that Lawrence lacked until a few years ago. The deficiency has been supplied with a speed and on a scale of which no one dreamed. What has been accomplished reflects great credit on the enthusiastic, far-sighted, and energetic trustees: Dr. M. F. Sullivan, president of the board of trade; James Barnes of the American Woolen Co.; Walter H. Summersby, agent of the Atlantic Cotton Mills; A. X. Dooley, attorney at law; John B. Cameron of the Central Labor Union; and the principal and chief executive officer, William H. Dooley. Principal Dooley has made an extensive study of industrial school methods in nine European countries. The result is that Lawrence and the surrounding cities and towns are now provided with the means of educating in a systematic manner their large number of textile and metal workers. No entrance examinations are held, the only qualification being that the applicant for admission be an operative. The school is free. Text-books are edited by the instructors, and printed by the commission. The problems, drawings, and notes are practical, the drawings and notes coming from the shop, so that the school keeps in touch with the industries. These notes and problems are obtained by means of a question box. The instructors are practical men, working in the industries and conversant with the needs of the operatives.

Practical Instruction in Reading and Making Drawings.

The evening instruction appeals to the student immediately at the beginning of his work. For example, a young machinist had received a reprimand from his foreman because he could not read a working drawing with sufficient skill to do his daily work properly. He enrolled in the mechanical drawing course in the evening drawing school, thinking this course would meet his deficiency. He found that the first two lessons were concerned with lettering plates, the next three with drawing straight and curved lines and the handling of instruments, and that the remainder of the term was spent on the projection of points, lines, surfaces and solids. During all this time he was receiving in his daily work the same reprimands, and was therefore debating in his own mind the value of the drawing course. It is undoubtedly true that the drawing course this teacher had outlined in the drawing school is a proper one for teaching mechanical drawing for those who are to be draftsmen, but the average apprentice machinist, as well as this young man, does not see the direct application of this instruction to his work. He enrolled in the drawing school for a definite purpose. To be sure it was a narrow one, but nevertheless it had economic value to him. As the result of this young machinist's experience, the principal immediately offered a course in blue-print reading and arithmetic for machinists. This is one of the most popular courses in the school.

The first lesson begins with some elementary instruction in the reading of simple drawings; to teach him in five lessons where to look for the dimensions denoting length, breadth, and thickness; to show him the principles of simple sectional drawings and have him comprehend the laying out

---

[*] For additional information on this subject see the following articles previously published in MACHINERY: Evening School of Trades—Rindge Manual Training School, Cambridge, Mass., July, 1908; Can a Boy Learn a Trade in a School? April, 1908; Promoting Industrial Education, May, 1907; A Step Toward Increased Facilities for Industrial Education, December, 1906; An Experiment in Industrial Training, September, 1906.

of holes for drilling. Instead of leaving school at the fifth lesson with no instruction which appealed to him, the students have received enough in those five lessons to fit them to meet the needs of their foreman, and are anxious to continue and receive the more definite and thorough instruction in the theory of mechanical drawing so as to be able to make sketches of machines and parts by means of a ruler and compass. It is not the aim of this course to teach the students to make pretty picture drawings.

Practical Mathematics.

The instruction in the various branches of mathematics is adapted to meet the needs of the mill operative, the machinist and the steam engineer. The terms used in the class room savor of the shop and mill. For example, the method of finding the heating capacity of a boiler does not appeal to the weaver in the mill, and, on the other hand, finding the size pulley for a certain loom does not awaken the interest in the steam engineer as much as the problem involving the same operations dealing with work in the boiler room.

Students Classed by Vocations.

All our students are classified into vocational classes according to their trade. For example, there is a class in arithmetic for engineers and a separate class in the same class for boiler firemen. Again the textile designers have a class in arithmetic called cloth calculations and the loom-fixers a class called loom calculations. This idea carries out the plan of the old workingman's guilds. Each guild was formed for the purpose of social intercourse and mental stimulus. Each trade had its own guild. The daily trade experiences of each member became the property of all members. Discussion relating to the practices of their chosen trade occupied their attention. So, to-day, workingmen have common trade interests. Our evening students are grouped according to their occupations and in this way have an opportunity to talk over these interests. The teacher acts as a leader and draws out the students in telling their trade experiences and, through the expression of these various opinions of the work, practical solution of the particular problem at hand is obtained. It is difficult to get students to recite and express themselves at the blackboard. A free discussion of the point at issue makes the student lose his self-consciousness and before he is aware of it he is at the board illustrating his particular method of solution. Of course such discussions are under the wise guidance of the teacher.

Provision for Irregular Attendance.

Provision is made for students who cannot attend but once or twice a week. It is quite common for students to stay away because they cannot attend "regularly." This applies to a great many textile workers. In prosperous times the mills are run evenings and the employes are expected to work overtime. But they can usually get away for one night in the week during such times. They cannot always tell definitely what nights they will be called upon to work. Students who are working overtime are allowed to attend any night during the week after the work is fairly started. Such a plan is feasible. Boiler firemen alternate in working day and night. A fireman who works days this week will work nights next week, and so on. The week he works nights he attends the day classes, and the next week he attends the evening classes.

Scope of Instruction.

A certificate is awarded each person completing a course. Day classes are formed for the convenience of those who are unable to attend the evening sessions. The school is in a position to compete with any of its kind, over $32,000 being represented in its up-to-date woolen, worsted, cotton and steam machinery. Classes in the following subjects will be formed for both day and evening pupils: Woolen and worsted spinning, woolen and worsted weaving, woolen and worsted finishing, dobby and jacquard weaving, cotton spinning, cotton weaving, loom fixing and loom calculations, mill arithmetic and mill bookkeeping, elementary and advanced textile designs, elementary and advanced cloth calculations, industrial and commercial electricity, steam engineering for firemen, steam engineering for engineers, arithmetic for firemen and engineers, blue-print reading, machine drawing and arithmetic for machinists, shop arithmetic, industrial and commercial chemistry, experimental and practical dyeing and dressmaking for working girls.

The courses of woolen and worsted manufacturing are arranged to meet the daily needs of those working in these industries. Instruction is given in all the various processes employed in adapting the wool fiber to cloth, namely: Sorting, scouring, carding, combing, spinning, designing, weaving, dyeing and finishing.

Cotton Course, Dyeing and Chemistry.

The cotton courses are designed to meet the needs of the men working in these industries—to make better workers of them and to train them to think and take an interest in their work. If a sufficient number registers, classes will be formed in picking, carding, drawing, roving, spinning, combing, designing and weaving. In connection with this work a course in knitting is offered. The equipment of the department is of the best up-to-date cotton machinery.

Experimental laboratory, dye house and industrial chemical laboratory work is carried on in a building located in an ideal spot for a dye house. It is situated on the banks of the Merrimac just above the falls, away from the class rooms and dwellings. It is modeled after one of the most practical experimental laboratories in the country.

Steam Engineering and Electricity.

One of the strongest departments of the school is the course in steam engineering and electricity. The course consists of lectures by practical men who are specialists in their respective branches; arithmetic and practical mathematics for engineers, firemen, etc., and laboratory practice in steam engineering. The steam engineering laboratory is one of the best equipped laboratories in the country, consisting of different types of boilers, steam heating apparatus with appurtenances, different pumps in sections, sectional valves and gages, all the boiler accessories, steam engines, generator and many other machines. In addition to all these, pictures, blue-prints and sketches of the above apparatus and other machines are on the wall for study. All the lectures, classes and demonstrations are carefully planned to meet the needs of those working in the trades. Classes are formed afternoons for those working nights, and evening sessions are conducted for those laboring days. This is the first free engineering laboratory in this country.

Limitations of Present Schools.

The purpose of most of our present technical and textile schools is to give the highest possible instruction in science, and to give this knowledge to the operatives of the industry. In order to enter these schools, the student must be a graduate of a high school and have received a thorough preparatory training. Most of the present textile and metal workers have never received over four years schooling and this was before twelve years of age, and the average boy cannot afford to remain unproductive beyond the age of seventeen. Hence the schools fail to provide an education for the great mass of our future industrial workers. The education received in these schools often exceeds the real needs of the metal and textile industries. Hence there is a loss of time which could be better devoted to obtaining practical skill. Then again most of our boys cannot afford to pay $150, the tuition necessary to enter our present textile and technical schools. Neither are there free scholarships provided. In consequence of these considerations, there is found to be need of an industrial or technical school somewhat less pretentious in its course of study, somewhat lower in its requirements, and giving instruction of a character more directly vocational or more directly industrial. This is the aim of the proposed secondary industrial school in Lawrence—a school much needed in every industrial community. A canvass has been made in the city of Lawrence and over five hundred boys have signified their intention of attending such a school, a school to provide a three years' learning for a boy in either the metal or textile industries.

More people fail from lack of confidence in themselves than from lack of ability.—*The Silent Partner.*

DESIGN AND CONSTRUCTION OF METAL-WORKING SHOPS—4.

WILLIAM P. SARGENT.*

DEFINITE PLANNING.

The general plan for a works designed to employ 1,500 men has already been presented, and we are now ready to take up the definite planning. The more designing, subject to approval, that the construction engineer can have done by outside parties, the quicker and better the plant can be built. This policy is recommended for the reason that no one person can have that definite knowledge of all subjects possessed by those who specialize in a certain line. The designers belonging to the plant can be more profitably employed on work which cannot be carried out except under the engineer's constant supervision.

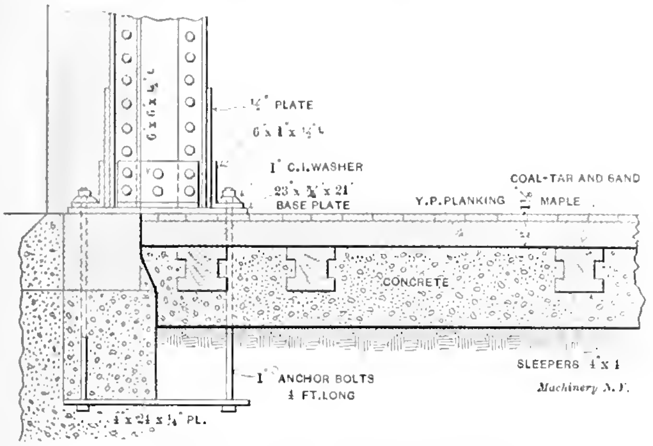

Fig. 28. Section of Flooring, Ground Floor.

An architect should be employed for the buildings, and the engineer should give general instructions and follow up the designs of the buildings; by acting in an advisory capacity the general ideas of the engineer can be closely incorporated. The architect should be made to understand that shop buildings are for use and not for ornament, and should be required to take the responsibility of the accuracy of the figures embodied in his plans. The engineer and the architect should work up the steel design sufficiently to arrive at the tonnage in order to give the steel companies the information required for making bids; it is good policy to permit the steel companies to make the detail design of the structural work, and to enter bids at a tonnage price, the prices being based on an approximate tonnage erected within a given time. The engineer has control of the tonnage on account of the detail construction being subject to his approval.

Data for the Architect.

The following data should be furnished the architect:

1. The block plan and cross sections, already made up.

2. The cost range, within which the buildings are to be designed. For present prices, this should be from $1.50 to $1.65 per square foot for the main buildings.

3. The column spacing determined by considerations of actual necessity and of economy in the cost of steel work: for the erecting shop No. 6, 25 feet, to tie with the span of the wing shops; for the machine shops Nos. 1, 2, 3, and 4, and forge shop No. 5, 16 feet, because of economy and the fact that the bents in the old shops are 12 feet and are almost wide enough; for the foundry No. 8, 20 feet. For the pattern storage building No. 9, 16 feet is suggested, but the previous caution, respecting the laying out of the pattern rack system and the window spacing, should be considered.

4. The bearing power of the soil (obtained from actual tests) and the nature of the foundations proper. Concrete is almost universally used. The cheapest type of foundation consists of a footing 12 to 18 inches thick, for the column piers, and a plain foundation wall uniform in thickness, about two feet deep, between the piers. Reinforcement is used in the footings to prevent breaking in the corner where the pier starts, and in the bottom of the wall to prevent cracking. This type of foundation requires no forms for the footings, and but a plain form for the wall and piers.

5. The loads for which the steel work should be designed. The snow load varies with the latitude, and there is plenty of data to govern. With a gravel roof laid on plank sheathing, 40 pounds per square foot of projected area is often assumed for the total load on the trusses, in the Central States. For the floor loads for the machine shop galleries, 250 pounds live load is sufficient for the class of work to be done. Anyone who has not studied the weight on loaded floors will be surprised at the amount of material and machines required to load a floor to even 150 pounds; in this case we need extra rigidity to reduce the vibrations caused by rapidly moving cranes. For the sand floor, the steel work should be designed for a safe load of 400 pounds and the concrete floor should be designed for a safe load of 600 pounds. The sand will often come in wet and may be 8 to 10 feet high at times, equivalent to a load of 1,000 to 1,500 pounds. For the pattern storage assume a load of 120 pounds, based on an equivalent of 4 feet of patterns solid on the floor. It is well to design this building for the addition of another floor in the future, as this added space can thus be obtained at less price than by building on the ground.

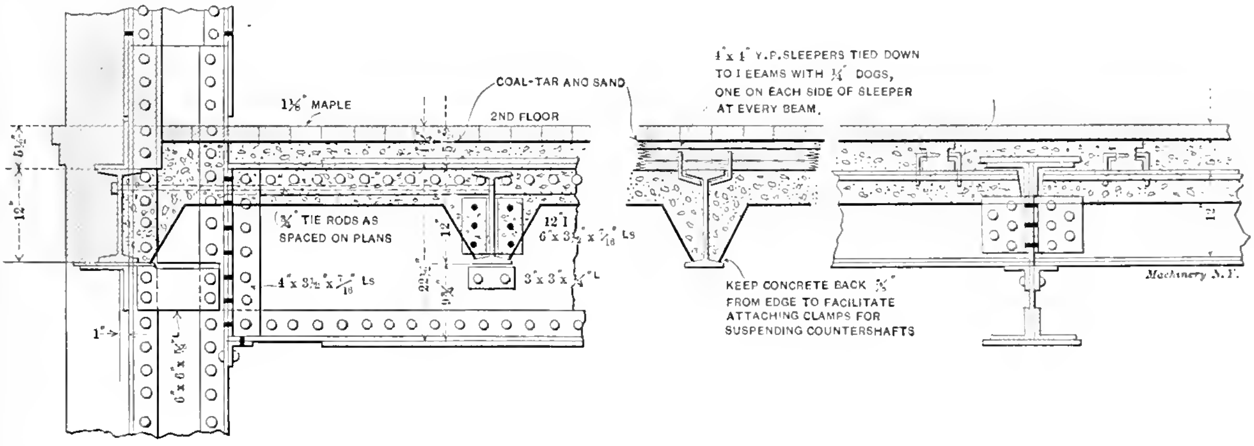

Fig. 29. Section of Flooring in Galleries.

6. The maximum wheel loads of the cranes and the distribution of the wheel loads on the crane girders. The table given on page 19 of Ketchum's "Mill Buildings" is representative for the loads of most cranes. Often the wheel load is taken as equal to the rated capacity of the crane. This is very safe.

7. Brick curtain walls 8 inches thick are sufficient, if built between the columns and well supported by the horizontal members of the steel work. An 8-inch brick wall will conduct nearly 45 per cent more heat than a 12-inch wall, but there is such a small percentage of brick surface that this factor of heat loss will not justify the expense of a wall thicker than 8 inches.

8. Window data. There should be swinging windows as close to the ceiling as possible, and part fixed sash, and part sliding sash, below these to within 4 feet 6 inches of the floor,

---

* Address: 315 South First St., Rockford, Ill.

except where crane girders and intervening brickwork interrupt. The frames, sash, and glass should be standardized to a few types and sizes.

9. Steel rolling doors for the larger openings, and sliding doors for the openings through which freight cars do not pass, should be provided. There should be a wicket door in each sliding door, and enough other small doors to permit of going from one shop to another, in winter, without opening up the large doors.

10. Floors should be made as follows: 6 to 12 inches of gravel concrete with 4 x 4-inch sleepers embedded; then a layer of fine sand and coal-tar; then 2-inch tongued and grooved yellow-pine planking which is spiked to the sleepers. The sleepers should be on 24-inch centers. On the planking is laid a 1⅛ x 4-inch square edge maple top floor. This floor will cost from 22 to 30 cents a square foot, according to the thickness of the concrete. The contract for the floors in buildings where machine foundations are to go in, should be let separately on a square foot basis. This avoids laying out the tools at an early time, and gives the shop officials time to decide on a satisfactory layout. Fig. 28 shows section of ground floor, and Fig. 29 gallery floor.

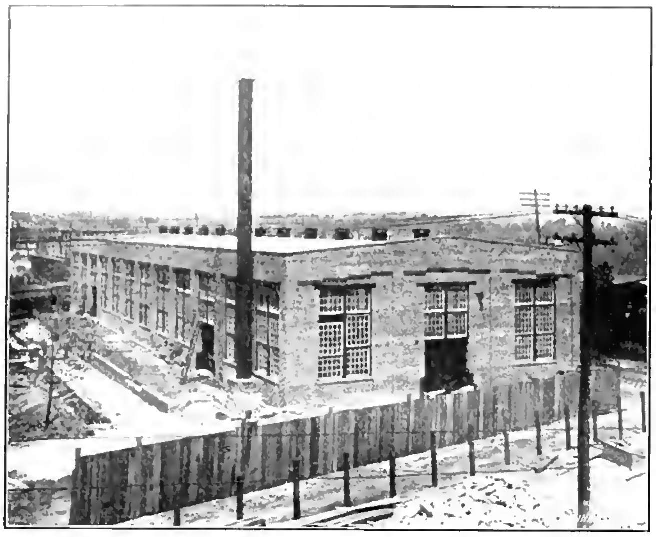

Fig. 30. General Appearance of Shop Building such as Specified.

11. Fire-proof vaults should he provided in No. 8 building, foundry office, and on all floors of the No. 9 building.

12. Locating wash rooms and closets in large works is always a problem; placing them on the mezzanine floors, wherever possible, is about the best solution; and this is possible with the headroom that we have provided.

Fig. 30 shows the general appearance of the type of design outlined above.

General Work for the Engineering Force.

While the architect is working up the shop building plans, the power plant should be designed complete, under the engineer's supervision. The drawings should be prepared early, as deliveries on power apparatus are long, even in dull times. Standard apparatus should be used if the conditions permit.

At about this point in planning shop improvements, the need of a detailed list of the matters requiring consideration, becomes apparent. A good way to get up a reasonably correct list at the start is for the engineer to sit down with some one of his men, conversant with the general plan and experienced on construction work; then with the survey plat, block plan and photographs of the site before them, they list, independently, every item that comes to each man's mind. The two lists when combined should agree fairly well.

The following list gives the main headings that, in general, would enter into such a list. Besides the building numbers of the block plan, the yard space North is designated by the letter *A*; the space East by *B*; the space South, inside the fence, by *C*; the space South, outside of the fence, by *D*; the yard spaces between the wing shops by E_1, E_2, E_3; between the machine shops and foundry by *F*; and between the foundry and pattern storage building by *G*.

Suggested Itemized List of Details Necessary to Complete the Plant.

Required definite planning, securing bids and prices, contracting and purchasing, constructing or executing of the following: Clearing the site, selection of grades for floors, tracks, etc., staking out buildings, tracks and fences.

Underground Work.

Sewers.—Storm sewers, to take care of roof drains and surface water in yards.—Sanitary sewers, to reach all buildings, excepting Nos. 10 and 11.

Water Service.—Fire and sprinkler mains, to reach all buildings and hydrants in yards.—Shop service, to provide drinking water, for flushing, and for wash rooms.—Condenser main from steam and discharge pipe.

Power Mains.—Heat to all buildings excepting Nos. 10 and 11.—Steam to forge shop No. 5 and dry-kiln No. 10.—Air to all main buildings.—Oil to No. 5 and No. 8.

Foundations.—Building foundations.—Holes in building foundations for service mains and for power tunnel.—Machine foundations in shops and in power plant.—Crane runway foundations in yards.—Pits in erecting shop and foundry.—Power tunnel between buildings.

Work Above Ground.

Lighting.—All shop interiors, the yards between the shops, all gateways and main avenues within the works.

Power.—To all shops and yard cranes.

Plumbing.—Air piping.—Water piping.—Sprinkler system.—Gravity tank.

Tracks and Equipment.—Tracks, switches.—Track scale.—Scale house.—Locomotive shed.—Watchmen's sheds.—Switch engine.—Locomotive crane.

Telephone system.

Structural Steel.—Roof loads, floor loads, crane loads, column loads.—Provision for extensions, for attachment of jib cranes, for support of counter-shafts and line-shafts, for fireproofing, for attachment of trolley hoist runways, for support of top end of window-frame, for support of pipe coils.—Elevator guides and framing, railings, anchor bolt diagram, anchor bolts, plates and column foot-plates.

Concrete Floors.—In all buildings excepting No. 5, No. 8 and No. 11.

Cement Floors.—For all wash rooms, boiler room, pattern storage rooms.—Treads for stairs, stair landings.

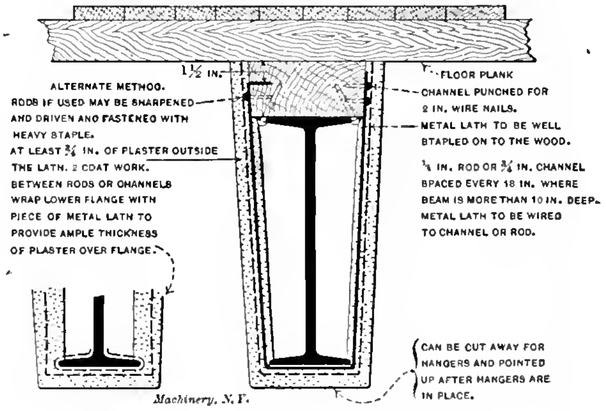

Fig. 31. Fire-proofing of Steel Beams.

Fire-proofing.—Fire doors in all fire walls.—Metal frames and wire-glass windows at junction of wing shops and No. 6 building, on foundry side of boiler house, on either side of fire walls.—Concrete or mortar protection of exposed steel work in No. 9 building. (Fig. 31 shows an economical method of protecting beams and columns, suggested by the Associated Factory Mutual Insurance Company.)

Concrete Roofs.—Over charging floors, over dry kiln.

Walls.—Brickwork, anchors, pilasters, parapets, coping, wood for lumber shed.

Windows.—Widths, heights of frames, size of sash, size of glass, pivot windows, balanced sash, weighted sash.

Doors.—Rolling, sliding, wicket, and small doors.

Roof.—Gravel, sheathing, wood purlins, saddles, strainers, downspouts flashing and counterflashing, ladders.

Floors.—Under planking, top floor, troughs for piping, industrial tracks.

Miscellaneous.—Stairways, vaults, core-ovens, offices, elevators, cranes, trolley hoists, traveling jib cranes.

Power Plant Equipment.—Engines, generators, switchboard, boilers, stokers, ash and coal handling apparatus, feed-water heaters, water softeners, condensers, feed-pumps, fire-pump, compressors, receiver, engine room crane.

The preceding list does not enumerate the details, as each building has its own characteristics. Each building should be taken separately and the general heads enlarged upon according to the conditions. The listed items should be checked off, as soon as the drawings required are under way. Consulting with the various foremen of departments will constantly add to the list, as various improvements are suggested. These little things bring the cost up amazingly, and that is the reason why the engineer should hold to a broad range in his original estimate.

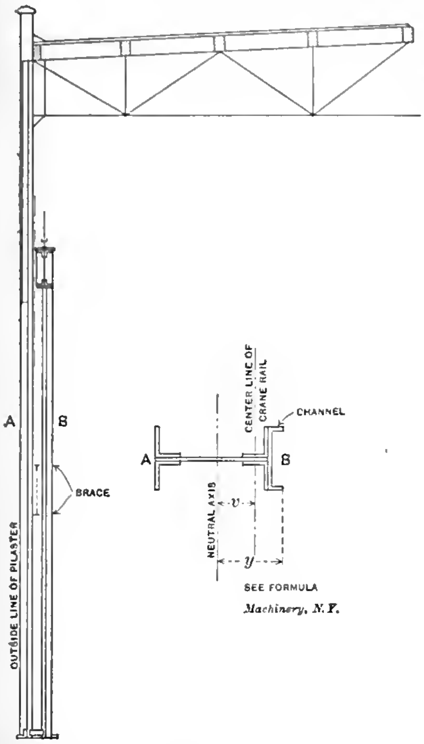

Fig. 32. Economical Form of Truss and Column.

Time Chart to Govern Work.

After listing the details of the work, a time chart can be made out, to be used in controlling the commencement and completion of the various details. This time chart or schedule is the most important record used in completing a series of improvements within a definite time. It is as important, as a train schedule is to a railroad.

The construction of a large plant, naturally, is separated into divisions, each complete in itself. The time chart should be divided accordingly, for instance, machine shop No. 1, machine shop No. 2, etc., and into general divisions which cover the work that cannot be charged to the separate buildings.

We should have a chart for each division, and each class of work for each division should have columns as follows: Drawings, dates of commencement and completion; account number, against which to charge cost; name of contractor; date of order or contract; date when work should be commenced; date when commencement is promised; date of promised delivery; date of delivery; date when work should be completed; date of promised completion; date of actual completion; estimated cost; actual cost; notes. Each item of work should have three lines, so that revisions can be made without erasing the original dates. Revisions generally are necessary, as a spell of bad weather, or a strike, can throw out of gear the best laid plans. The dates should be adhered to, and the contractors should be held to their promises irrespective of the state of subsequent work. The following instance shows the importance of this latter statement. The general contractor on a certain building, was delaying the completion of the foundations, giving as a reason *that the steel work was not in sight*. At the same time, investigation developed that the steel company was delaying *because the foundations were not completed.*

Foundations.

The depth of the foundations will depend upon the depth of excavation required to reach a soil with a minimum bearing power of two tons per square foot. The figures given in "Trautwine" are safe for estimating, but actual tests should give the data for specific cases. The footings should be proportioned to sustain the actual dead load of buildings and an average of the added loads on the building superstructure, omitting the snow load. For the crushing strength of the concrete piers, 250 pounds per square inch should not be exceeded for plain concrete, and 700 pounds per square inch for reinforced piers. The area of the footings will be about 7.5 times as great for a gravel subsoil as the area of steel column foot plates. The total weight bearing on the foundations will approximate 300 pounds per square foot of ground floor space for gallery shops, such as Nos. 1, 2, 3, 4, and 8; 250 pounds for high shops without galleries, such as No. 6; and 200 pounds for low shops without galleries. These loads will require, respectively, 1/50, 1/60, and 1/90 cubic yard of excavation, and 1/75, 1/90, and 1/135 cubic yard of concrete per square foot of ground floor space. The foundation wall for carrying the weight of brick work between the columns, if made about 2 feet deep and reinforced, will cost only half as much as foundations that are carried down to the level of the column footings.

Structural Steel Details.

In order to secure sufficient strength of steel work at a low cost, the following points should be watched, either in the design or in the checking. Crane loads and concentrated loads on the trusses add complexity to an otherwise simple proposition.

Trusses.—The stress diagrams should first be checked. The stresses in the upper and lower chords can be found approximately by the formula:

$$\text{Maximum stress per square inch} = \frac{W \times L}{8 \times D},$$

in which W = the total weight on both columns (including the weight of the truss); L = the length of the span between columns; D = the average depth of the truss in feet. The writer has compared the weight of a number of trusses for flat pitch roofs, for column spacings of 16 and 20 feet, with plank roofs and wood purlins, and none exceeds 5 pounds per square foot of projected area of roof. Calculations based on a total load of 40 pounds per square foot of projected area should be safe for the latitude of Chicago and the South, and 50 pounds for New England. One of the leading structural firms in the Central West recommends for flat roofs the form of truss shown in Fig. 32, the height in the center being about one-tenth of the span. Angle sections are used and the price, erected, in the vicinity of Cincinnati is about $60 per ton (October, 1908). The height specified requires about 25 per

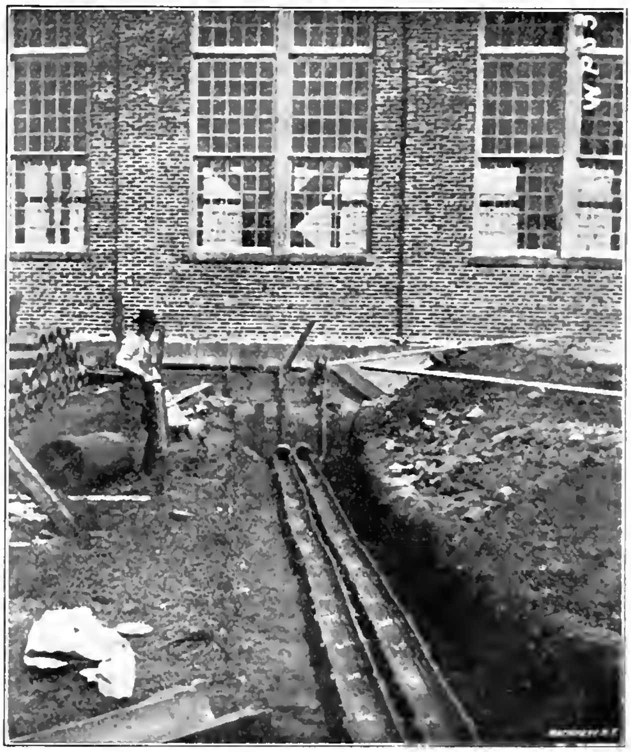

Fig. 33. Laying Split Tile Pipe for Running Pipes Underground.

cent more metal than if made one-eighth of the span, but the added cost, at $60 per ton, for the shallower truss is less than the added cost of the brickwork in the walls for the higher truss; and it will not take any more time to erect the heavier truss, but will require more time to build the higher wall. The allowable stress per square inch of the various truss members can be found in Kidder's "Architects and Builders' Pocketbook," pages 463 to 470, or on pages 143 and 144 of the Cambria, or on page 209 of the Jones & Laughlin handbook.

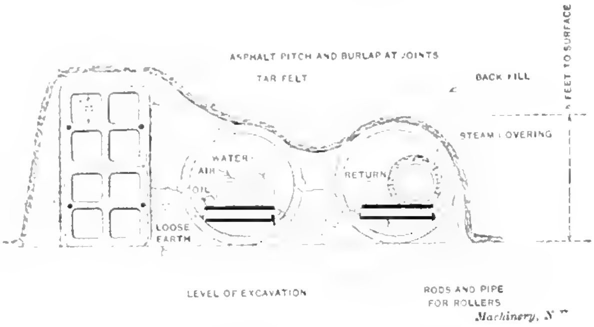

Fig. 34. Section of Conduits shown in Fig. 33.

Columns.—Many different forms of columns are used to support roof and crane girders. The column, shown in Fig. 32, is probably as economical as any. In a general way, the angles on the girder side (sometimes reinforced with a channel) are designed to support the crane loads, and the angles on the other side are designed to carry the roof. This form of column will cost from $65 to $70 per ton erected, at the present time. The area of section required for this form of column is found by the formula

$$A = \frac{I}{p}\left(P + \frac{3\,V P_e}{y}\right)$$

in which A = area of column section,

p = maximum allowable stress per square inch,

P = total load, both eccentric and concentric,

P_e = eccentric load,

V = distance of eccentric load from neutral axis of the column,

y = distance of extreme fiber from the neutral axis on the loaded side.

The number of formulas giving values of p are many, but the values given in the steel companies' handbooks are a good basis, as they are tabulated. Increasing these values about 7 per cent will give the allowable stresses according to the Chicago building code. Increasing them 11 per cent will give approximately the stresses used by the steel companies in calculating the safe loads for their special forms of columns.

For columns for very light loads, built into walls, single I-beams can be used, costing about $56 per ton, erected. Short columns, made up of four angles, laced, require the least area of section for light loads, and will cost about $75 per ton, erected.

Crane Girders.—These should preferably be made of angles and plates with a generous depth, as deep girders help to stiffen the columns, and minimize the effects of the longitudinal thrust of the cranes, which is a great deal more than generally assumed. From records of current consumption of 30 ton cranes, starting with load, the thrust on each girder is equal to 40 pounds multiplied by the number of tons load and the total weight of the crane.

Lintels—Channel girders with cast iron separators are the cheapest for a given load, but lintels made up of an I-beam, with a plate riveted to the bottom flange, are neater, as the steel is not exposed to view. In general, sections less than ¼ inch should not be used, and in forge shops a sixteenth of an inch should be added, as the extra thirty-second on a side is better protection against the destructive action of the gases than any paint, although the paint should be there too.

Stairs.—These should be formed of channels for horses, and the treads of channels with flanges turned up, and filled in with cement and cast-iron chips mixed. Pipe railings should be better secured to the channel horses than by the usual means of malleable fittings, as these are rather too weak.

Elevator Towers.—Where hydraulic plunger elevators are not used, towers made up of angles diagonally braced should be built from the ground up, thus relieving the floors of this load. The hatchway should be 2 inches longer than the desired length of platform and about 2 feet wider, to provide for guides, counterweights and cables. The tower should have a platform at least 15 feet above the upper floor for the winding engine. It is a mistake to merely provide openings for an elevator and to leave the means of support as an after consideration.

Anchors, etc.—Holes should be provided in columns and girts for anchors for the brickwork, and in lintels for attaching the window frames. A light angle on either side of the frame and extending down to the next lintel or girt, with holes punched at intervals of 4 feet, will permit of erecting the frames in advance of the brickwork and will obviate the use of jamb-blocks (wooden blocks built into brickwork and nailed to the frames).

Relation of Types of Construction to Insurance Rates.

The following table shows the basing rates of one of the Inspection Bureaus of the Central States, and the modifying factors, as applying to industrial plants.

RATE IN CENTS PER $100 PER YEAR, ON BUILDINGS AND CONTENTS.

	Machine Shops.	Foundries, Non-combustible Cupola Platforms.	Pattern Storage.
Two-story mill construction, 10,000 square feet area on each floor	100	135	85
Steel or brick construction	85	115	70
Reinforced concrete or fireproofed steel construction, buildings	25-50	30-65	20-45
Reinforced concrete or fireproofed steel construction, contents	50-75	65-100	45-65

When sprinklers are installed in any of the above classes, the rate on buildings is within a range of 20 to 35 cents, where there is from 50,000 to 75,000 square feet of sprinkled area. Additions to basing rates are made for more than 20,000 square feet in one area ground floor, and more than 10,000 square feet on second floor, and when cupola is less than 10 feet above roof. Defective wiring carries a charge of 10 cents, and when there is no city fire protection 25 cents is added to all rates. Rates are modified for A. D. T. watchman service, stand pipe and hose, chemical extinguishers, etc. In large plants, where a blanket policy covers, the insurance companies are not always strict about enforcing underwriters' rules, but it is to the owner's interest to make the plant safe and avoid as far as possible the loss due to interrupted business caused by a serious fire. Therefore, preventative means, such as enclosed elevator hatchways, stairways with metal lath and plaster, wire glass windows, fire doors, etc., are well justified.

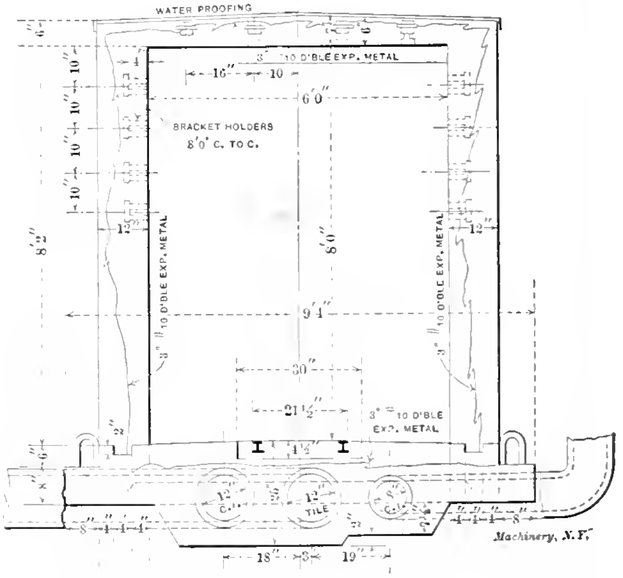

Fig. 35. Section of Tunnel for Pipes and Electric Conductors and Transportation of Castings.

Power, Steam and Water Distribution.

Electric Mains.—The private plant has a choice between overhead work and underground conduits or tunnels. The advantages of overhead distribution are first cost and efficiency. For underground distribution there is a choice between multiple tile ducts having spaces for four or six conductors, and tunnels used also for steam and water and air pipes. This is objectionable as it is difficult to keep the wires away from the hot or warm pipes at all points.

Pipe Mains.—Underground work is the most natural means of distribution. The general method is to group all piping and wiring into a tunnel. This gives perfect accessibility, but the expense is hardly justified unless the tunnel is necessary as a means of communication between various parts of the plant. A compromise method of distribution is by means of split, or lidded tile pipe. There is not the accessibility, as in a tunnel, but the difference in first cost is so greatly in favor of the split tile, that the expense for occasional excavating and repair of a leak is well justified. The pipe mains, laid in split tile, can be tested as severely as desired before putting on the lid and back-filling. A leak in a steam pipe is easily found on account of the heating of the ground in the vicinity of the leak. Fig. 33 shows two runs of this pipe, ready for the pipes. Fig. 34 is the cross-section of this line and shows the simplicity of this means of underground distribution. A tunnel must be necessarily large enough for added pipes and for men to work. Fig. 35 shows a cross-section of a tunnel for both power and transferring castings, and Fig. 36, a tunnel for power distribution alone.

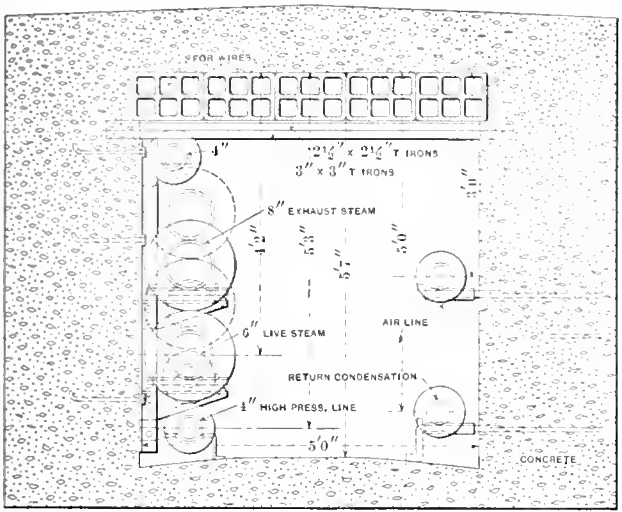

Fig. 36. Cross-section of Tunnel used for Pipes and Electric Conductors only.

The work shown in Figs. 33 and 34, for a distance of 260 feet, actually cost, in 1907, per lineal foot, complete, ready for use, with steam, water and current, $3.30, excluding the cost of the copper cables; all labor and material, excepting cables and wrought iron, $2.00. These costs were within 5 per cent of the estimate. In comparison, the estimated cost of a tunnel 4 feet by 6 feet inside was about $7.00 per foot, ready for piping and wiring. Adding to this figure the actual cost of piping, and labor of installing, $1.30, and the cost is $8.30 as compared with $3.30.

* * *

The Schlick gyroscopic apparatus for preventing the rolling of ships at sea has lately been installed on the British passenger steamer *Lochiel*. According to *Engineering*, the apparatus has proved a success in actual use, and decreased rolling of a total angle of 32 degrees to a roll from 2 to 4 degrees, an amount which is barely perceptible to the passenger. The apparatus has previously been tried in England on an experimental basis, but this is the first time that it has been installed in a British passenger steamship. The gyroscope is driven electrically, and requires very little attention. The design has been simplified, is more compact than the previous one, and takes up a comparatively small space in the steamer. It can be easily thrown in or out of action according to the requirements.

INVENTORS VS. EMPLOYERS AND ASSOCIATES.*

E. C. SMITH †‡

"What did *you* invent?" This question was propounded to one of two alleged joint inventors by an astute attorney. It developed, as the attorney expected, that the interrogated party had no part in the conception and development of the device invented, but merely a pecuniary interest therein. Therefore the patent at issue was void, because it had been falsely sworn to, one of the parties to the patent application having taken oath that he was a co-inventor when he was not.

A misconception, considerably widespread, exists concerning "invention"—the mental conception, and the embodiment of the mental conception—and the title "inventor." The embodied invention possesses property value which can be secured for a term of years by "letters patent." This property value, or right and title in and to a patented invention, is transferable. It can be shared with others or disposed of in toto, but only by assignment.

The title to inventorship is not transferable, for the simple reason that the mental process or act of inventing is not transferable.[1] The astronomer who discovers a new star is *the* discoverer. The discovery is his act and though he may see fit to attribute a share in the discovery to another, the statement is false unless that other was directly instrumental in the discovery. It is not sufficient that he was with the discoverer at the time. Even though he provided the instruments with which the discovery was made, he is not the discoverer or a co-discoverer. In the same way, the inventor may not share his title to inventorship with his friend as a courtesy, or with him who finances his efforts as a measure of security to the latter's property rights in the invention. Notwithstanding the simplicity of the foregoing proposition, its dictates are frequently transgressed, and the following actual examples indicate various forms in which the transgression takes effect.

"I want *B* to go in with me on this patent. He has helped me out a lot of times, and I want him to share the credit and profit of this thing with me."

Again: "*C* has worked on this thing with me and I am going to let him in on the patent as one of the inventors, to encourage him. He hasn't really invented anything, but has made some good constructions. It's good policy to call him one of the inventors."

The third case is piratically startling. A skilled mechanic was employed and paid to develop a certain machine. He, in turn, delegated a skilled designer to the work, leaving it in the designer's hand and devoting no attention to it personally, whatever. The designer made some patentable improvements and his employer blandly told him to prepare the requisite patent application drawings, and he himself would apply for the patents. The designer, however, knew his own status in the matter and insisted that the application should be filed in his own name, which was proper under the circumstances.

The first two cases are by no means uncommon, and well illustrate how a desired end may be defeated by improper procedure. The third example is also of a not uncommon practice, and it illustrates a peculiar condition, *viz.:* the attitude of certain employers who seem to think modern employment is akin to feudal servitude or vassalage, and that the wages and salaries they pay accord a lien on the

† Address, R. F. D. 4, Attleboro, Mass.

‡ Edwin C. Smith was born in Elizabeth, N. J., 1869, and received a technical education in the Massachusetts Institute of Technology. He has been employed by the Union Hill Trimmer Co., Boston, Mass., Lockwood, Greene & Co., Boston, Mass.; Universal Winding Co., Providence, R. I., and the Mossberg Wrench Co., Attleboro, Mass., with which concerns he has been draftsman, assistant superintendent, and manager. He had charge of the obtaining of patents, both domestic and foreign, for the Universal Winding Co., and has made patents and patent law a special study. Mr. Smith has had extended experience with economical interchangeable manufacture and special tools required therein.

[1] Robinson on Patents, § 363[1]: "No concession, on the part of the real inventor, that someone else is the inventor or the first inventor, can either change the fact, or confer upon the latter the right to patent the invention as his own."—Hammond vs. Pratt (1879), Vol. 16, Official Gazette, p. 1235. "Parties have no right, by contract, falsely to concede priority of invention."

body, mind, and spirit of each of their employes. Referring to the first two examples, they are subject to the same conditions as are cited in the opening paragraph. Whether one attempts to share inventorship in acceptance of a proffered courtesy, or as a means to protect his financial interest, by subscribing to a patent as inventor, he not only fails of his purpose, but wrecks the whole patent value as well, annulling the rights of the real inventor as well as his own.

The third example is of two types, one of the employer who does not know his own status with reference to inventions made by his employes; the other, of the employer who does know, but takes long chances through lack of knowledge on the part of his employes. In either case, the employers should realize that their interests can be best protected by specific contracts or agreements whereby the employe binds himself to turn over to his employer whatever invention he may make during his employment, which pertains to the business. This is fair, because the stimulus to improve and invent is frequently derived from the atmosphere of invention existing in the particular shop where the employe works; but the fact that one is an employe does not bind him to turn his inventions over to his employer, unless some contract or agreement exists whereby he is compelled to do so.

Employment to make a specific invention or improvement constitutes such an agreement.[2] If one is especially employed to invent, develop, or perfect a device for a given business, obviously, whatever is derived from this work belongs to the proprietor of the business, so far as it pertains to that business. But the proprietor cannot subscribe to a patent application as inventor, unless he himself actually created the patentable improvement. If initiated by the designer, then he alone is the inventor.

On the other hand, mere constructive work is not invention. An invention may be made by one having no experience in construction or in the operation of machines or manipulation of implements. He may be unable to make a correct working drawing. He must, however, have in mind a definite construction which he can so impart to a skilled mechanic, that the latter can produce a working construction. It may be necessary to impart his idea orally, dictating the forms and arrangement of parts, or by sketch or some model, however crude and lacking in the attributes of workmanship or sound constructional embodiment. The information or instruction so imparted must, however, comprise and convey *means* for attaining the end desired. An employer recently claimed to be inventor of a device produced by one of his employes because, he contended, the invention had been made at his own instance. It developed that "his own instance" consisted only in seeing a certain insufficiency in some apparatus of which he was proprietor. He had tried to overcome the deficiency, and had ceased from trying. Months after, an employe who was not a constructive mechanic had, without hint or help, solved the problem simply and satisfactorily. In this case, the employe was the inventor and subscribed as such to the patent application.[3] It is well established that recognition of a need of improvement or advantage of a change is not invention.[4] To constitute invention, the mental process which recognizes the deficiency must develop into a mental act of discovery or determination of specific means to supply the remedy for the deficiency.

The relation of an inventor to his associates requires consideration. The development of any substantial invention and many smaller ones usually requires the concurrent application of many minds. The inventor's work is frequently that of a pioneer. His roads into new fields of endeavor are frequently only blazed trails. Draftsmen, pattern-makers and skilled constructors follow the paths he makes, developing his crude embodiments of accomplishment into permanent structure or fabric. An experienced inventor has remarked, "An inventor is rarely a skillful mechanic. Nervous anxiety to 'see the wheels go round,' precludes that patience and concentration demanded in fine work."

Because of this fact, there are frequently heard on the part of an inventor's associates, such invidious remarks as: "That was really my idea"; or even: "It's really my invention. He had only a crude idea. I constructed it so it was practical." Such individuals lose sight of the consideration of their employment; *i. e.*, knowledge and skill given in the highest degree in their power.

Those who have associated with others in the work of inventive development can readily recall instances where two or more have "thought of the same thing at the same time." The stimulus of the inventor's creative thought seems to permeate and fructify the mental processes of those about him. It being usually impossible for an inventor to personally carry out all the details of his invention, it is inevitable that his associates who further and develop his ideas shall produce creations having the attributes of invention, but it is fair to conjecture as to the extent of their progress, had he not imparted the first impulse by his primary inventive act. This view is recognized by the courts, and such inventions, termed ancillary inventions, are considered as having been engendered by the parent conception or stimulated by concordant effort on the part of associates or of others operating under the inventor's supervision. Being, therefore, considered a part of the parent invention, they are deemed to belong to the inventor himself so far as title to inventorship is concerned, and the right to subscribe its inventor to the patent applications.[5]

This is manifestly fair, for otherwise an inventor would be at the mercy of the cupidity and covetousness of unfair and mercenary associates. Without such consideration for the inventor's rights, he would be obliged to dispense with associates, and the delay entailed by his efforts to personally and alone work out an invention in all its details would defeat the spirit and purpose of the patent establishment, ***viz.:*** prompt public disclosure for advantage to industrial advancement. Care should be exercised, however, to distinguish between primary and ancillary invention. Unless the individual who devises an improvement is distinctly associated with the development of the machine or invention to which his improvement pertains, the chances are that he himself is the inventor of the improvement devised and should subscribe to the patent application.

For example, a maker of milling machines has in hand the reconstruction of his index head. While he is developing a new construction, one of his milling machine operators who has no knowledge of the development work in process but who recognizes the deficiency of the existing index head, invents a new index head embodying the very ideas on which his employer is working. Assuming that the milling machine operator first conceives and completes his index head, he

[2] Joliet Mfg. Co. vs. Dice I 11,649 (1883); "When a workman is hired to invent, the employer will own the inventions which fall within the scope of the contract, while the others will belong to the employe."—Robinson, Vol. 2, p. 637: "If he (the employer) contracts for his employe's inventive skill, for its exercise in his behalf, he may thereby become the equitable owner of the inventions which result, and be entitled to an assignment of the patents when they are obtained."

[3] Pressed Steel Car Co. vs. Hansen, 137 F 403: "An employer has no right to the patent for an invention made by an employe, in the absence of an express contract or agreement of specific employment to make the invention."—Agawam vs. Jordan, 74 U. S. 583,602: "No one is entitled to a patent for that which he did not invent, unless he can show a legal title to the same from the inventor or by operation of law."

[4] Robinson on Patents, § 394-1: Collar Co. vs. Van Deusen: "Evans, the assignor of the plaintiffs, was a manufacturer, and claimed to be the inventor, of paper collars. He * * * employed various paper-makers to experiment toward the production of such a paper as he required. As they presented to him, from time to time, the fruits of their experiments, he pointed out to them the particulars in which their papers were still deficient but gave them no information as to the ingredients to be used or the methods to be employed in arriving at the necessary results. It was held that he was neither the inventor of the paper finally produced, nor of the process by which it was made; that he had merely pointed out an end to be obtained, not the means of its attainment, and was not entitled to appropriate the discoveries of the paper-makers as his own invention."

[5] Robinson on Patents, § 414 Ref. Annin vs. Wrenn. "An employe hired to assist an inventor in making improvements and to use his inventive skill for that purpose cannot claim, hold or transfer to a person having knowledge of such contract, any invention so made against his employer, but the inventions are the property of the employer, and if patented by the employe, a bill to compel their conveyance will lie."—New England Motor Co. vs. B. F. Sturtevant Co., 140 F 866 (N. Y. 1905): "When an employe discloses an invention to his employer who reduced it to practice, the employer is nevertheless entitled to be considered the inventor, especially where he diligently files an application therefor."—Knag vs. Green, Official Gazette, Vol. 127, p. 1581: "Where one conceives the principle or plan of an invention and employs another to perfect the details and realize his conception, though the latter may make valuable improvements therein, such improved result belongs to the employer."—Official Gazette, Vol. 128, p. 3291: "Inventors are often compelled to have their conceptions embodied in construction by skilled mechanics or manufacturers, whose practical knowledge often enables them to suggest and make valuable improvements in simplifying and perfecting machines or devices. Those are things they are employed and paid to do."

alone is the inventor, and not only can he alone subscribe to the patent application as inventor, but unless he is under an appropriate contract or agreement, he is not bound to turn the invention over to his employer.

On the other hand, suppose the proprietor turns the matter of improvement over to an employe, but imparts no data other than a statement of the insufficiencies to be overcome; and further that whatever improvements made are the products of the employe's creative thought. Then the employe is the inventor, and he only can properly subscribe to the patent application; but inasmuch as he is specifically employed to do this work, he is bound and can be compelled to assign the patent to his employer.[2]

But again, suppose that besides the mere statement of insufficiency the proprietor perceives the general form which the improvements must assume and imparts these by sketches, notes or otherwise to the employe, then the latter's creations, even though they attain the dignity or possess attributes of invention, are only ancillary, and the employer properly subscribes to the patent application as inventor.[5]

DEVELOPMENT OF A HIGH-SPEED MILLING CUTTER WITH INSERTED BLADES.*

While during the last few years the milling machine has been developed for high power and speed, the milling cutter has not advanced as rapidly. The user is thus confronted by the unsatisfactory condition of having the output of his milling machine limited by cutters of inadequate capacity. This refers in particular to inserted blade cutters. In order to eliminate the faults existing in present designs of such cutters, and permit an increase in their capacity, the authors of the paper abstracted have developed a new design which will be described below.

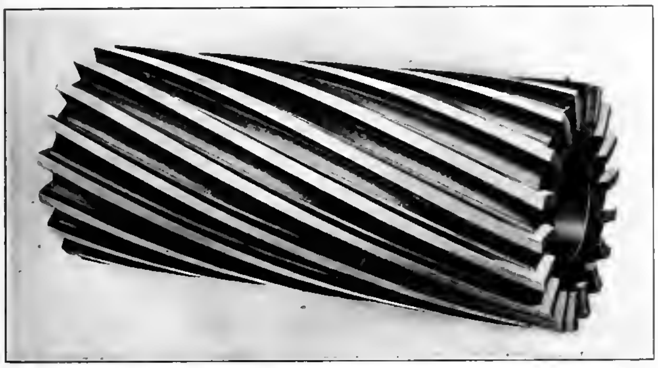

Fig. 1. Inserted Blade High-speed Milling Cutter with Helically-bent Blades.

Investigations showed that there was no existing standard governing the construction of inserted teeth milling cutters, nor any record of exhaustive tests made for determining the most effective pitch, clearance angles, or front slope and lip angles to be employed. The first point considered in constructing the new cutter was, therefore, the shape of the blade, and the conclusion was arrived at that in order to maintain a prescribed slope and lip angle throughout the entire length of the blade, it must be bent to form a helix. On blades so shaped it is possible to provide a continuous cutting edge with a constant lip angle. The most effective angle of the lead or helix of the blade was found to be about 20 degrees. For facilitating computation a formula (diameter × 9 = pitch) was adopted, which gives 19 degrees 15 minutes as the angle of helix

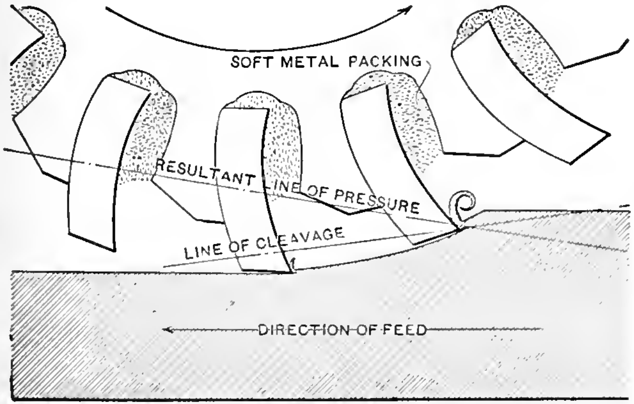

Fig. 2. Method of Inserting Blades in Cutter Body.

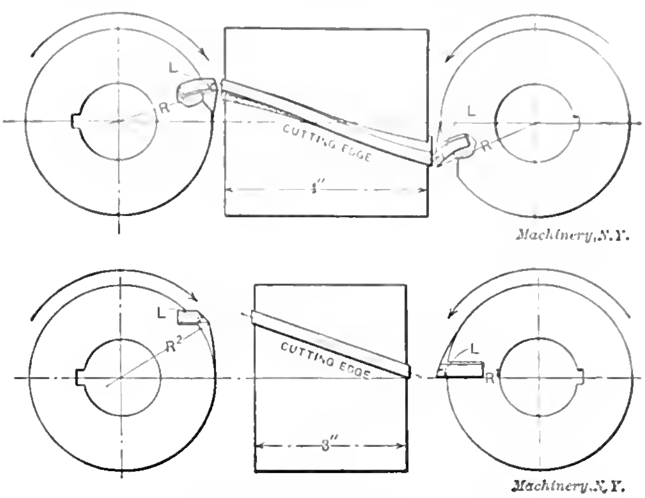
The next point to consider was the form of the grooves in the cutter body. Ordinarily these are planed approximately rectangular in section with a slight amount of undercutting to hold the blade in place. It was conceived, however, that this grooving of the cutter body could be done better and faster by milling than by planing, and that an undercut groove might be produced at one setting by a saw set in a certain relation to the cutter blank. In order to form the blades accurately to the shape of the groove, it was necessary to design a bending machine of great power, capable of squeezing the blades at once to proper form, not only as regards the helix, but also as regards the correct curvature in a direction normal to the helix, the grooves being curved in this direction also.



Figs. 3 and 4. Comparison between Lip Angles obtained with Helically-bent Blades and Straight Blades.

The final point considered was the method of securing the blades. It was found that ordinary mechanical fastenings were not desirable both because of excessive cost and on account of inability to withstand vibration and remain rigid. Experiments were therefore made with various alloys until a proper combination was obtained, capable of flowing freely, of cooling without shrinkage, of withstanding great strains without crumbling, and of permitting quick removal of the blade.

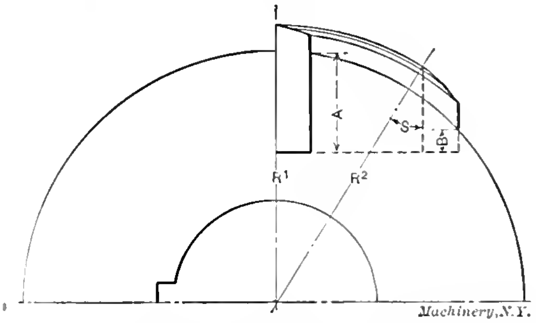


Fig. 5. Cutter with Straight Inserted Blade, seen from the End. Note changing Cutting Angle.

A device was designed for compressing the alloy in the slot after it had been poured, and a device was also made for removing the alloy when replacing the blades. With the alloy compressed in the slots, the blades are so firmly secured that they may be broken off by force without affecting the binding qualities of the alloy.

The cutter developed along the lines outlined above is shown in Fig. 1. The claims made for this cutter are that it can be made of moderate diameter, although having inserted blades; that a greater number of blades may be provided than in regular cutters of this type; and that the cutter's capacity for removing metal is equal to the requirement of high power milling machines.

---

* Abstract of paper by Wilfred Lewis and Wm. H. Taylor, read before the American Society of Mechanical Engineers, December meeting, 1908.

RESULTS OF EXPERIMENTS WITH HIGH SPEED MILLING CUTTERS WITH INSERTED HELICALLY-BENT BLADES.

The line engravings will give a clear idea of the actual construction of the cutter. Fig. 2 illustrates the form of the slot and blade, and shows also the space occupied by the bonding alloy or "metal packing." Figs. 3 and 4 show the difference between the lip angles obtained with cutters made according to the principles laid down, with a helically-bent blade, and with cutters made with straight blades as is the common but objectionable practice. In Fig. 3 the angle is constant, no matter how long the blade, while in Fig. 4 the lip angle changes constantly from maximum at R_1 to minimum at R_2. In Fig. 5 the actual conditions of a cutter having straight inserted blades and seen from the end are still further exhibited. That the cutting action of such a cutter differs for every point on the blade is plainly in evidence.

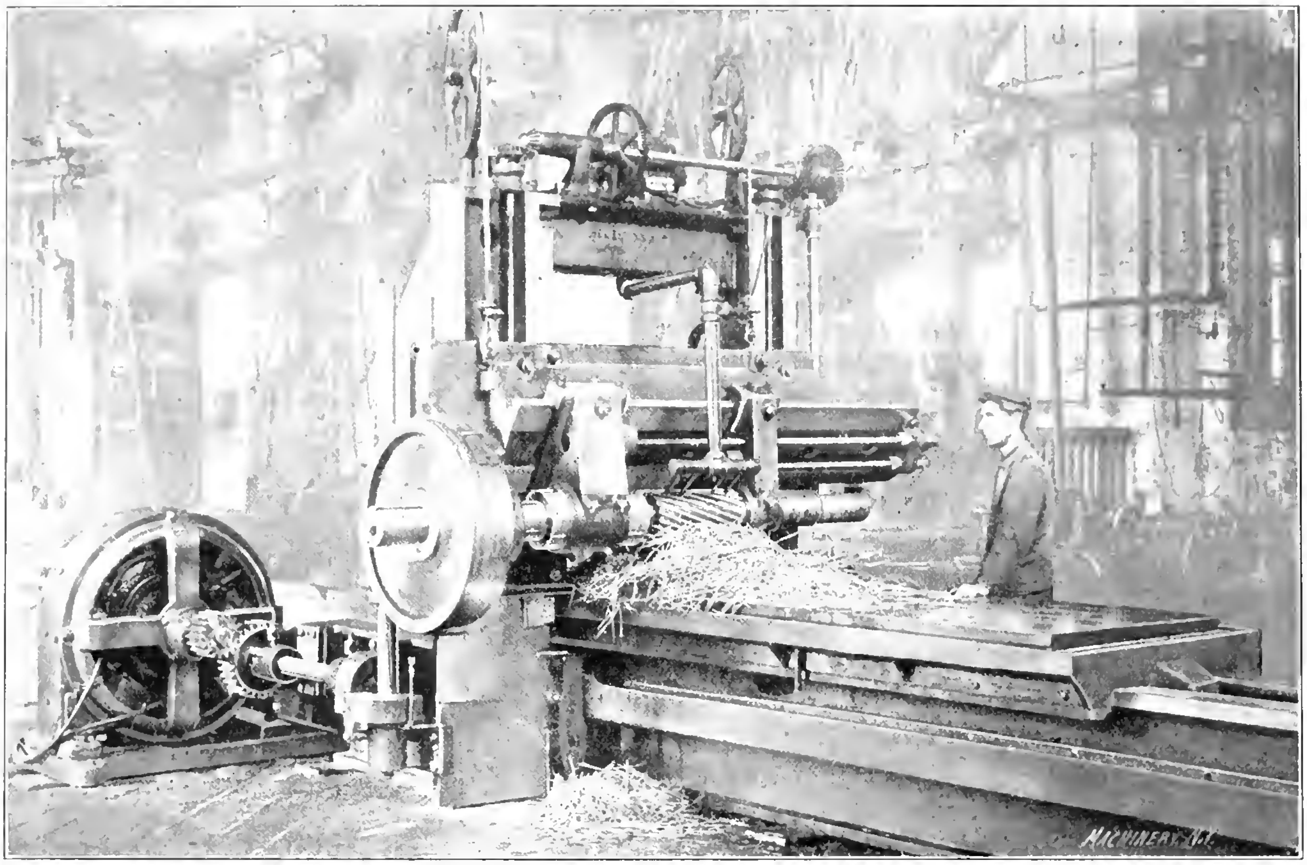

Fig. 6. High-speed Milling Cutter in use on High-power Milling Machine of the Planer Type.

Fig. 7 shows some of the chips cut by the cutter described, and in Fig. 6 the capacity of the cutter is well illustrated by the amount of chips removed by a single cut across the surface of the work.

In the paper under review, attention is called to the fact that experiments have conclusively demonstrated that nicking the blades of milling cutters does not constitute an altogether desirable feature. The part of the blade behind the nick which covers the gap formed by the nick in the blade preceding must take care of double the feed of the remainder of the tooth; this causes chatter and produces an uneven machined surface.

Much stress is laid on the use of lubrication during milling. A copious stream of lubricant falling at slow velocity should be thrown directly upon the chip at the point of removal. Heat generated by the pressure of the chip is the chief cause of wear; it softens the lip surface, causing it to crumble off. It was conclusively shown by experiments made that 33 per cent in cutting speed can be gained in milling steel and wrought iron, and 15 per cent in milling cast iron, by throwing a heavy stream of lubricant upon the cutter the entire length of its cutting edge.

A table is appended showing some of the actual results obtained in the experiments undertaken. The machine used in the experiments recorded was a 42-inch Bement-Miles milling machine, driven by a Westinghouse constant-speed 40 H.P. motor. The material cut was 30 per cent carbon steel. The cutter was 8 inches in diameter, 18 inches face, and of the type described.

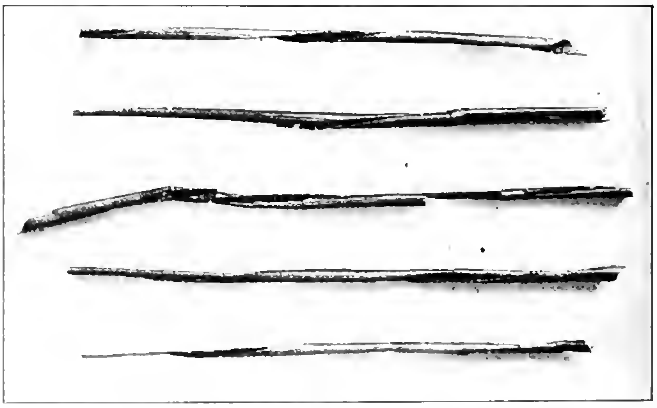

Fig. 7. Chips produced by the Cutter described.

KEYWAY GAGING IN SHAFTS AND HUBS.

Z. Y.

But little attention seems to have been given in the technical press to the gaging of keyways. The necessity for this work being inspected and gaged led to the devising of the appliances illustrated and described in this article.

A standard size of key had been previously adopted for each shaft, of which particulars are given in Table II, the key being square at the large end, and for shafts from 3/4 inch to 2 inches, inclusive, advancing by even eighths, the key was one-fourth the diameter of the shaft. Reference to the table will give the other dimensions, but it may be noticed that the depth of the key in the shaft was to be half the width of the key, this depth to be taken at the edge of the groove.

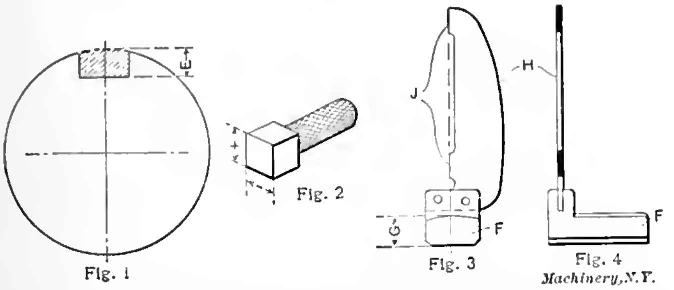

Fig. 1 Fig. 2 Fig. 3 Fig. 4

Fig. 1. Undesirable Method of Gaging Keyway Depth. Fig. 2. Limit Gage for Width of Keyway. Figs. 3 and 4. Gage used in Conjunction with Center-head, Fig. 5, for Determining Depth of Keyway and Parallelism of Sides with Radial Line through its Center.

After these points had been decided, the question arose as to the best way to indicate these dimensions on the drawings and how to measure the finished work.

With regard to the shafts, it would be an easy matter, with a micrometer depth-gage or other means, to measure the depth of the groove from the full diameter of the shaft, as at *E* in Fig. 1; but there was an objection to this, *viz.*, the difference there might be between the diameter of the shaft and the bore of the hub, although both were nominally the same diameter; for if the diameter of the shaft varied say by 0.002 inch or 0.003 inch, then this variation would also become apparent in the space available for the key, when assembled. The same argument applies to hubs, and on this account the method of dimensioning as shown in Table II was adopted, which was to measure what remains of the shaft after cutting the keyway, and to measure the keyway across the bore in the case of hubs, this latter measurement being taken at the deep end of the groove. If the keyways are correctly cut in accordance with these rules, then the dimension *B* subtracted from the dimension *A* should equal the thickness of the key at a certain predetermined distance from the head. The advantage of this system of measuring the depth of a keyway is apparent, for, as has been explained, the keyway space will not vary even though there be slight variations in the diameter of the shaft or bore of the hub, providing, of course, the work of cutting the keyways is done accurately; consequently, the time spent in fitting keys can be reduced to a minimum as they can be machined practically to a finished size.

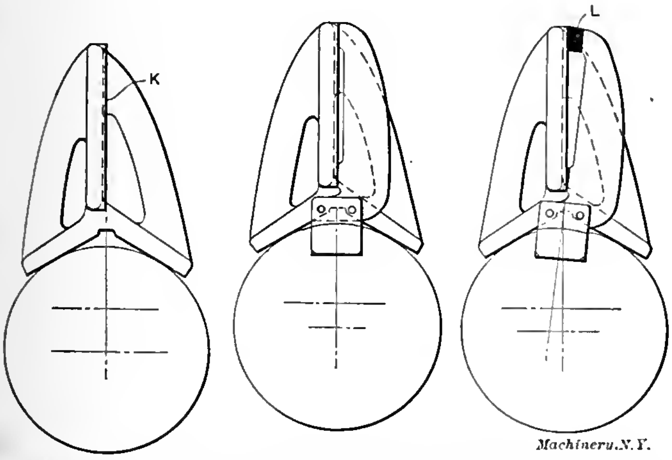

Fig. 5. Center-head used with Gage shown in Figs. 3 and 4. **Fig. 6. Keyway with Sides Parallel with Radial Line through its Center.** **Fig. 7. Keyway with Sides not Parallel with Radial Line through its Center.**

The permanence and stability of wheels upon their shafts depends very largely upon the fitting of the keys in their keyways, and this fitting, in turn, depends upon the keyway itself. If, for example, the keyway in the shaft is not parallel with the shaft's axis, or if the sides of the keyway are not parallel with a radial line passing through its center, the key, though it may seem tight enough when it is first driven in, will have such a poor bearing that the wheel or pulley will soon work loose. Therefore it was deemed advisable to gage the keyways in both shaft and hub as outlined in Table I.

TABLE I.

For Shafts.	For Hubs
(1) Width of groove.	(5) Width of groove.
(2) Depth of groove.	(6) Depth of groove.
(3) If sides are parallel with a radial line through center.	(7) If sides are parallel with a radial line through center.
(4) If groove is parallel with axis of shaft.	(8) If parallel with axis of hub.
	(9) Angle of taper at the bottom of the groove.

Quite a number of gages of different kinds were considered which would properly gage one or more of the points required, but those considered best for the various purposes are those shown in the following: Commencing with the gaging of the shafts, and taken in the same order as tabulated in Table I, the following were the methods adopted:

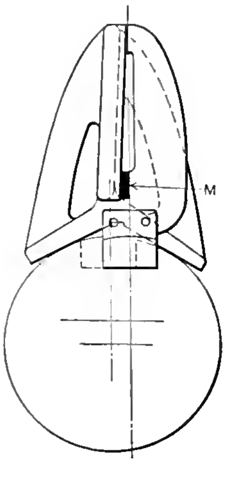

Fig. 8. Keyway not Parallel with Axis of Shaft.

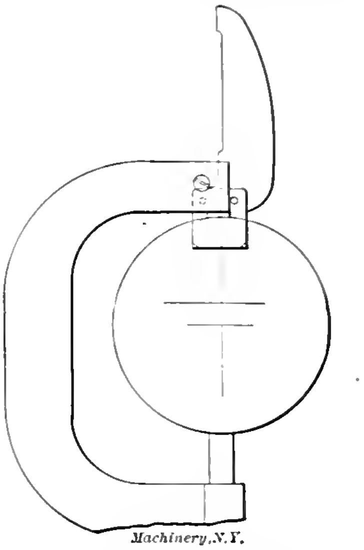

Fig. 9. Testing Depth of Keyway.

Gaging the Shaft.

1. Width of groove. This did not call for any special gages other than those in use, an ordinary rectangular limit gage as Fig. 2 being quite suitable.

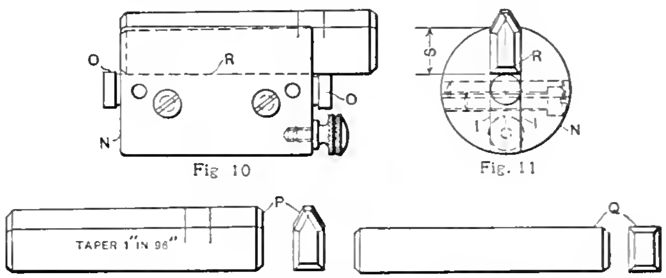

Fig. 10 Fig. 11 Fig. 12 Fig. 13

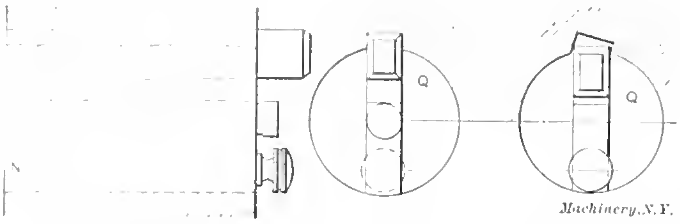
Figs. 10, 11, 12 and 13. Gages for Testing Depth, Parallelism of Sides with Radial Line through Center, Parallelism with Axis, and Taper of Keyway in Hub.

2, 3, and 4. The device used for (2) was also used for (3) and (4), and can best be described by reference to the illustrations. Fig. 3 shows an end view and Fig. 4 a side view of one of the gages, one such gage being required for each different width of groove. They are used in conjunction with the center-head, Fig. 5. The block *F* is a steel key, hardened and ground, the width being the same as the small width of

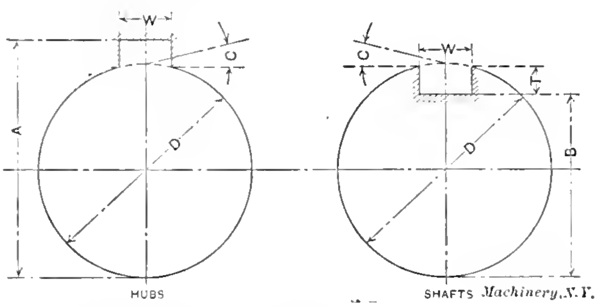
the limit gage Fig. 2. The length is twice the width, and the dimension *G* equals the nominal diameter of the shaft minus the figures in column *B*, Table II. Attached to one end of the key is the blade *H*, which is also hardened. After being attached to the base, the edge *J* was ground so that it was exactly central between, and parallel to, the sides of the key. The center head, Fig. 5, is of cast iron, the V base being finished to an angle of 120 degrees. The face *K* is carefully finished so that it lies in a plane bisecting the angular base, and therefore, when the base is placed on a shaft, the face *K* will always be in a plane passing through the center of the shaft.



Figs. 14 and 15. Gage for Testing Keyway in Hub, and Exaggerated Illustration of Keyway which is not Parallel with a Radial Line passing through its Center

Now, if when gaging a keyway it has been found correct for width, the gage Fig. 3 can be placed in the groove, and by placing the center-head on the shaft, and bringing it up against the blade, it can be seen at once if the groove is correct, for, if it is, the edges *J* and *K* will coincide as in Fig. 6. If the gages are used at both ends of the groove, the gaging can be done for both (3) and (4); for, should the groove be correct at one end, but not parallel with the axis of the shaft, the gaging will indicate, as shown exaggerated in Fig. 8. If the sides of the groove are not cut parallel with a radial line, but the groove is parallel with the axis of the shaft, the gaging will show as in Figs. 7 or 8 at both ends of the groove. By using feelers at *L* or *M*, any inaccuracy can be measured, and if this is found to be within the limits allowed, it then remains to gage for (2). This is done by using the gage Fig. 3, and measuring the diameter of the shaft by micrometer in combination with the gage, as in Fig. 9. If the depth of the groove is correct, the resulting dimension should equal the nominal diameter of the shaft.

TABLE II.



D = nominal diameter of shafts.

W = width of key $= \dfrac{D}{4}$ or nearest $\frac{1}{32}''$ less, up to and including $2\frac{1}{2}''$ or nearest $\frac{1}{16}''$ above $2\frac{1}{2}''$.

T = depth of groove measured at edge $= \dfrac{W}{2}$.

$C = D \times 0.0159$ when $W = \dfrac{D}{4}$.

Key groove in hub tapers 1 inch in 96 = $\frac{1}{8}''$ per foot.

A' = depth of groove measured across bore at wide end.

Key groove in shaft is uniform in depth.

Gaging Grooves in Hubs.

5. Width of Groove. As in the case of shafts, the limit gage, Fig. 2, is used.

6, 7, 8 and 9. For these steps the gages Figs. 10, 11, 12, and 13 are used. These consist of plugs *N* and two keys *P* and *Q*. These plugs were made up of three main parts each and hardened and ground on the faces before finally assembling, the face *R* being ground parallel to the center of the plug, and the width between the jaws being the same as the small width of the limit gage Fig. 2. The bosses *O*, at the end of the center part, are ground to this size, and then the faces *I* and *R* ground to these bosses. After assembling, the outside diameter is ground to the small end of the cylindrical limit gages in general use. One such plug is required for each different bore. The keys *P* and *Q* are also of steel, hardened and ground, and are a good sliding fit between the jaws of their respective plugs. The sides of the key *Q* are parallel to each other, and are slightly less than *S* in Fig. 11. The key *P* had its edges ground so that the angle between them was the same angle as the keyway taper, *viz.*, 1 in 96, or ⅛ inch per foot.

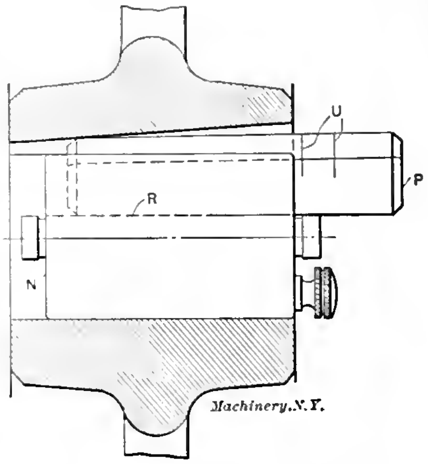

Fig. 16 Testing Angle of the Taper.

For gaging a keyway in a hub, if it has been found correct for width, the plug *N* can be placed in the bore, and if the groove is correct for (7) and (8) the key *Q* will freely pass out of the plug jaw into the groove in the hub, as in Fig. 14; but if incorrectly cut, then the key cannot enter to the full depth in the groove in the hub, this being shown exaggerated in Fig. 15. Of course it is possible for the groove to be apparently correct for (7) at one end of the bore, but if not correct for (8), it will be impossible to enter key *Q*. If the groove is correct for (7) and (8), then for the angle of taper (9) and depth of groove (6) the key *P* is used in a similar manner to key *Q*. By making this key separate from the plug, it is easy to feel if the groove is the correct taper on the bottom, for if the angle to which the groove has been cut is too great, the key will touch at its small end as in Fig. 16, or *vice versa*, a slight difference being easily felt. By making marks on the key *P*, as at *U*, any desired limits for (6) can be set.

* * *

An interesting method of insulating wire is mentioned in the *Brass World*. Some metallic oxides such, for instance, as the oxide of chromium, are insulators. Use is made of this fact in making and using resistance wire, containing nickel, iron manganese and chromium. The wire is heated, and an oxide forms on the surface, consisting of a mixture of all the metals. If treated with sulphuric acid, all the oxides, except the chromium oxide, are dissolved, and in this way a film of chromium oxide is obtained on the wire, which acts as an insulator.

Good enough is the deadly enemy of best.—*Speed.*

JIGS AND FIXTURES—9.

EINAR MORIN.[*]

EXAMPLES OF CLOSED OR BOX JIGS.

In the previous installment of this series, the development of a closed or box jig was treated. In the present installment a number of examples of closed jig designs will be shown and described. As was pointed out in the first installment in the April issue, when reference was made to different classes of jigs, there is no distinct division line between open and closed drill jigs, so that in many cases it is rather inconsistent to attempt to make any such distinction.

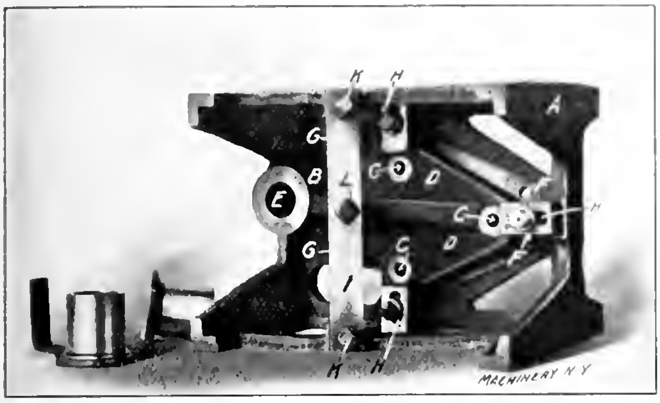

Fig. 97. Box Jig which Resembles the Open Type.

In Fig. 97, for instance, is shown a box jig which looks like a typical open jig. The jig body *A* is made in one solid piece, cored out as shown, in order to make it lighter. The piece to be drilled, *B*, shown inserted in the jig, has all its holes drilled in this jig, the holes being the screw holes *C*, the dowel pin holes *D*, and the large bearing hole *E*. The bosses of the three screw holes *C* are also faced on the top, and the bearing is faced on both sides while the work is held in the jig. The work is located against two dowel pins driven into the holes *F*, and against two lugs at *G*, not visible in the engraving, located on either side of the work. In these lugs are placed set-screws or adjustable sliding points such as described in the June issue. It may seem incorrect not to locate the bracket in regard to the hole *E* for the bearing, so as to be sure to bring the hole concentric with the outside of the boss. This ordinarily is a good rule to follow, but in this particular case it is essential that the screw holes be placed in a certain relation to the outline of the bracket in order to permit this to match up with the pad on the machine on which the bracket is used. Brackets of this shape may be cast very uniformly, so that locating them in the manner described will not seriously interfere with drilling the hole *E* approximately in the center of its boss. The work is firmly held in the jig by the three straps *H*, care being taken in designing the jig that these straps are placed so they will not interfere with the facing tool.

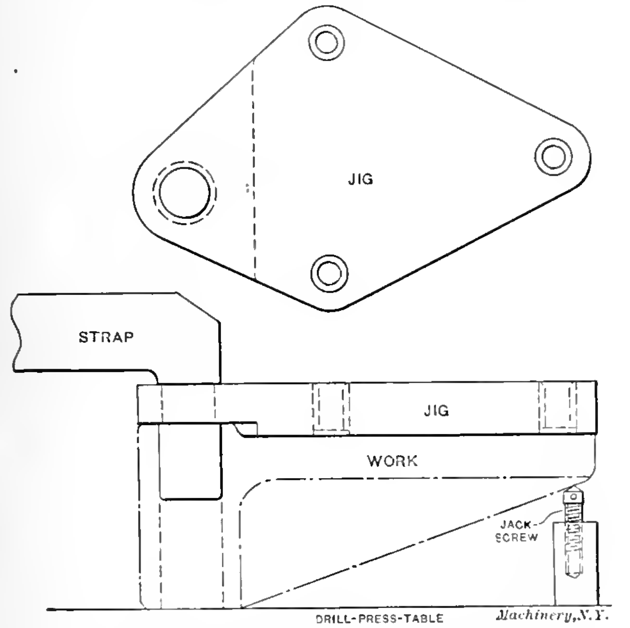

Fig. 98. Simple Form of Plate Jig for Drilling Bracket shown in Fig. 97, after Hole E has been bored in the Lathe.

The swinging strap *I*, which really is the only thing that makes this jig a closed jig, serves the sole purpose of taking the thrust of the heavy cutting tools when drilling the hole *E* and of steadying the work when facing off the two ends of the hub. The two collar-head screws *K* hold the strap to the jig body and the set-screw *L* bears against the work. This strap is easily swung out of the way simply by loosening one of the collar-head screws, a slot being milled at one end of the strap to permit this. Stationary bushings were used for the screw hole and dowel holes, but for the bearing hole *E* three loose bushings and a lining bushing are employed. The hole *E* is first opened up by a small twist drill, which makes the work considerably easier for the so-called rose-bit drill. The latter drill leaves 1/16 inch of stock for the rose reamer to remove, which produces a very smooth, straight and concentric hole. The last operation is the facing of the holes. The holes just drilled are now used to guide the pilots of the facing tools, and as the operation is performed while the work is held in the jig, it is important that the locating or strapping arrangements are not in the way.

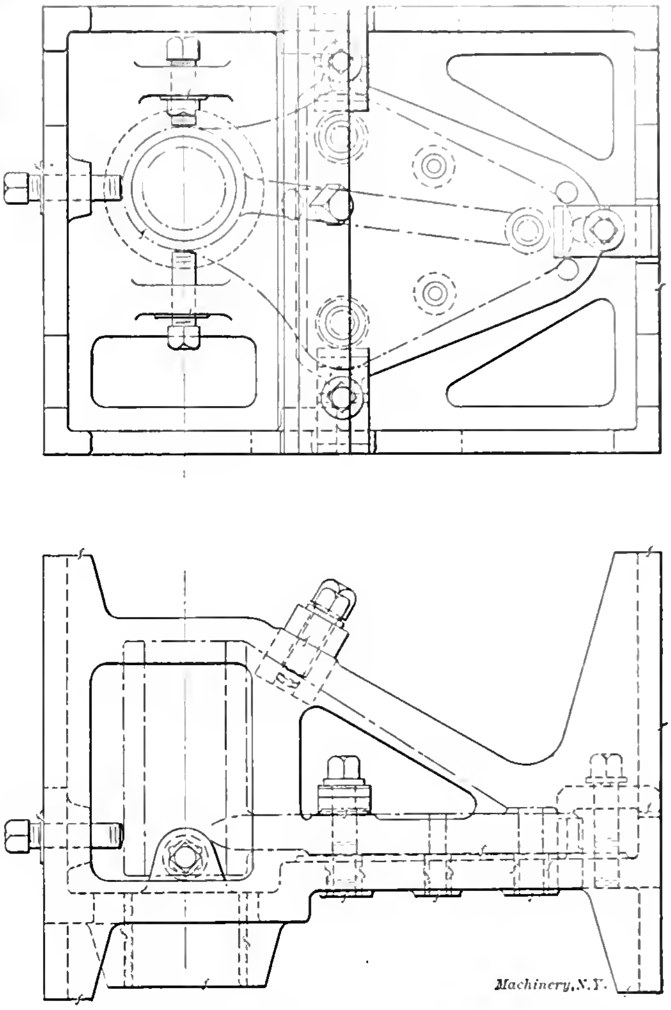

Fig. 99. Plan and Elevation of the Jig shown in Fig 97.

In connection with the opening up of a hole with a smaller drill, it may be mentioned that it is not only for large holes that this method of procedure will save time, but even for smaller holes, down to ¼ inch in diameter, drilled in steel, time will be saved by opening up the hole with a still smaller drill.

The use of lubrication in jigs is a very important item, the most common lubricant being oil or vaseline, but also soap solution is used. The objection to the latter is that unless the machine and tools are carefully cleaned, it is likely to cause rusting. Using a lubricant freely will save the guiding arrangements, such as the drill bushings, the pilots on coun-

---

[*] Address: 833 West Sixth St., Plainfield, N. J.

terbores, etc., to a great extent. The line drawing of the jig in Fig. 97 is shown in Fig. 99 and a clear idea of the design of the jig will be had by studying this line engraving. The bracket *B*, in Fig. 97, could have been drilled in a different way than described, which will sometimes be an advantage. It could be held in a chuck, and the hole *E* reamed and faced in a lathe, which would insure that the hole would be perfectly central with the outside of the boss. Then a jig could be designed, locating the work by a stud entering in hole *E*, as indicated in Fig. 98, additional dowel pins and set-screws being used for locating the piece sidewise. The whole arrangement could be held down to the table by a strap and bolt, a jack screw supporting it at the overhanging end.

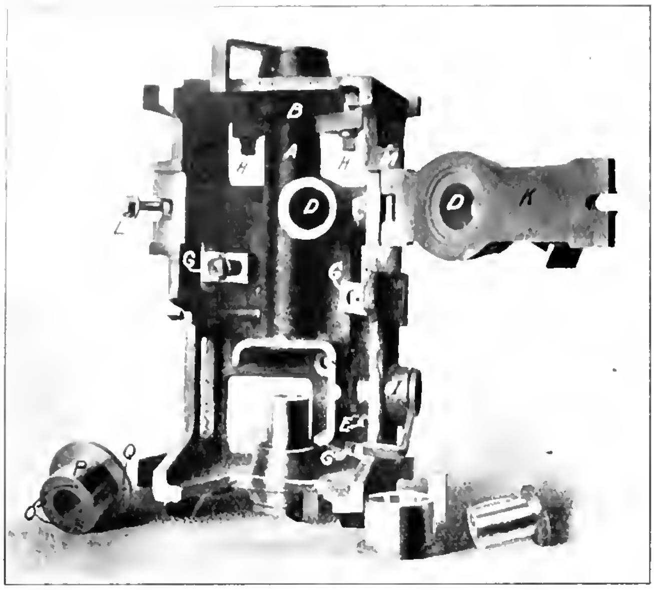

Fig. 100. Box Jig for Casing drilled from Five Directions.

Fig. 100 shows another jig of the closed type, with the work inserted. The piece *A* is a casing, and the holes to be drilled vary greatly in size. The casing rests on the flat, finished bottom surface of the jig and is brought up squarely against a finished pad at *B*. It further locates against the finished lug *C* in order to insure getting the proper amount of metal around the hole *D*. At the bottom it is located against the sliding point *E*, the latter being adjustable because the location of the work is determined by the other locating points and surfaces. The work is held against the locating points by the long set-screw shown to the left. This clamping arrangement, however, is not to be recommended because this screw must be screwed back a considerable distance in order to permit insertion and removal of the work. An eye-bolt used in the manner described in the installment in the August issue would have given better service. The three straps *G* hold the work against the bottom surface, and the two straps *H* hold it against the finished surface at *B*. There is not a long finished hole through the casing, as would be assumed from its appearance, but simply a short bearing at each end, the remaining part of the hole being cored out. For this reason the hole is drilled and reamed instead of being bored out, as the latter operation would be a slower one. While the two short bearings are so far apart, the guiding bushings come so close to these bearings that the alignment can be made very good. The screw holes and dowel pin holes at the bottom of the casing are not shown in the half-tone, as the inserted casing is not yet drilled. The hole drilled from bushing *I* is a rather important hole, and the bushing required a long bearing in order to guide the drills straight when drilling. When this jig was made, the projecting lug which was provided solid with the jig body, to give a bearing to the jig bushing, came so much out of the way in the rough casting for the jig that half of the lining bushing would have been exposed. It was therefore planed off and a bushing of the type shown in Fig. 9 in the May installment inserted instead, in order to provide for a long bearing.

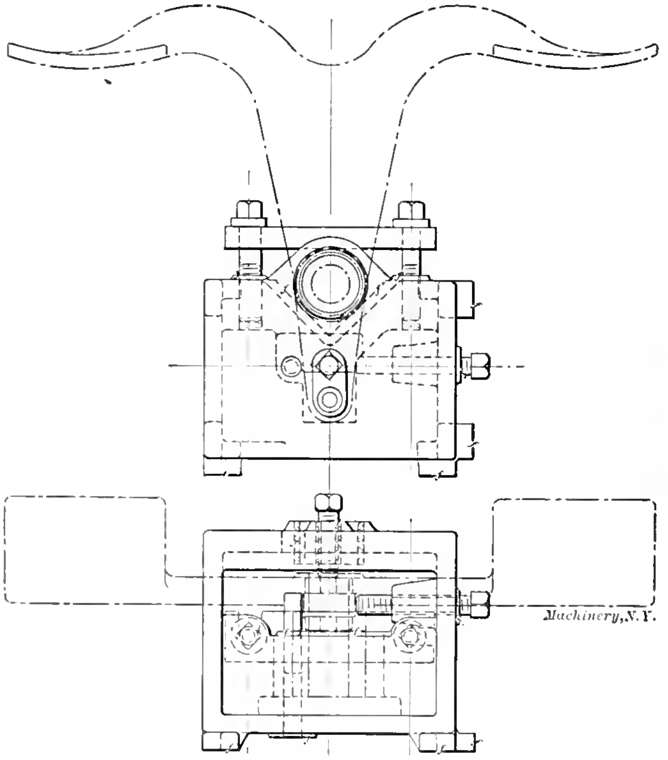

Fig. 101 Box Jig for Drilling Work shown in Dash-dotted Lines.

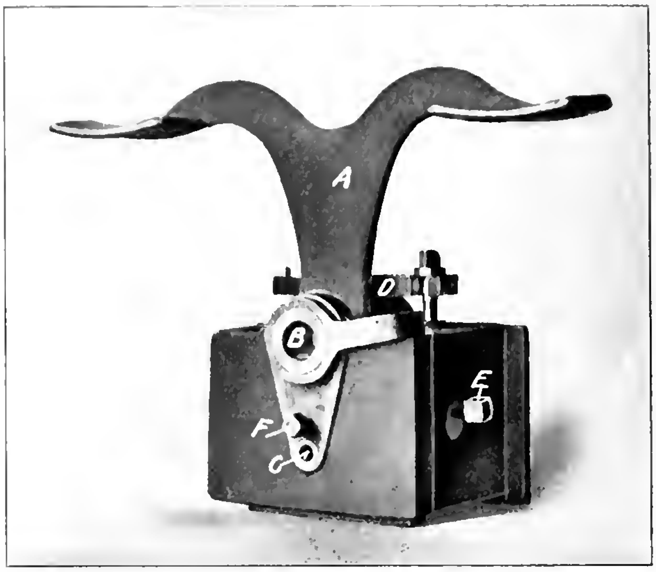

Fig. 102. Jig shown in Detail in Fig. 101.

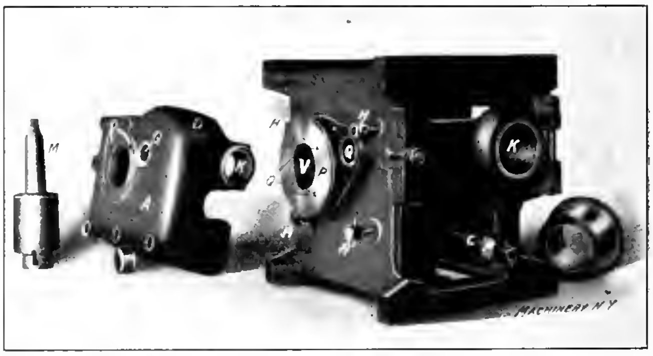

Fig. 103. Jig of Typical Design, and Work for which it is used.

Leaf *K*, which carries the bushings for drilling the hole *D*, fits into a slot planed out in the jig body and is held down by the eye-bolt *L*. Two lugs *M* are provided on the main casting for holding the pin on which the leaf swivels, the construction being of the same type as illustrated in Fig. 50, July installment. Around the hole *D* there are three small tap holes *O* which are drilled by the guiding afforded by the bushing *P*, which is made of cast-iron and provided with small steel bushings placed inside as illustrated in Fig. 16, May installment. In the bushing *P* is another hole *Q* which

fits over a pin located in the top of the leaf and which insures that the three screw holes will come in the right position. It should be noted that large portions of the jig body are cored out at top and bottom in order to make it light and easy to handle. Of course some metal is also saved by the construction of jigs in this manner, but comparing the price of cast iron with the total price of a finished jig of this type, the saving in this respect is so insignificant that it is not worth while mentioning. The leaf K is also made of cast iron, being of particularly large size, and it is planed at the places where it has a bearing on the jig body.

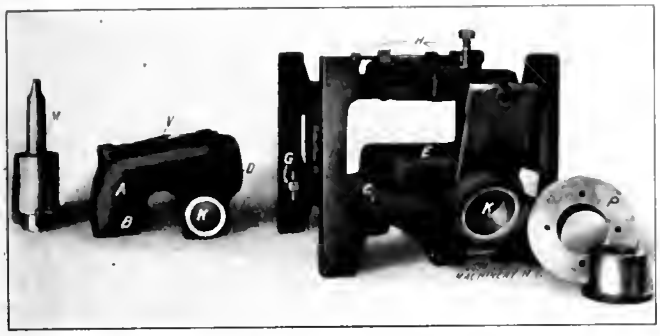

Fig. 104. Another View of the Jig in Fig. 103.

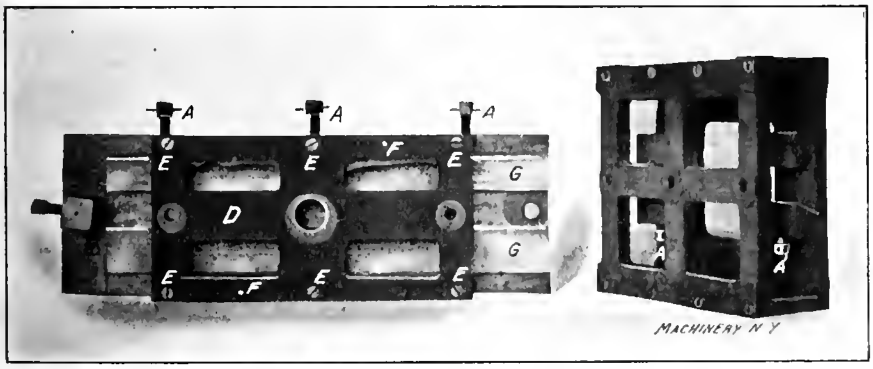
Fig. 102 shows a closed jig about which there can be no doubt that it should be classified as a box jig. The piece of work drilled, the foot trip A, has two holes B and C which are drilled in this jig. The cylindrical hub of the work is located against V-blocks and held in place by a swinging strap D. The work is further located against a stop pin placed opposite the set-screw E. The trip is located sidewise by being brought against another stop by the set-screw F. One-quarter of a turn of the collar-head screw on the top of the jig releases the swinging strap which is then turned out of the way; this permits the trip to be removed and another to be inserted. Half a turn or less of the set-screws is enough to release and clamp the work against the stops mentioned. A line engraving of this jig is shown in Fig. 101 which gives a better idea of some of the details of the construction.

In Figs. 103 and 104 are shown two views of another type of closed drill jig. The work A, to be drilled, is shown at the left in both illustrations, and consists of a special lathe apron with large bearing holes, screw holes, and dowel pin holes to be drilled. The apron is located in the jig column in the same manner as it is located on the lathe carriage, in this case by a tongue which may be seen at B in Fig. 104. This tongue fits into the slot C in the jig, care being taken in the construction of the jig that the slot is deep enough so as to prevent the tongue from bearing in the bottom of the slot. A good solid bearing should be provided, however, for the finished surface on both sides of the tongue. The surface D should also have a solid bearing on the surface E in the jig, the difference in height between the two bearing surfaces in the jig being exactly the same as between the two bearing surfaces on the lathe carriage where a lathe apron is to be fitted. The work is brought up against, and further located by a dowel pin at the further end of the slot by the set-screw in the block F, Fig. 103. As it is rather difficult to get the tongues on all the pieces exactly the correct width for a good fit in the slot, this latter is sometimes planed a little wider and the tongue is brought up against one side of the slot by set-screws. In the case in hand, a few thousandths inch clearance is provided in the slot and the set-screw G in Fig. 104 is used for bringing the work against the further edge which stands in correct relation to the holes to be drilled. The apron is held down against the bottom surface of the jig by four heavy set-screws H.



Figs. 105 and 106. Jigs in which the Work is Located by means of Beveled Surfaces.

It will be noticed that the jig is open right through the sides in order to facilitate the finishing of the pads at the ends of the work, and a swinging leaf like the one previously described, reaches across one side for holding the lining and loose bushings for the hole K which is drilled and rose-reamed in the usual way. The large hole V, Fig. 103, is bored out with a special boring tool M, as there are no standard drills obtainable for this large size of hole. This special boring tool is guided by a cast iron bushing which fits into the lining bushing; it is provided with two cutters, one for roughing and one for finishing. The small screw holes O around the large hole V are drilled from the bushing P. For drilling the rest of the holes, except the hole Q, stationary bushings are used. The screw holes ought to be drilled simultaneously in a multiple spindle drill. The jig is provided with feet and cored out in convenient places in order to make it as light as possible to handle. Lugs project wherever necessary to give ample bearings to the lining bushings and, in turn, to the loose guiding bushings.

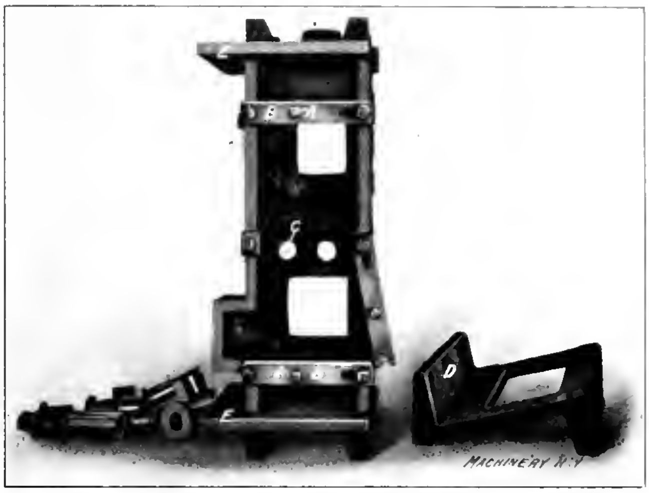


Fig. 107. Jig for Drilling Holes at other than 90-degree Angles.

Figs. 105 and 106 show two closed jigs made up of two main parts which are planed and assembled by screws and dowels as indicated, the reason for making the jigs in this way being the ease of planing the bottom section. The work drilled in these jigs, some special slides, is located by the dove-tail and held up against one dove-tail side by set-screws A, as shown in both illustrations. In Fig. 105 the work is located endwise against a dowel pin and is held up against this stop by a set-screw through the block shown to the left. This block must be taken out when the slide is inserted, this being the reason why a lug cast directly in place, through which the set-screw could pass, is not used. The top plate D is held down on the main body by six fillister-head screws E, and two dowel pins F to prevent it from shifting. No clamping arrangements, except the set-screws A, are necessary. The holes being drilled from the top, the main body of the jig takes the thrust. These jigs are also used in multiple spindle drills.

One objectionable feature of the jig in Fig. 106 is that set-screws A are difficult of access. There are, therefore, holes piercing the heads of the set-screws in two directions in order to allow a pin to be used when tightening the screws. A better idea, however, would be to have the screw heads extend out through the wall, and if this were solid, to have cored or

drilled holes to permit the heads of the screws to pass through.

In Fig. 107 is another closed drill jig in which the work is located against the finished seats and held down by the set-screws *A* in the straps *B*. All the holes, except the holes marked *C*, are drilled in the usual manner, the jig standing on its own feet, but when drilling the holes *C*, which come on an angle, the special stand *D* is employed which brings the holes in the right position for drilling, as illustrated in Fig. 108. If only the holes *C* were to be drilled, the feet on the side opposite the guiding bushing for these holes could have been planed off, so that they would have been in a plane perpendicular to the axis of the holes. The principles determining the design of jigs of this type were outlined in the November issue. This last jig has a peculiar apperance on account of the end walls coming up square, as shown in the illustrations, but this design was adopted only to simplify matters for the patternmaker, it being easier to make up the pattern this way.

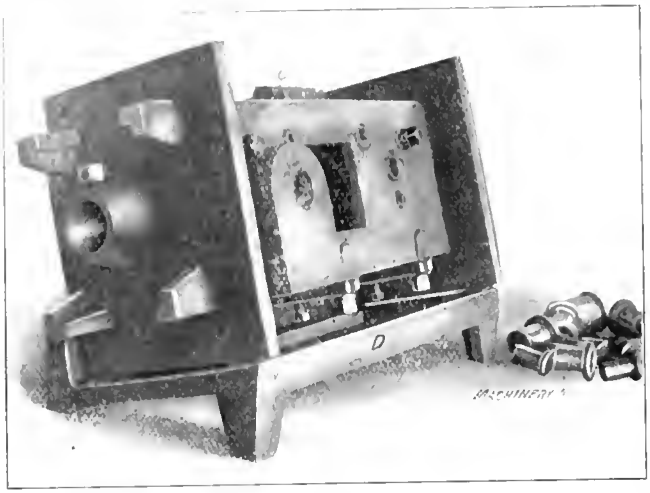

Fig. 108 Jig in Fig. 107 in Position for Drilling Holes at an Oblique Angle with the rest.

* * *

The great improvement in mechanical construction made possible by alloy steels, is startling to those even who are most familiar with their characteristics. For example, modern ordnance which hurls a 12-inch shell at an initial velocity of 2,500 feet per second, is only made possible with carbon steels by adopting the built-up structure by which one tube is shrunk upon another until the core is put into a state of compression nearly equal to the tensile stress that will be exerted upon it by the explosion of the powder charge. The elastic limit of ordinary steel is too low to resist the great pressure, and the layers of steel next to the powder chamber of a single-tube gun would be stretched more and more with each succeeding explosion until the piece burst. The built-up structure distributes the internal pressure more or less equally throughout the barrel and thus enables it to withstand an indefinite number of firings. But high-grade alloy steels may enable us to revert to the simple tube forms again for heavy guns. A gun tube used in the Davis double torpedo made of vanadium steel one inch thick and weighing only 350 pounds, successfully withstands a powder charge sufficient to propel a 10-inch shell with a velocity of 1,100 feet per second!

* * *

The recent sale of 2,000 practically unused breech-loading Springfield muskets for 69 cents apiece by a New York department store is a good example of the enormous waste of war and preparation for war. These weapons cost the United States Government $18 each, and for years were considered to be the best army gun in the world, but the rapid improvements in shoulder arms during the past fifteen years have made the model obsolete, as well as several others that followed it. Thousands of obsolete arms are sold at auction by the governments of the world every year for little more than their value as old metal, but still the armories go on year after year turning out new models at tremendous cost—for what?

GRINDER KINKS.

PAUL W. ABBOTT.*

The following article will deal with some of the kinks used in our tool-room by the tool grinders, some I have seen around the shop, and others which I have used myself. They are all good, practical kinks which are in use every day.

Fig. 1 is a hand grinding rest which is very handy for use on the universal grinder. It is adjustable up and down for height, and is used for hand grinding circular and straight form tools, sharpening metal slotting saws, formed cutters, etc. Fig. 3 shows the application of the hand rest to the grinding of saw teeth in a blank. The tooth rest used in connection with this operation is shown in Fig. 2. These saws are first ground on an arbor, the old teeth being ground off, leaving a perfect circle. The operator then puts on this device, setting the tooth rest so that the teeth will be about ¼ inch apart, and grinds around by hand, not quite bringing each tooth to a sharp point. On the last nine or ten teeth he evens up any inaccuracy in the spacing, the wheel being trued off to the exact shape of tooth space wanted.

Fig. 4 shows a device for accurately sharpening formed cutters up to 3 inches diameter, which is used when the cutter grinder has another job in it, or could be used to advantage where there was no surface or cutter grinder. The device consists of the cast iron slide *B*, at the end of which is a tapped hole *C*, with a small fillister head screw which holds the various sizes of bushings which fit the holes in the cutters. On the same end is the index pin *D*, which is adjustable back and forth. In operation, the hand rest shown in Fig. 1 is also used, and the pins *A* are lined up parallel with the forward travel of the wheel and so that the cutting face of the wheel is on a line with the center of the bushing. The cutter is then slipped on over the bushing and the index pin is set so that the required amount will be ground from the face of the tooth. The operator brings the wheel up to the proper position and then pushes the slide forward until the wheel has reached the bottom of the tooth space; he then withdraws the slide and indexes to the next tooth, and so on, tooth after tooth. It will be noticed that the index pin rests against the back of the tooth, which means that upon the previous milling of the teeth depends the accuracy of the grinding; but on the standard cutters furnished by numerous concerns this spacing will be found accurate enough.

Fig. 5 is a center for the head-stock for holding small forming tools of odd size, or threaded pieces which are to be ground on the periphery. The tools are simply clamped to the face of the center, and trued up by an indicator. Fig. 6 is a device for grinding snap gages for the tool grinder, where there is no surface grinder for this class of work. The shank of this device is made to fit the head-stock, and the gages are clamped to it by a small strap and two screws. This fixture revolves while in use, and the jaws of the gage are ground by feeding a thin wheel in and out by hand. Revolving the device insures perfectly straight gage faces. Fig. 7 shows a center for the universal grinder for holding a standard line of large end milling cutters with threaded holes, while sharpening. The head-stock is swung around at right angles to the ways, and with a long support for the tooth rest (Fig. 8), which is bolted to the platen, the cutters are ground very handily by throwing in the feed and grinding one tooth, and then, before the wheel comes back, indexing to the next tooth, and so on.

Fig. 9 shows a hardened roll which is ground all over, and Fig. 10 the fixture for the universal grinder for grinding the sides of this roll. This plate was made of cast iron, with both sides ground and with each hole ground to 0.0005 inch over standard size. Each hole has a ¼ inch set-screw, as shown at *A*. In operation, the plate is fastened to the face-plate by a draw-back rod, and the head-stock is swung around at right angles. As the plate revolves, 16 rolls are ground at once; first on one side, and then the plate is turned and the other side ground, the rolls being made to standard length by using a depth gage. The hardened roll shown in Fig. 11, which is used on swaging machines, is held by the centers shown in Figs. 12 and 13, when being ground. Fig. 12 is

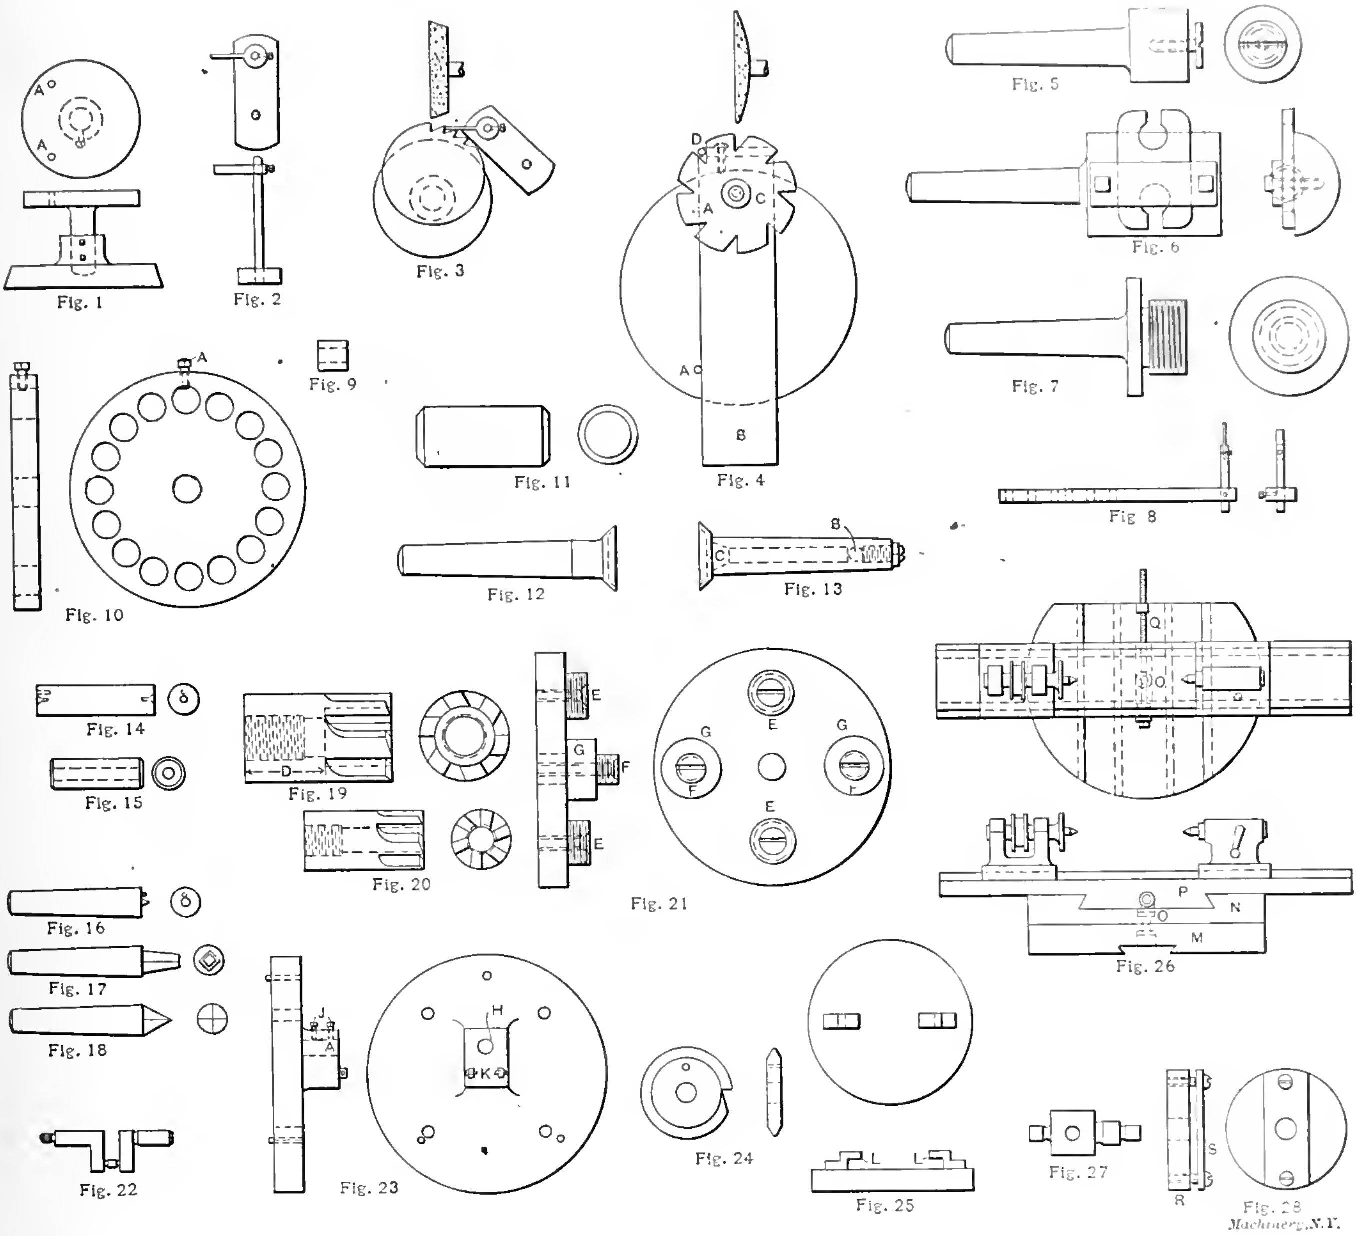
---

* Address: 318 S. River St., Wilkesbarre, Pa.

the head-stock center cupped out on the end to fit the beveled end of the roll. This center drives the roll by friction, the pressure being obtained by the spring tail-stock. Fig. 13 is the tail-center which is in two parts, the inner spindle running with the roll and being adjusted by the screw in the end so that the thrust is taken by the ball *B*, the tapered portions *C* just clearing each other. Other methods of grinding rolls are shown in Figs. 14 to 18. One example of grinding is shown in Fig. 14, and its center in Fig. 16. The roll is driven by a pin on the center, which engages with a corresponding hole in the work. A better method, which I have used, is to center the roll and then in one end drive a square 60-degree punch, using the square center shown in Fig. 18 for driving the work while grinding. Another good method for hollow rolls, such as shown in Fig. 15, is to use a 15-degree square center, such as shown in Fig. 17, the end of which just enters the hole.

Figs. 19 and 20 show two end mills. The smaller one is fastened inside of the larger when in use, and when in position rests against the bottom of the hole and projects outside a definite distance. The length *D* is standard in all these mills. Fig. 21 shows the fixture for grinding two pair of these mills at a time, so that the same amount will be taken off of both the short and long ones. Threaded bushings *E* fit the larger size mills, and *F*, the smaller. The collars *G* are of such a thickness that the cutting face of the smaller mill is brought into the same plane as the larger, and so when grinding, an equal amount is removed from the face of each mill. The plate is held to the face-plate by a draw-back rod. The head-stock is swung at right angles, and with the fixture revolving, the wheel traverses back and forth across the faces of the mills. The mills are then taken to a cutter grinder and backed off.

Fig. 22 shows a small crank-shaft, and Fig. 23 the fixture for grinding the pin. The bearings are first ground on centers in the usual way. The fixture is of cast iron and is held to the face-plate by screws and dowel pins. In the making of this fixture the hole *H* was ground out to the size of the bearing, and then the fixture was correctly located and doweled to the regular face-plate. The crank, while being ground, is held by the set-screws *J*, and the screws *K* which are set against the crank on either side.



Machinery,N.Y.

Various Tools and Fixtures for Miscellaneous Work on the Grinding Machine.

The grinding of formed cutters, similar to the one shown in Fig. 24, so that they will be interchangeable, is very interesting. The error limit is .00025 inch. The grinder used is a Norton universal tool and cutter grinder. After hardening, the cutters are first ground to a definite thickness. For this operation they are held against the face-plate by a draw-back chuck. The next operation is grinding the beveled sides, which is accomplished by holding the cutters against a small face-plate by a draw-back chuck. The correct angle of bevel is obtained with the protractor, and to get the correct diameter of the bevel sides, and to insure that the bevel sides stand exactly in the same relation to each other, the gage shown in Fig. 25 is used. This gage is hardened and ground all over, and the two gaging points *A* are set a predetermined distance apart and as near the same height from the platen as mechanical means can make them. It is ob-

vious that cutters which are all ground the same thickness, and which will pass through this gage with the beveled sides both touching the gage points with equal pressure, will interchange within pretty close limits. The operator grinds one bevel side at a time, trying the work every little while in this gage; when one side passes through the gage the cutter is turned around and the other bevel ground. For grinding the radius on the periphery and bringing the cutter to the correct diameter, the radius grinding fixture shown in Fig. 26 is used. The dovetailed base *M* is fitted to the platen of the grinder and upon this base is a sliding base *N* which is pivoted to *M* by a bolt *O*. Upon the base *N* there is an auxiliary platen *P* which can be adjusted back and forth by the screw *Q* for getting the proper radius. This auxiliary platen is made the same as the machine platen so that the regular head- and tail-stocks will go on it. A cutter is placed on a special arbor and the platen *P* adjusted to give the correct radius. The wheel is then brought up and the cutter is ground to the correct diameter, the curved face being obtained by swinging the base *N* back and forth by hand in an arc of a circle, with bolt *O* as a center.

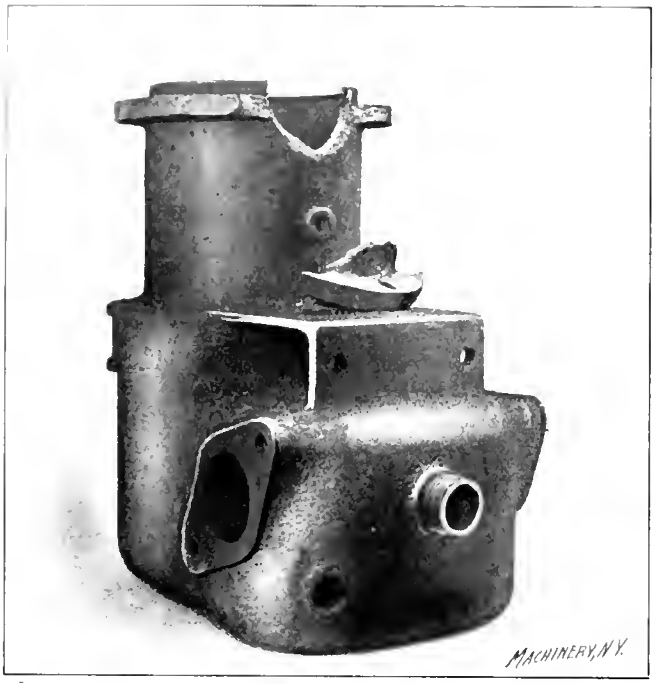


Fig. 1. Broken Cylinder to be repaired by Autogenous Welding.

Another ingenious scheme which I saw in the tool-room is shown in Fig. 28. The foreman brought along three or four pieces similar to the one shown in Fig. 27, and wanted the holes ground out. With an independent 4-jawed chuck this would have been easy, but there was no such chuck; and as there would never be any more of these pieces to be ground the fixture for doing the work had to be inexpensive. The face-plate could not be used as the pieces were smaller than the hole in the face-plate. The operator thought awhile, and then hunted around a few minutes and found a large washer *R*, tapped two holes in it, filed up the sheet steel strap *S*, and with a couple of machine screws was ready to begin. The washer was first put in the universal chuck and the outer side ground. One of the pieces was then clamped in place, and after putting on the internal grinding attachment it was ready to be ground.

* * *

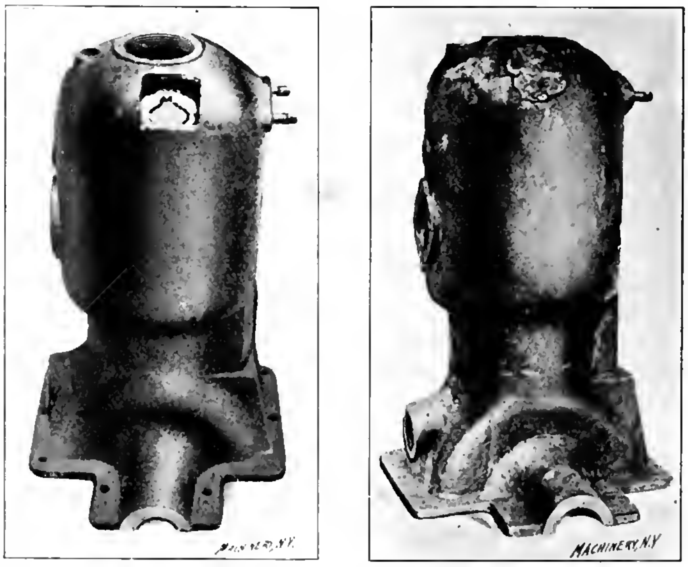
"From standing grain in the field to well-baked biscuits in twenty-two minutes was the record made in converting the raw material into the manufactured product at Waitsburg, Washington, recently." The foregoing, quoted from a newspaper, "is important if true." It indicates to what remarkable degree the mechanical processes of harvesting and preparing cereals for food have been developed. The statement appears incredible, however, because at least fifteen minutes would be required for baking, leaving only seven minutes for harvesting, threshing, grinding and preparing for the oven.

THE APPLICATION OF AUTOGENOUS WELDING TO AUTOMOBILE REPAIRS.[*]

HENRY CAVE.[†]

In the October, 1908, issue of MACHINERY, the apparatus used for autogenous welding was illustrated, and the principles involved discussed. In the present article a few applications of autogenous welding will be treated, particularly with reference to automobile repairs. As was stated in the article referred to, the metal to be welded is melted by the acetylene gas, burning with pure oxygen, and at the point of fusion the metals flow together and are practically "re-cast" locally, material being added when necessary from a rod of the same metal as the parts being welded. This applies to all metals, including cast iron and aluminum. These latter are mentioned specifically, because they are not commonly considered as possible to weld, and therefore serve better as an example showing the possibilities of autogenous welding.

Fig. 2. Enlarged View of Cylinder in Fig. 1, showing Part repaired without Impairing Finished Surface on Inside.



Figs. 3 and 4. Water-jacket of Cylinder, repaired from the Outside by filling in Cavity against Graphite Backing on the Inside.

One of the first principles to be understood in regard to autogenous welding is that the flame must actually come in contact with every particle of the metal welded. It is impossible to weld in places where this cannot be done. For

---

[*] For additional information on this subject, see Oxy-Acetylene Process of Metal Cutting and Autogenous Welding, October, 1908, and other articles there referred to.

[†] Address: Autogenous Welding Equipment Co., Springfield, Mass.

instance, if a small boss is required on a casting, it is not possible to cut out a thin disk of metal of the size of the boss, with the idea of welding it onto the casting. In a case like this, the metal would be added drop by drop until the required size is reached, and if the boss must be machined to size, metal must be added for finishing. Metal up to one-eighth of an inch in thickness can be butt-welded. The heat passing down the opening is sufficient to insure a weld clear through the thickness of the metal. If the thickness is greater, the sides must be first beveled off, allowing the welding flame to penetrate to the bottom of the joint. The metal at the bottom will then first flow together, and the groove caused by the beveling must be filled up by adding metal of the same kind. The beveling or grooving is usually done by grinding, chipping or filing. When beveling a broken part, care should be taken to leave enough of the original break to line up the parts with. The best practice is to leave three short sections on each fragment for this purpose. It is evident, from what has been said, that it is not possible to make a lap-weld with this apparatus. Therefore, when it is required to weld such parts as are usually brazed, as for example the joints of the exhaust manifold for automobiles, which are made from steel tubing, it is necessary to fit the two tubes so they butt together, and they should not be flanged as for brazing. Flanges and other fittings are welded to the pipe only at the edge, either at the outside or inside, or both. It is necessary to weld around only at one place if the pipe is a good fit in the flange.

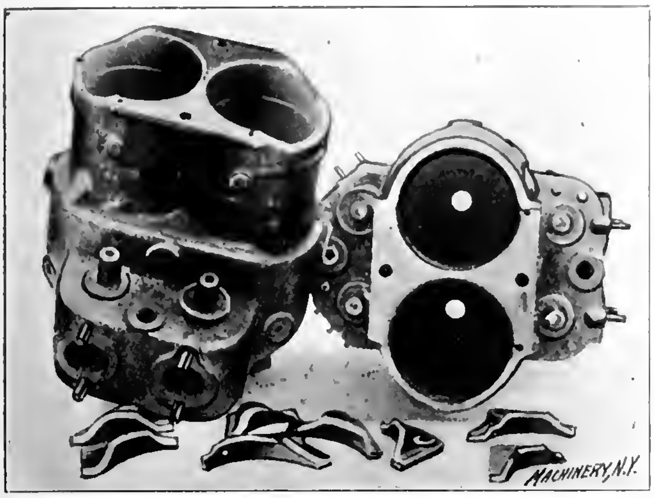


Fig. 5. A Badly-broken Casting, Illustrating the Possibilities of Autogenous Welding.

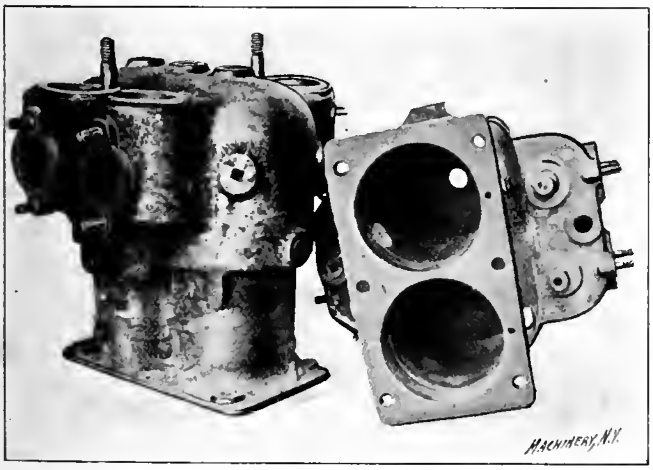

Fig. 6. Casting in Fig. 5 after having been repaired.

When a cut, crack or break passes through a machined surface as in the case of the cylinder, Figs. 1 and 2, and it is not necessary to eliminate all signs of the accident, the parts may be welded together entirely from the outside. The machined surface on the inside of the cylinder will not then be damaged, but the line of the crack can always be seen on the inside. If it is necessary to eliminate all signs of the break, then the crack must be welded on the machined side as well, and metal added which can be removed in remachining the parts.

It is sometimes impossible to gain access to both sides of a weld, as in the case of the two-cycle cylinder, Figs. 3 and 4 Then it will be necessary to make the weld entirely on the outside. In this particular case it is desirable that the inside be kept free from projections. To accomplish the repair in this case, a piece was therefore cut out of the jacket wall as shown in Fig. 3, and a block of graphite, which stands intense heat better than any other material, was fitted inside the cylinder. The weld was then made by filling in the hole, as shown in Fig. 4. When this was done, the graphite was removed, the inside surface being perfectly smooth. The outside of the cylinder in Fig. 4 can be trimmed off and finished, so that it will look the same as before the accident.

Figs. 5 and 6 illustrate a broken automobile cylinder successfully repaired. It will be seen from Fig. 5 that a great many parts are broken off and the repairing of this cylinder by welding gives a good illustration of the difficult class of repair work that can be carried out by the process. The illustrations show that autogenous welding can be extensively used, both in the manufacture of various kinds of machinery and in the repair shop. The saving of time which can be effected by quickly-made repairs, as compared with remaking castings, is plainly in evidence. The work illustrated in the accompanying engravings has been carried out at the demonstration plant of the Autogenous Welding Equipment Co., Springfield, Mass. It is likely that within comparatively few years the apparatus for carrying out autogenous welding will be recognized as part of the necessary equipment in any machine shop.

* * *

At the semi-annual meeting of the National Association of Cotton Manufacturers, at Saratoga Springs, N. Y., attention was called to the importance to manufacturers of reforestation. The president, Mr. Charles T. Plunkett, of Adams, Mass., in his address, touched on the subject, and afterwards several speakers in a discussion on the importance of forest preservation to manufacturers, voiced the opinion that the subject of forest preservation was of vital importance to everybody engaged in any kind of manufacture, and employing power. The energy stored up in our waterfalls will become comparatively useless if a fairly steady flow of water cannot be expected the year round. Reckless devastation of forests in the past and present makes it impossible to secure anything like an even flow in the streams of the country, and if the great amount of power that can be obtained from the waterfalls is not to be entirely lost in years to come, it is necessary that the hillsides should not be robbed of their natural capacity of acting as reservoirs for surplus water. Not only is this matter of importance from the point of view of power generation, but also on account of the destructive floods that of late have menaced many industrial properties in the country, along the banks of our larger rivers, most of which can be ascribed directly to the cause of permitting the regions along the upper course of the rivers to be stripped of their forests.

* * *

A special sub-committee of the British Society of Motor Manufacturers and Traders, has, as stated by the *Horseless Age*, evolved the following horse-power formula for gasoline engines:

$$\text{Horse-power} = KDN(D-1)(R+2),$$

in which formula,

K = a constant varying between 0.197 and 0.333,
D = the cylinder bore in inches,
R = the ratio of stroke to bore, and
N = the number of cylinders.

This formula, which is intended for use in connection with hill climbs and similar trials, takes into account that it is not possible to obtain as high mean pressures in large as in small engines, and also the ratio of bore to stroke. The source which we quote, unfortunately, does not give any information as to what conditions govern the selection of the value of the constant K.

WELDING.*

JAMES CRAN †

Up to comparatively recent years, the only process of welding wrought iron and steel was to heat the parts to be welded in a forge or furnace until they had reached a semi-melting condition, after which they were united by hammering. At the present time there are several distinct processes which give the same, or in some cases, better results than are possible by the ordinary process mentioned. Among these may be mentioned the Thermit process (see MACHINERY, March, 1903), the electric welding process (see MACHINERY, April, 1908), and the autogenous welding process (see MACHINERY, October, 1908).

The first mention of welding by electricity, was made by James P. Joule, of Manchester, England, in a paper published in 1856. It was, however, more than thirty years later before electricity became used for welding in the mechanical arts. One feature of importance in relation to the electric welding is that it makes possible not only the welding of iron and steel, but of metal widely dissimilar, as high carbon to low carbon steel, brass or copper to iron or steel, etc. It is, however, the writer's intention to deal in the following principally with welding as it is, or rather as it should be, done at the forge. It is the oldest, the most common, and, perhaps, the least understood of the welding processes. It has not received the attention that its importance merits, nor has it improved with other mechanical arts.

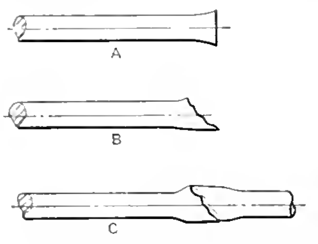

Fig. 1. Incorrect Upset and Scarfing for Plain Lap Welding.

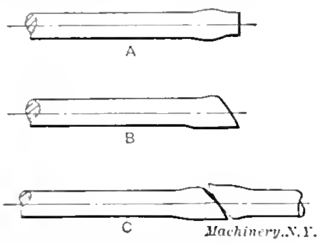

Fig 2. Correct Upset and Scarfing for Plain Lap Welding.

Brawn and muscle have generally been considered more essential to the blacksmith than brains, and thus the fact that preparing the pieces to be welded is of as much importance as the actual heating and hammering, is far too seldom taken into consideration. The preparation of work for welding depends greatly upon the shape of the forging and the class of work for which it is intended.

Plain Lap Weld.

The most common joint is the plain lap weld used on plain straight work, such as round, square, or flat stock, up to a certain weight and length. In nine cases out of every ten, the pieces are prepared and placed together for welding as shown in Fig. 1. The upsetting is done on the extreme ends of the pieces, as shown at *A*, and the greater part of the upset has to be drawn down to form a scarf, the face and sides of which are generally a series of steps or notches as indicated at *B*. The parts are placed in position for welding as shown at *C*. Some blacksmiths claim that notches on a scarf are an advantage and keep the pieces from slipping when being hammered together. This idea is responsible for a great deal of poor welding inasmuch as the notches make the best kind of a trap for slag or any foreign matter that is liable to adhere to them while heating. If this slag is closed in between the pieces, as it is almost sure to be when the points of the scarfs are welded first, as is generally done, all means of escape for slag or dirt is cut off and the welding will only be effected in spots. The defect will show up in machining if the weld does not come apart before.

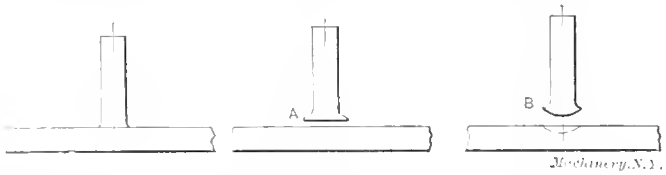

Fig. 3. Correct and Incorrect Methods of Scarfing for Jump Weld.

If pieces are prepared as shown in Fig. 2, defective welding will be reduced to the minimum. The upsetting should be done at least the thickness of the stock from the end, as at *A*, so that it will not be affected by the scarfing. This makes less upsetting necessary, and the scarfing is more easily done. The face and sides of the scarf should be fairly smooth, and crowned slightly in the center as at *B*, so that when they have been heated and brought together for welding, the center will be the first part to unite as shown at *C*. Any slag or dirt that may have adhered to the heated surfaces will be forced out as the welding proceeds from the center to the point of one scarf and then to the other.

Jump Weld.

In welding forgings of the style shown in Fig. 3, usually only one piece, the shank, is prepared. It is upset on the extreme end, the edges scarfed and thinned, and the face left perfectly level, as shown at *A*. When prepared in this manner, the chances are that a little slag will adhere to the flat surface and be closed in between the two pieces. The edges of the scarf will be the only parts to unite with the other piece, and will have to support the whole strain that may come on the forging.

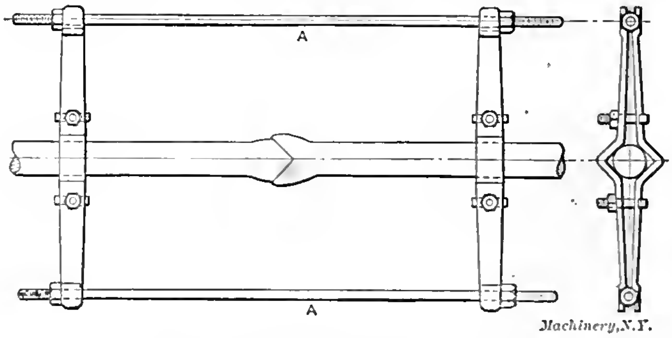

Fig. 8. Heavy Shafting prepared for Welding.

Work of this kind should be prepared as shown at *B*, the flat piece being hollowed out with a bob-punch as shown by the dotted line, and the shank upset and scarfed, as indicated, until it is just small enough so that the spherical portion will bear in the bottom of the impression, but not quite touch the sides. When heated to a welding temperature and placed in position, the first point of adhesion will be at the center, and two or three blows will upset the shank sufficiently to fill the impression. Any slag or dirt will be forced out as the welding proceeds, and a solid piece of work is insured when the weld is completed. This style of welding is known as jump welding.

Butt Weld.

Shafting and similar work, when made of wrought iron, can be butt-welded to advantage, the only preparation necessary being to upset the ends coming together, slightly crowning them in the center. The two ends are kept in alignment with a dowel pin as shown in Fig. 4. When heated to the proper temperature, the parts may be welded before they are removed from the forge by using a sledge hammer on one end, or, if the pieces are of large dimensions, a ram should be used. The welding commences at the center, and all slag or dirt is forced out as the pieces come together. By the time the weld is complete, the diameter around the heated parts will be found to have increased. This excess can be worked down to the same size as the rest of the piece either at the anvil or steam hammer while it is still at a welding temperature.

Welding Steel.

It is not advisable to butt-weld steel at the forge, as the pieces are liable to come apart when the upset portion is being worked down to the same size as the rest of the piece.

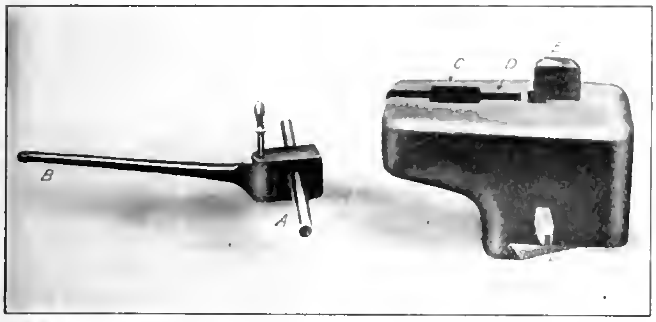

Fig. 9. Upsetting Attachment for Preparing Heavy Shafts for Welding.

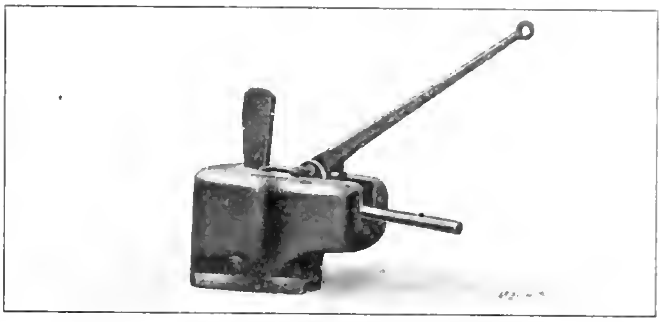

Fig. 10. Upsetting Attachment ready for Operation.

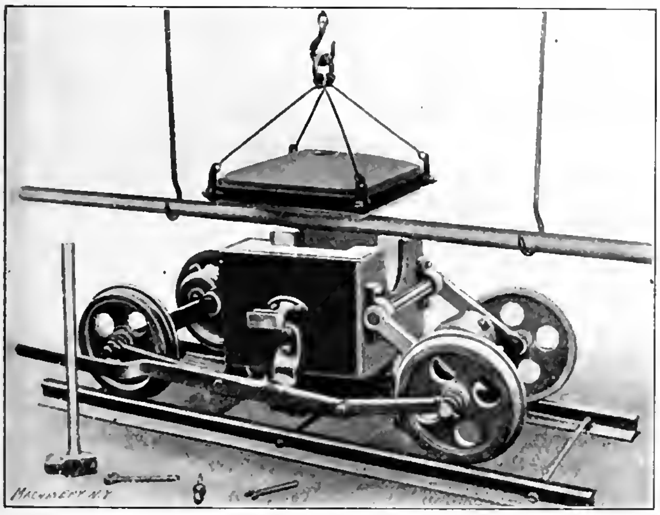

Fig. 11. Portable Forge ready for Use.

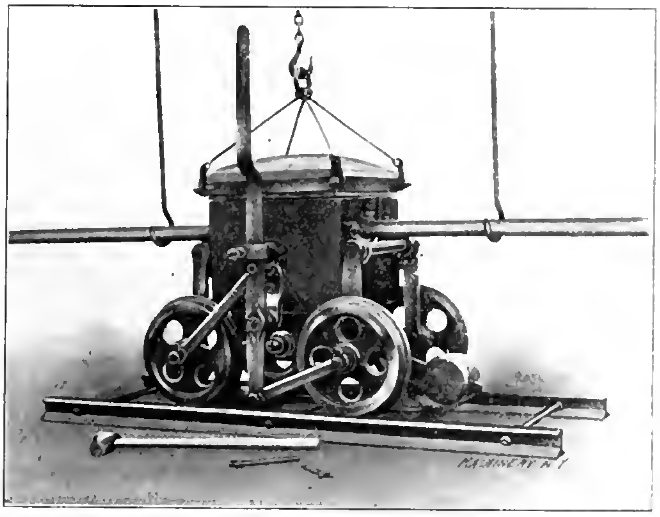

Fig. 12. Portable Forge in Raised Position.

All forgings either of ordinary machinery or carbon steel should be made from the solid, if possible. If this is impracticable, welding should be done either by the plain lap method or by split weld. The split weld is seldom used except upon very long or heavy work, such as shafting, lead-screws for long lathes, and similar work where the parts are either too long or too heavy to be heated separately and placed upon each other for welding with any degree of comfort or accuracy. Work of this kind is usually prepared for welding by being heated on the end and upset with a ram of the style shown in Fig. 5, which is suspended from above by a chain attached to the ring of the ram with a hook. The ram is arranged so that it can be adjusted to any height. It is swung horizontally by means of a rope attached to the shank or handle. Three or four men are needed to give it momentum and one man to guide it by the shank. An equal number of men are needed to keep the shaft in position when acted upon by the ram. When the pieces have been sufficiently upset, one is scarfed as shown at *A*, Fig. 6, and the other is split and scarfed in the shape of a snake's head as shown at *B*. A few sharp burrs are raised with a chisel on the sides of *A*. Part *B* is heated and closed in on the burrs which keep it in position, as shown at *C*. The parts are then placed on the forge, heated, and welded in the usual manner at the steam hammer.

Bars of the style shown in Fig. 7 are used to lift the shaft from the forge and convey it to the hammer. One man is required for each end of the bar; sometimes as many as a dozen or more bars are used, according to the length and weight of the work. When the diameter exceeds three inches, the separate pieces are usually held in position by means of clamps, as shown in Fig. 8. When the heat has been raised sufficiently high for welding the pieces, they may be forced together, before removing them from the forge, by using a sledge hammer or a ram on one end of the work. When the pieces have been fairly united, the tie rods *A* are removed, allowing the work to be turned in the fire so that all sides can be brought as near as possible to the same temperature. The shaft is then lifted from the forge to the steam hammer, where the welded portion is worked down to about the same diameter as the remainder, using the clamps which are still left in position for handling and turning it.

Making Long Lead-screws.

Lead-screws frequently are as long as sixty feet, and occasionally eighty feet or over. Defective welding on this class of work is very serious as it renders the screws practically useless. When work of this nature exceeds the length of the longest lathe in the shop, two or three bars, together equaling in length about the capacity of the available lathe, are welded together, turned, and the thread cut to within about three feet of the end of the bar. This is then returned to the blacksmith shop where a few more lengths are welded on, which are also turned and threaded. This is repeated until the full length has been reached.

To facilitate handling and to reduce the cost of such work, the writer designed the upsetting attachment for the steam hammer, shown in Fig. 9, which takes the place of the ram and can be used with considerably less help, the blacksmith, his helper, and the steam hammer operator being all that is required. To use the attachment, the anvil block is removed from the steam hammer, and the fixture is keyed in its place. The ends of the bars to be upset are heated, placed in V-blocks *A*, which are notched or toothed inside to insure their bearing being firm upon the work, the grip being just

behind the heated portion. The V-blocks are brought to bear upon the work by means of a lever and cam *B*. The V-blocks with the work held firmly between them are placed in a recess *C* in the end of the fixture, thereby preventing them from moving backwards. A steel plate made to slide in groove *D* comes in contact with the hot end of the work. The plate is forced forward in the groove by wedge *E*, driven home by the steam hammer. Should the wedge in any way become cramped, it can be removed by a small wedge *F* which crosses its point near the lower side of the attachment. If the amount of upsetting done at one operation is insufficient, the grip can be released upon the work in the V-blocks, the shaft pushed through as far as it will go, and the operation repeated. A fixture of this style can be arranged to form collars or in fact any kind of work where upsetting is necessary. In Fig. 10, the device is shown ready for operation.

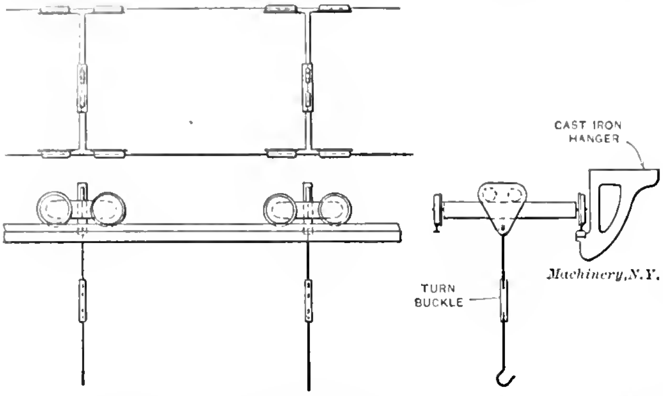

Fig. 13. Diagram of Trolley System in Blacksmith Shop for Handling Long Lead-screws.

Portable Forge for Welding.

Figs. 11 and 12 show a portable forge specially designed by the writer for heating long work to be welded. The general arrangements are such as to afford greater convenience in heating and handling this class of work than is possible with an ordinary forge. By its use a saving of at least 75 per cent in help is effected. In Fig. 11 the work is shown in position ready for heating and supported by hooks. The body of the forge is made deep enough to support the sides of the fire which necessarily have to be high enough to allow the work to be covered by it. The forge is lined with fire brick to prevent the sides getting overheated and warped. The top is covered with a large fire brick bound around the edges with iron straps, and supported by a chain from above. A hole in the center of the brick allows smoke and gases to escape; this hole can be closed or partly closed, when necessary, with a piece of sheet iron or boiler plate. The fire brick cover gives all the advantages and none of the disadvantages of a hollow fire for welding, as it can be placed in position or removed without in the least disturbing the fire. The forge is mounted on wheels attached to the body with axles which can be spread by means of a lever and link motion (see Figs. 11 and 12), allowing the body to drop far enough for work to be removed without lifting it to clear the sides of the fire. To make the forge easily raised and lowered, the body is counterweighted, the weights being made to slide on levers so that they can be adjusted to give a perfect balance. They are held in position with set-screws. The other ends of the levers are connected to the body with links, and work in fulcrums attached to the track on which the wheels rest. The fulcrums are just high enough to clear the bottom of the air chamber when the forge is raised to its full height, which allows it to be easily removed from the track when the levers are disconnected. Fig. 11 shows the forge lowered, and the brick cover suspended by the chain clear of the work. The latter can be conveyed to the steam hammer, as it rests in hooks connected with an overhead trolley. Fig. 12 shows a view of the forge when raised to its highest position by linkage.

Air is supplied from a blower through a flexible hose attached to a flanged pipe. The shut-off can be opened or closed from either side of the forge by means of the two small levers. When in use, the forge has to be placed so that when the work to be welded is in position for heating it will be on a level with the lower die of the steam hammer. It is necessary to use a trolley system of the style indicated in Fig. 13 to convey the work from the forge to the steam hammer and from the steam hammer to the forge. The side track should be long enough to allow handling the longest work and wide enough to reach from the forge to the steam hammer. The cross trolleys, of which there should be at least four, support the work in hooks fitted with turnbuckles so that they can be adjusted to the proper length. With four or more cross trolleys the longest work can be perfectly balanced and conveyed from forge to steam hammer without any danger of bending or distorting the hot portion. This type of forge can be used for purposes other than welding. By closing the opening on one side, it could be used as a furnace for heating any kind of forging within its capacity. Being portable, it can be placed near a steam or trip hammer or any other place where it would be most convenient for the work being done.

Fig. 14 shows the style of tuyere used in the forge already described. This type of tuyere can be used with any kind of a forge and will give better results and less trouble than the average tuyere in general use, especially in welding. It being in the shape of half a sphere, clinkers and slag will not choke it but will form a ring around the base and as a rule can be removed from the fire without breaking them up. Most of tuyeres in general use are usually flat or slightly hollow. Slag or clinkers accumulate in the center, and are a source of annoyance in doing any kind of forge work, especially welding. The tuyere here shown has a single hole to admit air which tends to concentrate the heat and keep the fire from spreading. No bolts or screws are needed to keep it in position; a little fireclay packed between it and the bottom of the forge is all that is necessary to make it air-tight at the base and keep it in place.

In all kinds of welding it is important that there be a fair depth of fire between the tuyere and the work so that the oxygen in the air will be consumed before it reaches the pieces being heated; otherwise the work will scale and only unite with difficulty if it unites at all.

For any kind of welding, hollow fires should be used when the shape of the work will permit. In no case should the work be allowed to come in contact with the fuel any more than is necessary.

Fluxes for Welding.

Wrought iron can be welded in a clean, well-kept fire without necessarily using a flux of any kind except when the work is very thin. Fine, clean sand will answer the purpose. With steel of any kind it is different, as there is no kind of steel that will stand the same amount of heat as wrought iron will. A flux of some kind must be used to get the separate pieces in a condition to adhere to each other. There is a large variety of welding compounds on the market; some of them are suited for one class of welding, some of them for other classes. Welding plates or any of the gritty brands are suitable for any kind of welding when the pieces are heated separately. For pieces put together previous to welding, as in split welds, or when taking a second heat, usually termed a "wash," a compound or flux that will flow freely should be used.

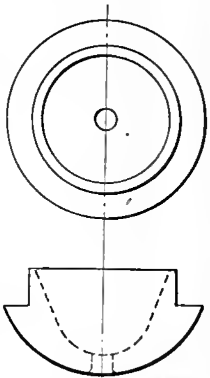

Fig. 14. Tuyere for Portable Forge in Figs. 11 and 12.

When borax is used for a flux it will give the best results if burned, which can be done by heating it in a crucible until it has been reduced to a liquid state. It should then be poured on a flat surface to form a sheet. When cold it can easily be broken up and pulverized. This can be used as it is, or it can be mixed with an equal quantity of fine, clean sand and about 25 per cent of iron (not steel) filings or small chips.

Too much care or attention cannot be given to welding. Poor welding may mean a railway wreck, a steamship disaster, or a number of other things likely to endanger life and property.

A GERMAN DESIGN OF FRICTION SPINDLE PRESS.

So-called friction spindle presses are used to a very large extent on the European continent, and especially in Germany, for forging and stamping purposes. A type of this class of press in an improved form, brought out by the firm of Brüder Boye, Berlin, Germany, is illustrated in Fig. 1. American readers will at once recognize that presses of this type are seldom, if ever, seen in this country.

There is one pulley with a friction wheel on each side of the press, mounted on horizontal shafts in such a manner that either of the friction wheels may be shifted to engage the rim of the heavy central friction driving wheel, attached to a vertical screw. By means of this screw the ram of the press is raised or lowered. The advantages claimed for this type of machine are that it provides for an "elastic" blow, the drive not being positive, and that therefore this design does not require as large dimensions of standards, bearings, shafts, etc., as are required in presses with positive drive, in order to prevent breakage. Besides their use for drop forging, bolt-heading, etc., these presses are also used instead of hydraulic presses and steam hammers for general forging work. For these purposes they possess the advantage of smaller operating cost and cheaper foundations.

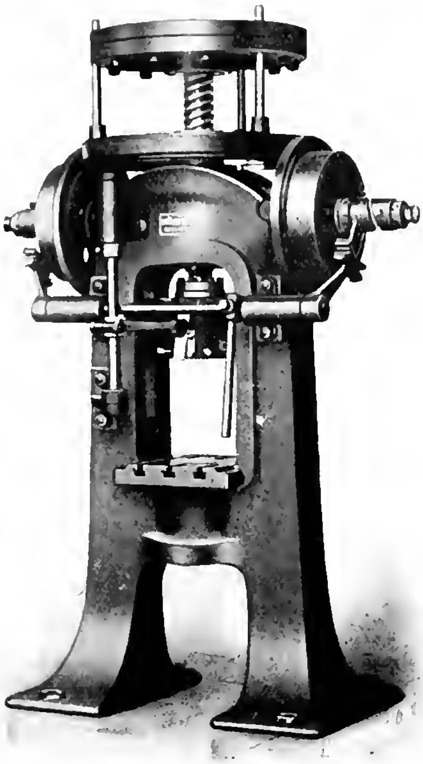

Fig. 1. Friction-driven Press built by Brüder Boye, Berlin, Germany.

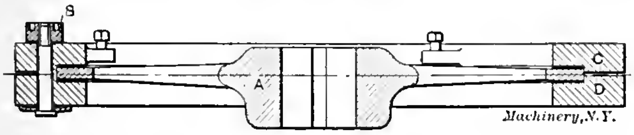

Fig. 2. Safety Fly-wheel used on Brüder Boye's Friction-driven Presses.

The type of press shown in Fig. 1 has been improved in several details over previous designs, the main features of improvement being a special safety fly-wheel, a new driving device and a special arrangement for the friction brake. The design of the fly-wheel, which is placed at the top of the machine at the upper end of the screw, is shown in Fig. 2, and known as Schull's system. In former constructions, it has been common to make the fly-wheels in a solid piece, rim, spokes and hub all cast together. The fly-wheel shown here is made in an entirely different way. It consists of a disk *A*, which forms the hub and the spokes of the fly-wheel, and of two fly-wheel rings *C* and *D*. Between the disk and the rings *C* and *D* are arranged segments or fiber disks. The fly-wheel rings *C* and *D* are tightened to the disk *A* by means of a number of nuts *B*, screwing onto bolts passing through the two rings. These nuts can be tightened only by means of a special spanner wrench having a form as shown in Fig. 3, for the smaller presses, and a form shown in Fig. 4 for the larger presses, the feature of this wrench being that it is provided with a friction attachment, making it impossible to tighten the nuts more than a certain amount, and thus providing for a chance of slip between disk *A* and rings *C* and *D*, if the resistance becomes great enough to overcome the friction between these parts. On account of the peculiar construction of the fly-wheel, this possibility of slip between the fly-wheel rim and the hub, which prevents the fly-wheel from giving out stored-up energy above a certain amount, eliminates breakage of the parts of the press. The capacity of the friction spindle press can also be increased largely on account of this fly-wheel construction, and it is interesting to note to what an extent this construction of fly-wheel permits the full capacity of the press to be taken advantage of. In Fig. 5 are shown four cylinders of tool steel. The first and third views show pieces compressed on an ordinary press of this type, the machine being used to the limit permissible, without risking breakage; whereas, the cylinders in the second and fourth views are compressed on the same press when equipped with the safety fly-wheel.

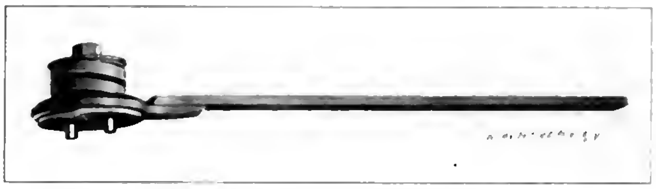

Fig. 3. Friction Wrench for Tightening Nuts in Fly-wheel

Fig. 4. Friction Wrench with Worm and Worm-wheel Drive, used for Large Sizes of Presses.

The driving device shown in Fig. 6 has also several points of interest. This differs considerably from that found in the old type presses. The fly-wheel on the older type serves at the same time as friction driving wheel, and as accumulator of energy. For this reason it was necessary to use large friction disks for turning the fly-wheel, and furthermore the whole driving device of the presses had to be arranged largely above the press. The mounting of the driving disks and the renewal of the leather covering was therefore rather difficult, so that this work was only done in cases where it became impossible to work further with the press. In the machine shown, however, the fly-wheel is used only as an accumulator of energy and the friction driving wheel *E* is separated from it, as shown in Fig. 6. The driving wheel is connected with the fly-wheel by means of pins *F* which pass with a free fit through holes in the fly-wheel. When the driving wheel *E* is rotated, the fly-wheel and the spindle which is connected with it are turned, and the ram is lifted or lowered as the case may be, and while the old presses are provided with

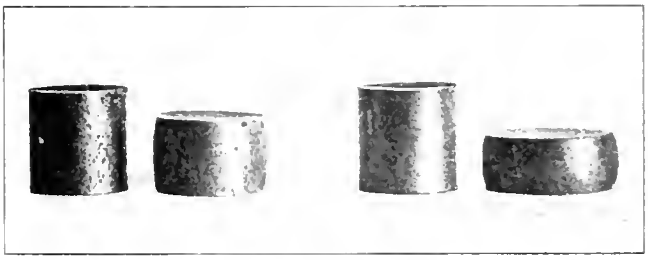

Fig. 5. Comparison of Capacity of Presses having Ordinery and Safety Fly-wheels.

large driving disks placed on movable shafts, it is possible in this design to arrange for smaller driving pulleys and fixed shafts on both sides of the press, as shown in Fig. 6. The control of the machine can be made simpler and more positive than in the old press. As indicated, the movement of the controller handle *P* is transmitted to a shaft provided with two arms *R*, having gear segments at their ends. (See detail view in upper right-hand corner, Fig. 6.) These segments mesh with other segments on arms attached to cams *K* and *O*, which in turn work against cam surfaces on the ends of bushings placed on the ends of the pulley shafts. By means of small springs the pulleys *L* and *H* are always held out of contact with the driving wheel *E*, but when the handle *P* is gripped by the operator and its shaft turned so that the segments *K* and *O*, with their cams, are brought against the cam surfaces on the bushings on the end of the pulley shafts, either one of the pulleys *H* and *L* are easily moved against the driving wheel *E*. When the controller handle is permitted to return to its original position, the pulleys *H* and *L* immediately move away from the driving gear. This driving device gives an easy and absolutely safe control of the machine. The cam bushings on the ends of the pulley shafts are held in place by set-screws, so that it is very easy to turn them at any time to any required angle, and to set them at the correct distance from the cam surface on the segment in order to obtain a good and precise working of the whole driving device.

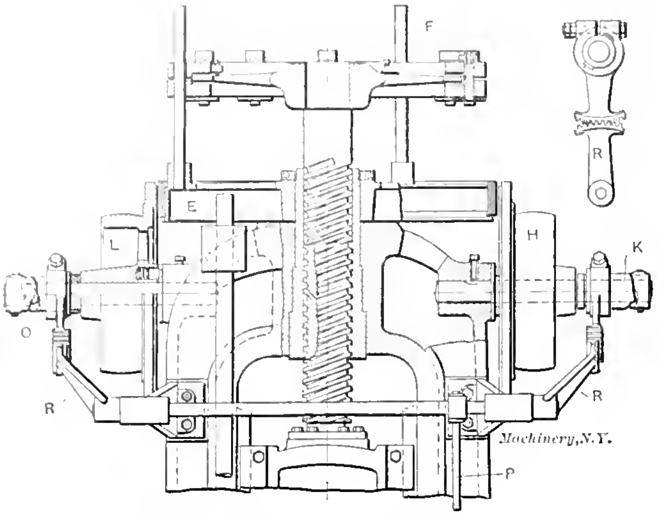

Fig 6. Section of Fly-wheel and Driving Arrangement

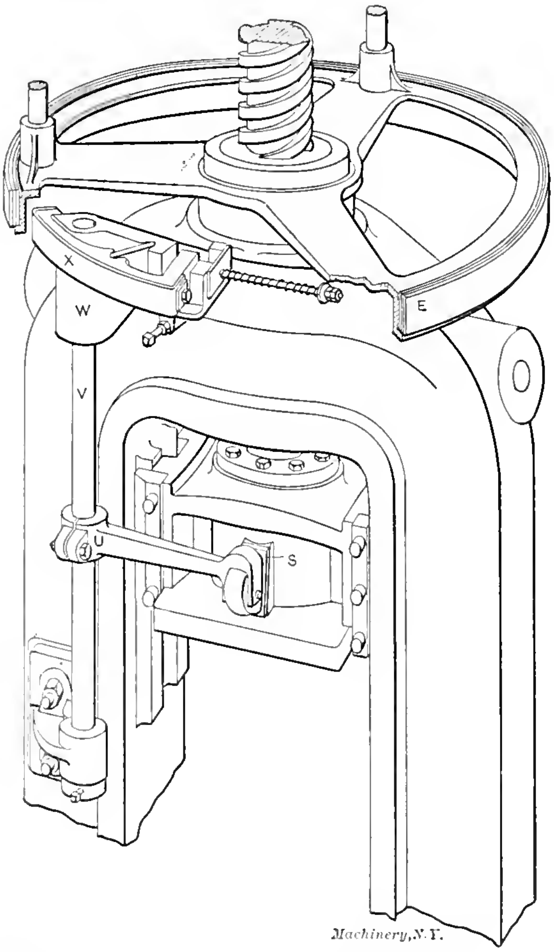

Fig. 7. Design and Action of Brake.

Another interesting feature of these presses is the arrangement of the brake for the movement of the driving pulley, as shown in Fig. 7. The oblique surface *S* on the ram of the press controls, through a roller, a lever *U* on the shaft *V*, which in turn carries the brake *W*. The part *X* of this brake is covered with leather, and acts upon the inner rim of the driving wheel *E*. The lever *U* can be set at any required place on the shaft *V* by means of the clamping arrangement shown. By this arrangement the ram can be stopped at a predetermined point, according to the setting of the lever *U*. The working of the brake is so precise that it is possible to control the movement of the ram within 1/16 inch, and it is therefore possible to use the smallest strokes with precision. The advantage of the brake is not only the precise control of of the ram, but also the added security to the operator.

* * *

TEMPER COLORS, AND TEMPERATURES AND COLORS FOR HARDENING.

The following tables of temper colors, and temperatures and colors for hardening are published in a booklet issued by the Halcomb Steel Co., Syracuse, N. Y., and Chicago, Ill. The temperatures tabulated are a result of personal investigations made by Mr. Garson Myers, manager Chicago branch; a gas furnace equipped with a pyrometer was used. After the records were made they were tested by two experienced tool steel hardeners, one using an electric heating furnace with a pyrometer and the other a magnetic heating furnace also connected with a pyrometer. Neither knew of the other's work, but there was an astonishing uniformity in the results of their independent investigations, corresponding very closely to the figures obtained by Mr. Myers. The company feels that it can without reserve or hesitation recommend that the temperatures and colors are absolutely reliable, having been twice verified by independent workers.

HEAT TEMPERATURES AND COLORS FOR HARDENING.

Degrees C.	Degrees F.	Colors.
400	752	Red heat, visible in the dark.
474	885	Red heat, visible in the twilight.
525	975	Red heat, visible in the daylight.
581	1077	Red heat, visible in the sunlight.
700	1292	Dark red.
800	1472	Dull cherry red.
900	1652	Cherry red.
1000	1832	Bright cherry red.
1100	2012	Orange red.
1200	2192	Orange yellow.
1300	2372	Yellow white.
1400	2552	White welding heat.
1500	2732	Brilliant white.
1600	2912	Dazzling white (bluish white).

The heat and temper colors to which tools should be drawn were contributed by a hardener and temperer of long experience, working on all grades of tool steels, and they also are considered to be perfectly reliable.

HEATS AND TEMPER COLORS OF STEEL.

Degrees C.	Degrees F.	Colors.
215.6	420	Very faint yellow.
221.1	430	Very pale yellow.
226.7	440	Light yellow.
232.2	450	Pale straw yellow.
237.8	460	Straw yellow.
243.3	470	Deep straw yellow.
248.9	480	Dark yellow.
254.4	490	Yellow brown.
260.0	500	Brown yellow.
265.6	510	Spotted red brown.
271.1	520	Brown purple.
276.7	530	Light purple.
282.2	540	Full purple.
287.8	550	Dark purple.
293.3	560	Full blue.
298.9	570	Dark blue.
315.6	600	Very dark blue.

ITEMS OF MECHANICAL INTEREST.

MANGANESE STEEL RAILS.

Within a few months after the elevated division of the Boston Elevated Railway Co. was open for traffic in June, 1901, it was found that the rails on the curves would wear out at a very rapid rate, and the question of maintenance and the cost of rail renewals became a very serious problem. It has been found, however, that manganese steel rails are far superior to ordinary bessemer rails, even when the difference in price is considered, and the accompanying illustrations, Figs. 1 and 2, will give a comparison of the tremendous difference between the wearing qualities of the two classes of rails. In Fig. 1 is shown an ordinary bessemer rail used for 44 days, the lower profile line showing the extent of the wear in this time, while in Fig. 2 is shown a manganese steel rail, which has been in use for 6 years, 3 months and 7 days, and is still in service. No better evidence than this could be shown of the superiority of the manganese steel rail.

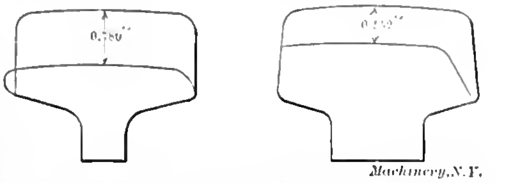

Fig. 1. Ordinary Bessemer Rail after 44 Days' Service on Curve near Park St. Station, Boston Elevated Railway.

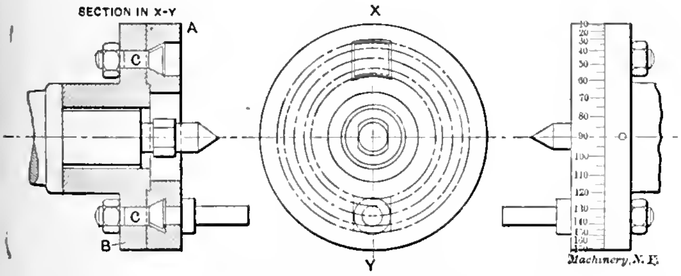
Fig. 2. Manganese Steel Rail after 6 Years' 3 Months' and 7 Days' Service. Rail still in use.

FACE-PLATE CONSTRUCTION FOR THREADING LATHES.

The accompanying illustration, taken from the *Zeitschrift für Werkzeugmaschinen und Werkzeuge*, issue of August 25, 1908, shows an interesting development of face-plate arrangement for threading lathes, brought out by the firm of Ferdinand Pless, Fechenheim, a. M., Germany. The face-plate is intended for facilitating the cutting of multiple threads in the lathe. As seen from the illustration, it consists of two parts, *A* and *B*, the part *A* being free to be rotated in relation to the part *B* when the bolts *C* are loosened. The driving pin for the lathe dog is attached to the plate *A*, and in cutting multiple threads, when one thread is finished, the bolts *C* are simply loosened, and the plate *A* turned around in relation to the spindle of the machine an amount corresponding to the type of thread being cut; thus, for instance, if a double thread is cut, the plate *A* is turned around one-half revolution, or 180 degrees; for triple thread, 120 degrees; for a quadruple thread, 90 degrees, etc. The periphery of plate *A* is graduated in degrees, and a zero line provided on plate *B*, so that the required setting is very easily obtained. On lathes which are constantly used for thread cutting the advantage of an arrangement of this type is very evident, as it saves employing any of the more or less cumbersome methods in vogue for moving the work in relation to the tool when cutting multiple threads.



Face-plate to facilitate the cutting of Multiple Threads in the Lathe.

NEW TYPE OF MILLING CUTTER.

An interesting milling cutter especially intended and made for fluting locomotive main and side rods, and for milling large keyways in axles, has been devised by Mr. T. R. Hellgren, of the Aurora shops of the Chicago, Burlington & Quincy Railroad. A general view of the cutter is shown in the half-tone Fig. 1; and the line engraving Fig. 2, shows the dimensions for a 9-inch diameter cutter with 2½-inch face. It will be seen that the characteristic feature of the cutter is that every alternate full tooth is cut on a right-hand and left-hand spiral, respectively, and one-half tooth is cut in between every two full teeth, this tooth being on the same spiral as the full tooth in front of it. While this cutter will be rather expensive to manufacture, it is evident that it possesses a cutting action far superior to that of cutters having the teeth either straight across the face of the cutter, or all inclined to the same spiral angle. The inventor has applied for a patent on his idea, for which he claims that the greatest advantage is that in the first place the work is not struck by any two points on the same tooth at the same time, thereby overcoming the objection to cutters with straight teeth, and secondly that no severe side strains are produced on the arbor as is the case with cutters having spiral teeth in one direction only.

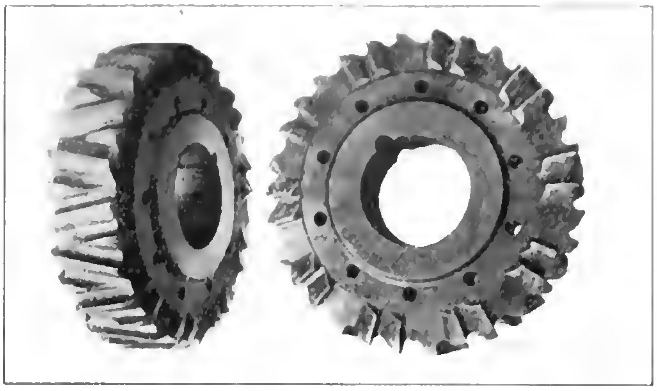


Fig. 1. General Appearance of Hellgren's New Type of Milling Cutter.

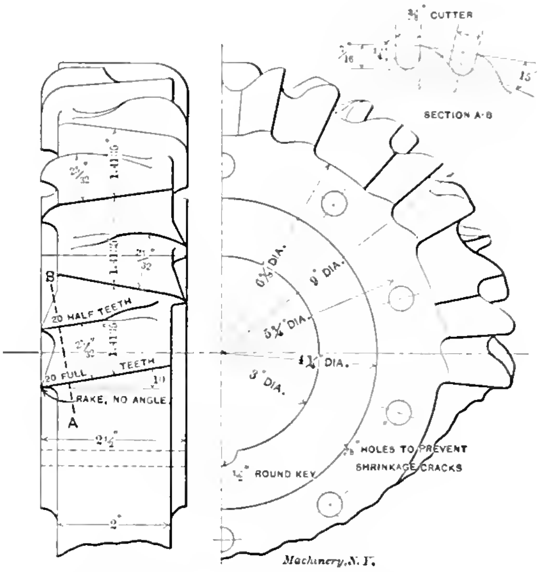

Fig. 2. Detail Drawing of New Type of Milling Cutter.

* * *

An ingenious and interesting use of the telautograph—an instrument for reproducing writing at a distance, invented by Prof. Elisha Gray—was made by a number of New York daily newspapers to bulletin election returns. In this instrument the operator's pencil is connected to levers and the motion of writing is reproduced by similar levers at the receiving station, the receiving pencil making an exact copy of the writing, sketches, etc., made at the transmitting station. The reproducing instruments in the bulletin machines were placed in the focus of the lantern so that the writing was thrown onto screens, magnified many times and legible several hundred feet away. The scheme was eminently satisfactory, there being no loss of time between the receipt of the news and the preparation of copy, as is the case with the ordinary projector using the usual style of copy. Moreover, there was the interest of following the movements of the pencil on the screen, noting its hesitation when spelling such words as "Onondaga," and the other human characteristics with which it was uncannily endowed.

DESIGN CONSTRUCTION—OPERATION.

PUBLISHED MONTHLY BY

THE INDUSTRIAL PRESS,
49-55 LAFAYETTE STREET, CORNER OF LEONARD,
NEW YORK CITY.

Alexander Luchars, President and Treasurer.
Matthew J. O'Neill, Secretary.

Fred E. Rogers, Editor.
Ralph E. Flanders, Erik Oberg, Franklin D. Jones, Associate Editors.

The receipt of a subscription is acknowledged by sending the current issue. Checks and money orders should be made to THE INDUSTRIAL PRESS. Money enclosed in letters is at the risk of the sender. Changes of address must reach us by the 15th to take effect on the following month; give old address as well as new. Single copies can be obtained through any newsdealer.

We solicit communications from practical men on subjects pertaining to machinery, for which the necessary illustrations will be made at our expense. All copy must reach us by the 5th of the month preceding publication.

DECEMBER, 1908.

PAID CIRCULATION FOR NOVEMBER, 1908, 21,086 COPIES.

MACHINERY is published in four editions. The practical work of the shop is thoroughly covered in the Shop Edition—$1.00 a year, comprising more than 430 reading pages and 36 Shop Operation Sheets, containing step-by-step illustrated directions for performing 36 different shop operations. The Engineering Edition—$2.00 a year, coated paper $2.50—contains all the matter in the Shop Edition, including Shop Operation Sheets, and about 250 pages a year of additional matter, which includes a review of mechanical literature, and forty-eight 6 x 9 data sheets filled with condensed data on machine design, engineering practice and shop work. The Foreign Edition, $3.00 a year, comprises the same matter as the Engineering. RAILWAY MACHINERY, $2.00 a year, is a special edition, including a variety of matter for railway shop work—same size as Engineering and same number of data sheets.

TOOL-MAKING AND MANUFACTURING.

It is a matter of common knowledge with our readers that interchangeable manufacturing is *cheap* manufacturing, when compared with the old-time method of making the parts of machines without the use of jigs, fixtures and gages. That the identical parts of modern products, such as rifles, revolvers, watches, typewriters, and hundreds of other articles of common use are interchangeable, is really an incidental feature of the jig and fixture system—a very valuable feature, it is true; but not the fundamental reason for its general use, as some well-informed mechanics seem to think. Two machines, or a dozen, could be made from the same drawings without any of the identical parts being exactly the same, or anywhere near it, as a tool-maker would regard the measurements; and all these machines would give perfect satisfaction. If only a limited number of a given type of machine or tool is to be produced, it is a serious problem to discover whether it would be best to build jigs and fixtures for so-called interchangeable manufacture, but really cheap manufacture, or to avoid the heavy tool-making expense and build the product "every one like itself." The manufacturing cost by the latter method would be greater than by the use of jigs, fixtures, press tools, and other features of modern manufacturing, but the over-head expense of that equipment might swamp the enterprise should the output be comparatively small.

A valuable tool was patented a few months ago by a tool-maker, which may be used widely, but is not likely to be sold in large numbers. By this we mean that it is not a tool that every mechanic would want, but one that almost every up-to-date shop would supply in its tool-room when its merits became known. The inventor and his promoters are at a stand-still as regards manufacturing, because of the lack of the comparatively large capital required for the elaborate equipment which they believe should be provided. Being tool-makers, they are unable to entertain the idea of producing the tool by any other than the familiar, exact system.

If every manufacturing business in successful operation to-day had been obliged to start with a first-class equipment, doubtless many of them never would have reached their present state of development. It is quite feasible to turn out many products by a system that is not strictly interchangeable, but which answers practical purposes very well, save that the manufacturing cost cannot be made as low as by the interchangeable system when the tool equipment has once been provided. In the tool above referred to, the matter of interchangeability of the parts and of exact accuracy is not important, save in one detail; and this can be readily provided for by well-known processes familiar to mechanics.

The training of a tool-maker tends to make him ignore the common methods of manufacture, wherein extreme precision and interchangeability are virtually sacrificed to practical conditions that must be met if the business is to be started without heavy initial outlay. After a business has been successfully launched, the refinements of modern manufacture can be developed with profit; but it is better to start without them than not to start at all.

* * *

METHODS OF REWARDING LABOR.

At the annual convention of the National Machine Tool Builders' Association in New York, a paper was presented by Mr. Harrington Emerson on various methods of paying employes, with a statement of the advantages and disadvantages of each to the employer and the employe. Mr. Emerson has developed a system under which labor is individualized, each man being rated according to his personal efficiency. A standard day's work is established by rigid investigation, and the employe's personal efficiency is determined accordingly. The skilled and rapid worker does more, and is paid more, than his less skillful and slower shopmates.

The discussion following the paper was animated, the general sentiment seeming to be that no one could determine a standard for a day's labor, and that the determination of a standard was the crux of the problem. Conditions and practices are constantly changing and improving, and a full day's work now may be a small product a year from now. The tremendous influence of the discovery of high-speed steel was quoted to show what changes in machine work are made by inventions and discoveries, and it was mentioned that some kinds of lathe turning now require only from one-half to one-quarter the time required with ordinary carbon steel tools.

Students of economics realize the practical need for an equitable wage system, but they cannot help deprecating attempts to reward labor according to its production. In the last analysis it seems to us that the schemes devised for stimulating labor production are merely thinly disguised plans for getting more out of the men for a *living wage*. Labor may profit temporarily by the introduction of premium, bonus or piece-work plans, but eventually all wages are determined by the law of supply and demand, and will be at best a living wage only, under our present economic system. The man who works with his hands and brain, without ownership in the enterprise, must expect that the larger profit on his product will be absorbed by others, who, through their ownership of land and public or private utilities, occupy strategic positions. The workman is benefited by increased production, but not directly, except temporarily.

The competitive system pits one man against another, and increases production; but it also pits one concern against another, and tends to reduce the selling prices of the product. It is doubtful, in the end, if either the employe or the employer profits materially by greatly increased production per capita, except as the general standard of living is raised. The net result of the last century of progress, during which machine tools, railroads, steamships, telegraphs, telephones and hundreds of other great wealth producers have originated, is that mankind eats better, sleeps better, lives better than before; but the great majority is not released from the necessity of constant labor. Working people simply get more for what they do—and require more.

We hope that the appeal to selfishness made by all the present plans for rewarding labor, will some day give way to methods addressed to the nobler characteristics of mankind—pride in production and quality, sense of civic duty, a keener understanding of one's duty to his fellowmen and of the need for cooperation, and the application of the golden rule in all its bearings. But before this millennium will arrive, both employer and employe must handle the question from a totally different standpoint from what they do at present.

FORFEITURE OF PATENT RIGHTS.

E. C. SMITH.*

The writer has read with interest the editorial in the November issue regarding patented inventions which are wilfully kept dormant or suffered to remain so, but the sentiment regarding forfeiture is not concurred with. In the first place, an invention is not one of the "bounties of nature," nor can it be properly considered or treated as such. In that category are the natural elements and their various combinations in the mineral formations, animal and vegetable life, and in physical formations of the earth. They are the sensible and tangible products of nature's creative action, and we believe them provided for and essential to the welfare and conservation of the race. In this aspect it is inexpedient that they should be subject, either in part or as a whole, to exclusive privilege for a few, or their use and enjoyment limited by a few.

Inventions are thought creations and their corporeal embodiments are the visible and tangible products of creative mental acts. They are mental progeny just as children are physical progeny, and are therefore akin to the individual. The inventor's right to his invention is therefore deemed inherent and inviolable.

That patents were originally devised to accord the patentee exclusive use of the patented art or article, for the purpose of assuring him a reasonable reward for his enterprise is unquestionably true, but it must be remembered that the first patents were granted largely, if not almost exclusively, for importation of industries rather than for the discovery or creation of new arts or devices. With the development and growth of individual inventive resource there has also developed the sentiment that the products of such individual effort essentially belong to the individual. Inasmuch as invention is incorporeal property and unsusceptible of precise definition like real and personal property, special means were devised for its protection and the protection of the inventor's rights. To conserve these rights the patent system has been established. Under this system the public enters into a contract with the inventor whereby his rights may be defended. To secure his means of defense—the letters-patent—the inventor must disclose his invention completely. This disclosure, as I understand it, is not so much for the purpose of enabling others to practice that particular invention as to enlighten them as to the mode of practice, opening up new fields of endeavor and directing inventive thought in new lines.

It must be admitted that a patented invention even though kept dormant for seventeen years, is more valuable to the public than if unpatented and undisclosed. If the result secured by the invention is peculiarly desirable then the desire to secure the same or similar results by other means will whet the inventive wit the keener.

Laying aside academic considerations, there are practical and cogent reasons for not causing forfeiture of patents on account of non-practice of inventions. It sometimes happens that the invention disclosed in a patent containing broad, basic and therefore valuable claims, is in a form less desirable for use and less economical of production than that of a subordinate patent. It is not unusual for the proprietor of one patent, the invention of which is practiced, to have several other patents covering less desirable forms of construction which are not practiced.

Many inventors diligently pursue the commercial exploitation of their inventions without success for the greater part of the life of their patents. Surely it were unfair to deprive the generic inventor of his basic claims unless he manufactures continuously for seventeen years a device that is undesirable and expensive, simply because it is the patented embodiment of those broad claims. Equally unjust would it be to compel a proprietor of several patents to manufacture several alternative forms of apparatus for seventeen years, with all the attendant cost for plant, material and labor, simply to maintain those patents. Superlatively unjust were it to deprive a man of his patent rights because of failure to practice his inventions, when that failure is due to adverse circumstances.

Any question as to "best use" would start a train of technicalities in an action for forfeiture or in defending against an action for infringement more involved than any of our present day patent litigation is cumbered with, and the merits of a case would turn on matters of opinion rather than fact. The only way in which the justice or injustice of such forfeiture or defence against infringement could be ascertained would be by a hearing before some tribunal which would only slightly mitigate and not entirely correct abuse. How many grasping corporations and enviously malign individuals would harry poor inventors with actions for forfeiture? How much incentive would one have to invent were there hung above his head the Damoclean sword of forfeiture proceedings?

The path of the inventor is sufficiently precarious as it is, without adding further obstructions and detriments, and seventeen years is a short period to wait, even for the inventor who derives satisfaction from withholding his patented device from public use. The rights of the public are better cared for with respect to patents than ever before. To secure a patent an inventor must exercise diligence in applying for a patent and in prosecuting his application. But when his patent has been obtained, the inventor is secure in his exclusive rights, of which he can be divested only by due process and because of defective title, which must be conclusively proved.

The world owes much to the inventor, and if some wanton vagary leads him to exercise his prerogative under letters-patent, to the extent of refusing the public the use of some one invention, it, in turn, should remember the multitude of inventions, the use of which it has had, and not overlook the sundry inventions it has wantonly filched or ruthlessly wrested from the inventor.

[The arguments presented by our correspondent in favor of the rights of inventors to protection in non-worked patent rights, are undoubtedly correct from a legal point of view, and that we concur with this opinion was plainly stated in the editorial referred to. From an ethical point of view, however, it appears that the inventor who prevents others from using an invention which he will not or cannot use himself, resembles very much the dog in the manger. In the case of an invention it is not merely a question of it being a creation of a certain individual, and that he, therefore, has an absolute and exclusive right to the profit afforded by the patent, because, during the seventeen years a patent is in force, a number of other inventors may independently work out and invent practically the same appliance or method as has formerly been invented; and while in the case of patents obtained and *used*, the first inventor naturally must be protected on account of priority, it is difficult to see his moral right to prevent others from using independently worked out ideas which he does *not* care to *use* himself. Besides, the question hardly involves inventors as individuals, because it is hard to conceive of an inventor who would acquire a patent and refuse to work it if it had any commercial value. It is much more a question of the ethics of the not unusual practice of corporations of buying up patents from individual inventors and keeping the patent dormant because it may interfere with some inferior product of theirs which they prefer to continue to place on the market. We do not think that the requirement of working a patent within a certain number of years after being granted would involve a hardship for inventors as individuals. On the contrary, it is likely that such a clause would prove beneficial to the real inventor's interests. That the idea is not new and that the principle stated is recognized as correct is evidenced by the fact that the patent laws of most European countries contain a clause requiring the patent to be worked within a certain number of years after being granted. If the inventor or others to whom he may assign the rights to his patent do not care or do not find it profitable to make any use of the patent, it is either impractical, and in such a case there could be little reasonable objection to infringement; or it is held out of use for commercial reasons which are not commendable, and thus actually work an injury to the very inventor who is supposed to be protected. It must be understood that the question raised in the editorial referred to was one not of whether the present law was correctly interpreted, but of whether the law corresponded to true moral principle.—EDITOR.]

ENGINEERING REVIEW.

CURRENT MECHANICAL EVENTS—LEADING ARTICLES OF THE TECHNICAL PRESS.

At the convention of the American Street and Interurban Engineering Association, at Atlantic City, last October, it was proposed that street car wheels should be made without flanges, and the flanges instead placed on the rails. Many plausible arguments were brought forward to show the superiority of such a system over the present one.

According to *Page's Weekly*, the company formed last summer at Hamburg for utilizing the forces of the tides near the mouth of the Elbe, to which reference was made in the June issue of MACHINERY, has raised a capital of $750,000, and various buildings connected with the undertaking are now in course of completion at Cuxhaven. It is intended to use the tides for the production of electric power for factories.

It is stated by the *Scientific American* that a company has been formed for boring another tunnel connecting Switzerland and Italy under the Alps. This tunnel will begin at Martingly in Switzerland, and come out at Courmayeur, Italy. It is planned to be 28 miles long, and is expected, it is said, to be completed in three years. So far, however, it exists only on paper, and like many of the engineering projects in the way of tunneling of late years, may remain in that state.

Among the concerns mentioned in our November issue as having joined the National Machine Tool Builders' Association was that of the Powell Tool Co., Worcester, Mass. As published it appeared as the Powell Planer Co., and as such was erroneous. The Powell Planer Co. was originally the name of the Woodward & Powell Planer Co. and the name is held to be the property of the said company. The Woodward & Powell Planer Co. has been a member of the National Machine Tool Builders' Association for the past six years.

It is stated in the monthly *Consular and Trade Reports* for September, issued by the Department of Commerce and Labor, that in extensive competitive tests carried out in France, a decrease in consumption of gasoline, amounting to 53 per cent per ton-mile, as compared with the results of similar tests performed in 1907, has been achieved. Sixty per cent of all the cars which entered the race made the entire tour, which occupied twenty-seven days, during which 2,175 miles were covered. The total average consumption of gasoline per ton-mile was 0.074 quart as compared with 0.157 quart in similar tests undertaken in 1907.

Remarkable steam economy was shown by a stationary, self-contained engine and boiler set of the portable engine type, built by the firm of R. Wolf, of Magdeburg, Germany, and recently tested by Professor M. Gutermuth, of Darmstadt. The tests are reported in the *Zeitschrift des Vereines deutscher Ingenieure* of October 3, 1908. When the engine tested developed 103 H.P., it showed a steam consumption of only 8.86 pounds per horse-power-hour, and a coal consumption (using coal of 13,900 B.T.U. per pound) of 1.06 pound per horse-power-hour. This engine works on superheated steam, and is compounded, having both cylinders seated in the smoke box, and therefore jacketed by the hot flue gases. The superheat at the entry into the high-pressure cylinder averaged 236 degrees F., and after having passed through a reheater, the steam entered into the low-pressure cylinder with a superheat of 200 degrees F. The mechanical efficiency of the engine alone varied from 93 to 95 per cent.

Consul Thomas H. Norton, of Chemnitz, Germany, states that electric steel melting furnaces are becoming more and more used at German iron works and that one important steel works, engaged in the production of tool steel products, intends to replace its whole battery of crucible furnaces by one large electric melting furnace, the cause for the change being the reduction of cost possible. The whole equipment consisted of thirty-two furnaces, each containing six crucibles, with a capacity of 77 pounds. These are to be replaced by an electric furnace capable of holding a charge of 2,200 pounds. The advantages of the electric process are stated briefly as follows: cheaper raw material can be employed in place of the more expensive Swedish iron formerly required; in melting quantities of one ton at a time, it is possible to produce more homogeneous masses of a well-defined grade; and, finally, the molten steel leaves the furnace at a much higher temperature than when prepared in crucibles, and is therefore in a more liquid condition, and is easily transferred to the ordinary ladles.

An interesting offer has been made by Sir Christopher Furness, of the Middleton Ship Building Yard, England. This works met last year with a loss of about $85,000, largely due to labor troubles, and as Sir Christopher realizes the injury both to the works and to the employes of conditions bringing about such losses, he has offered the yards for sale to the trade unions at a price to be decided upon by independent assessors. If this offer is not accepted, he offers an alternative proposition, agreeing to issue to the men preferred shares in the company, to be paid for by a deduction, from week to week, of five per cent of the wages. These shares would receive a fixed rate of interest of four per cent, whether the common shares received any dividend or not, and when the common shares receive five per cent as a yield on the capital investment, the balance of the profit is to be distributed between the common and the preferred stock. This experiment will bear watching, as it is a step toward that cooperation in the industries, which may be inevitable, in some form or other, in order to obtain industrial peace within industries organized on a large scale.

At the time of the discovery of the Taylor-White process of treating tungsten steel so as to greatly increase its cutting qualities, it was asserted in one of the English engineering journals, that the discovery was nothing new. Certain steel makers in England had anticipated the discovery, but, strangely enough, had not realized the commercial importance of the steel, and had taken no steps to put it on the market, contenting themselves with its use in their own work. The same discovery appears to have been made in the United States. A certain manufacturer of files and rasps had developed a high-speed steel for cutting files some time before the discovery of the Taylor-White process. It was not, of course, as efficient as present high-speed steels, but was far in advance of the carbon steels or air-hardening steels then in general use. In none of these cases does it appear that the importance of the discovery was recognized until Mr. Taylor and Mr. White demonstrated the tremendous increase in machine shop production that could be realized by using this steel for lathe and planer tools. A true discoverer is one who recognizes the value of his find and who makes it known to others so that there can be a common benefit derived from it.

The pyrometer for hardening and tempering steel is coming into general use. It does away with guess-work and enables the hardener to exactly reproduce a desired hardness and temper with a given brand of steel, as many times as is desired and whenever wanted, but the pyrometer is still an unknown instrument with many hardeners who are nevertheless doing good work without it. Being deprived of a pyrometer does not mean that the hardener is necessarily obliged to work by "judgment" and guess-work entirely. A simple test can be made of a brand of steel which will soon develop the proper temperature, as determined by the eye, which gives the best results. This test, mentioned in a booklet issued by the Halcomb Steel Co., Syracuse, N. Y., consists simply in taking small samples from a bar of steel and applying two or three different hardening heats. After hardening, break the samples and note the fracture. The heat

producing the finest grain, obviously, is the proper heat at which to harden that grade of steel. This, of course, applies to carbon tool steel. In this connection it may be mentioned that the Union Twist Drill Co., Athol, Mass., applies the fracture test to every bar of tool steel used. Thin disks are sawed from the ends of each heavy bar, and are hardened at the standard temperature which repeated tests have determined to be the best hardening temperature for the brand of steel employed. If the samples do not show the required fineness of texture in the fractures, the steel is rejected. It is no uncommon occurrence to find bars of steel which show different grades of fracture at opposite ends.

In the April, 1908, issue the use of an ordinary magnetic compass for ascertaining proper hardening heats for carbon steel tools was described by Mr. George T. Coles, with an illustration of use. This simple method has attracted much favorable attention, and is being practiced by many tool hardeners who have found it convenient and reliable. An extension of the idea has been patented in England, which has a certain advantage over the compass method. The drawback to the compass method is that the determination of the heat is in a sense, negative in character, the operator not receiving a definite warning the instant when the proper heat has been reached. All he knows is that when the tool has reached the hardening temperature it no longer attracts the compass, but he has no proof that it is not many degrees higher, except the heat appearance. This defect is overcome in the device referred to. An ordinary horseshoe magnet is provided with iron wire extensions to the poles, the poles being drilled axially before hardening and magnetization. A small horseshoe magnet will attract and hold small objects applied to the ends of the wire extensions, even though they are three or four inches in length. The pieces to be hardened are thus held magnetically at the extremity of the iron wire extensions in a blow-pipe flame over a jar of brine until they have acquired the proper hardening heat, when they drop off into the brine, having lost their magnetic attraction for the wires. The use of the wires, of course, is simply an expedient to avoid heating the magnet and causing destruction of its magnetic property, as would surely result if it was inserted in the flame directly. The process is automatic, but, unfortunately, it can be applied only to comparatively small parts, unless large, expensive and cumbersome apparatus is provided.

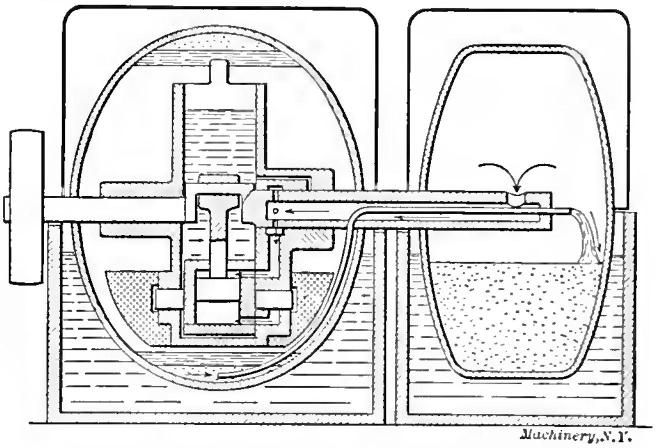
An interesting machine for testing rail wear is described and illustrated in the *Railway and Engineering Review* of October 24, 1908. Such a machine has been a subject of discussion for many years, and many ideas have been proposed, but few, if any, have ever taken practical shape. An exception to this general statement may be noted in the machine devised by the engineering department of the Pennsylvania Steel Co., and exhibited at the recent convention of the American Street and Railway Engineering Association. The apparatus is intended to test the relative wear of rails of different grades of steel. The test is conducted by bolting the rails to a circular cast iron base 20 feet in diameter, the rails forming a continuous circle. On these rails two car wheels, mounted at the ends of a heavy beam rotating on a pivot, are continuously running. A compression spring is mounted on the top of the revolving beam, which can be adjusted so as to exert pressure from zero to about 60,000 pounds on each car wheel. The vertical pressure exerted by each car wheel due to the dead load is about 7,500 pounds, so that by means of this apparatus a vertical pressure of about 67,500 pounds can be exerted on the head of the rails. In addition to the vertical pressure, lateral pressure is also exerted by means of compression springs mounted on the axle of each wheel, the maximum lateral pressure being from 15,500 pounds at 10 R.P.M., to 47,800 pounds at 85 R.P.M. The maximum speed at which the machine is designed to run is 85 R.P.M., which would correspond to a train speed of practically 61 miles per hour. As the conditions under which this machine will test the rails are very similar to those to which rails are subjected in the work, the machine will undoubtedly be of advantage in settling the question of rail wear.

A NEW ICE-MAKING MACHINE FOR DOMESTIC USE.

Scientific American, October 17, 1908.

Nearly all ice-making machines depend for their operation upon the property of certain substances to absorb a large amount of heat when changing from the liquid to the gaseous state. As a rule, anhydrous ammonia is the substance used, and this is forced through a closed cycle consisting of a compression chamber and an expansion chamber. In the latter chamber the ammonia expands into a gas, absorbing heat as it vaporizes. Then it is drawn into the compression chamber by a pump and compressed into a liquid, only to flow back into the expansion chamber and expand into a gas. Thus one chamber of the machine is made cold by the vaporizing ammonia, while the other develops heat because of the compressing of the gas. The heat from the compression chamber is dissipated by a radiator system, while the influence of the expansion chamber can be extended at will by a system of pipes through which brine is circulated.

The difficulty with refrigerating machines as commonly constructed is that long stuffing boxes are necessary to prevent leakage of the ammonia, and the friction developed in these stuffing boxes not only absorbs energy, but generates additional heat. The smaller the machine, the more serious are these losses, because of the pressure that must be maintained, which does not permit the friction to diminish in proportion to the capacity of the machine. For this reason, refrigerating machines for domestic use have not been as economical as those of large plants.



Small Rotary Ice Machine, which requires Little Attention.

Recently a machine has been invented by Prof. Audiffren, of Paris, based on the same principle as the ordinary ice machine, but so designed as to do away with all stuffing boxes, pressure gages, agitators, valves, or anything that would require the attention of an operator. As shown in the accompanying sectional view, it consists of two chambers or drums, which are connected by a hollow shaft. A solid extension of this shaft passes through the larger chamber, and at its outer end carries a pulley, which provides means for operating the machine. The shaft is sealed into the chambers, so that as the pulley revolves, the chambers revolve as well. Mounted to swing freely on the shaft within the larger drum is a small pump, which is kept vertical by means of a lead weight attached to its lower end. The piston of this pump is connected to a crank offset in the shaft, so that when the pulley is rotated, the shaft revolving with it will operate the piston. In the smaller machines the drums are charged with anhydrous sulphurous acid instead of ammonia. The pump serves to draw the gas from the smaller or expansion drum through the tubular shaft, compress it into a liquid, and discharge it into the larger or compression drum, whence it flows back through a pipe leading through the tubular shaft into the expansion drum. Here the liquid evaporates, and is returned to the compression chamber by the action of the pump. In order to provide sufficient lubrication, the pump is kept swimming in oil, the pump being fitted with a reservoir capable of carrying half a gallon of oil. The oil cannot escape, and such of it as leaks out of the pump is trapped and returned to the reservoir. Owing to the rapid rotation of the drum, the liquid acid is centrifugally

thrown against the inner periphery of the chamber, and any oil that leaks into the chamber is centrifugally separated from the heavier sulphurous acid, forming an annular layer within the acid layer. The illustration shows the acid and oil at the bottom and top of the compression chamber. At the top of the oil reservoir is a scoop, which extends upward sufficiently to dip into the oil, but without reaching the layer of sulphurous acid. This scoop collects the oil, causing it to fall back into the reservoir.

The expansion drum rotates in a small tank partly filled with water, and this forms a layer of ice over the drum when the machine is in action.

ELECTRIC HARDENING FURNACES.

C. R. Straube in the *Elekrotechnische Zeitschrift*, August 6, 1908.

In externally-fired furnaces, the heat losses are always considerable, and only a small part of the energy used in heating is utilized for raising the temperature of the metal to be hardened. There is also a disadvantage in employing gas or oil-fired furnaces in that the high temperatures rapidly destroy the crucibles. Electric hardening furnaces, therefore, possess marked advantages for this work over the various types of externally-fired furnaces. The electric furnace described in the following has been brought out by the Allgemeine Elektrictäts-Gesellschaft of Berlin, Germany. A bath of melted metallic salts is contained within a fire-brick crucible, inside of which, at two opposite sides, are fixed electrodes of iron very low in carbon, the melting point of which is higher than that of ordinary steel. This crucible is surrounded by a thick layer of asbestos, which is, in turn, imbedded in a layer of some heat-insulating material, the whole being held together by a steel case. The walls of the furnace are made so thick in relation to the dimensions of the crucible that the steel case of the apparatus may be touched with the hand without injury after having been in operation for 10 hours, at a temperature of 2,370 degrees F.

The soft iron supply conductors to the electrodes are connected to the secondary copper bars of a regulating transformer which transforms the normal voltage to the low voltage (5 to 70 volts) employed in the operation of the furnace. A typical arrangement of the equipment of a large works has the furnaces provided with a hood in a central position, and a quenching tank immediately beside the furnace on one side. By this latter arrangement a change in temperature caused by carrying pieces from the furnace to the water tank is reduced to a minimum. The tank is supplied with heating and cooling coils with steam or cold water, so that the temperature of the quenching bath can be easily regulated.

A pure metallic salt or a mixture of several salts is placed in the crucible and melted by the passage of an electric current. Potassium chloride which fuses at about 1,425 degrees F. is selected for carbon steel; for high-speed steels, barium chloride, which fuses at 1,740 degrees F., is employed. Mixtures of these two salts will give all intermediate temperatures. For low temperatures, say between 400 and 750 degrees F., postassium and sodium nitrates may be used, and for very high temperatures, magnesium fluoride and fluorspar. The salt is melted by a movable electrode and a small piece of arc-light carbon placed in the circuit between one of the fixed electrodes and the movable one. Sparking between the carbon and the movable electrode causes salt immediately adjacent to melt and very soon a circuit is set up through a part of the salt. As the movable electrode is gradually drawn away, it leaves behind a streak of melted salt, which is extended by degrees to the opposite electrode. When this point is reached, the fusion of the remainder of the salt proceeds at a rapid rate. The temperature produced depends on the voltage employed, and may be varied by changing the intensity of the current, which is accomplished by means of a regulating transformer.

Even at a temperature of 2,400 degrees F., attainable in laboratory tests but not usually employed in commercial hardening, the damage to the crucibles of the electric furnace is very small. Working ten hours a day with this temperature, a crucible will last six months, and for ordinary hardening temperatures, fifteen months.

EFFICIENCY TESTS OF MILLING MACHINES AND MILLING CUTTERS.

Abstract of Paper by Mr. A. L. DeLeeuw, read before the American Society of Mechanical Engineers, December, 1908, Meeting.

The design of standard machine tools was for many years, and has been until quite recently, a matter of practical experience, judgment and intuition, and might as well have been called guesswork. Special tools of unusual magnitude were built on somewhat more scientific principles, and this, perhaps, simply because the required dimensions were quite out of the scope of the designer's experience. It was not quite so easy to show judgment about a 6-inch as a 1½-inch lead-screw; and it would not have done at all to make the screw 12-inch just to make sure; though the instances are not at all rare when some machine part, screw or shaft, on some smaller machine was made double the required size, simply to be on the safe side.

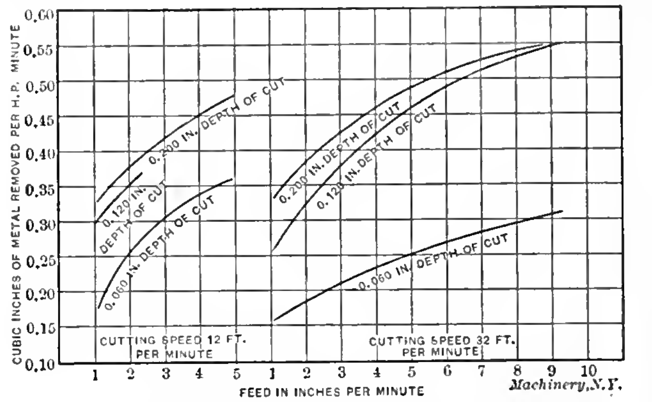


Fig. 1. Work of 1 H.P.-minute, measured in Cubic Inches of Metal removed, for Different Feeds and Cutting Speeds.

This condition was not due to ignorance on the part of designers or inability to apply engineering data, but to the fact that such data did not exist or were not public property when they did exist. Further, there was no inducement for the machine tool builder to spend time and money collecting data, as the tools, as built, filled all requirements to a reasonable extent.

This condition ceased to be satisfactory with the coming of the electric motor into the field of the machine tool builders. At first the wildest and most varied guesses were made as to the size of motor required to drive a certain tool. One builder would supply his machine with a 2½ H.P. motor, while another would equip the same size and style of machine with a 15 H.P. motor. This chaos was made worse by the fact that most purchasers of motor-driven tools would specify the size of motor to drive the machine. One user would condemn the machine tool builder because the 10 H.P. motor was entirely too small, and the next one because a 5 H.P. motor was much too large for the same machine.

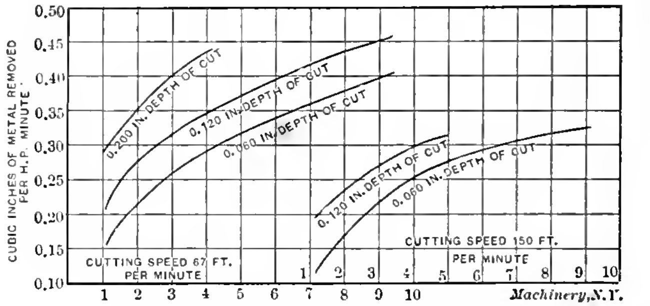

Fig. 2. Work of 1 H P.-minute, measured in Cubic Inches of Metal removed, for Different Feeds and Cutting Speeds.

This brought before the machine tool builder the fact that a machine was not always used to its full capacity and was sometimes badly overloaded. In sheer self-defense the machine builder was compelled to determine for himself the proper size of motor to be put on his machine, and he began to make tests and collect data; but although numerous tests have been made as to performance of machine tools, they have been confined almost exclusively to lathes. All other

machines seem to have been considered as following the lathe in cutting characteristics.

The author of the paper here abstracted therefore found it necessary to undertake a number of tests directly applied to milling machines, in order to collect data preliminary to the designing of a line of horizontal and vertical milling machines for the Cincinnati Milling Machine Company.

Specifications of Milling Machine Tests.

The main points to be settled were:

a. How much metal shall a machine of given size be capable of removing?
b. How much power is required for this work on existing machines?
c. Is it possible to improve on the efficiency of present machines and still produce a commercially successful machine?
d. How much power is required for the feed?
e. What is the efficiency of the feed mechanism?

The first question was a point to be decided by the sales manager rather than by the engineer, as it was greatly a matter of competition. As is quite usual in the design of a new line of machines, the desired capacity was placed somewhat higher than that of other makes of similar machines. To determine how much power was required to remove a given amount of metal, tests were made on various makes of machines. The metal to be cut was in all cases, both in these tests and in those to be described later, steel of the following specifications: carbon contents, 0.16 per cent; tensile strength per square inch, 52,378 pounds; limit of elasticity, 30,313 pounds.

The test blocks used were 18 inches long, 5½ inches wide and 5½ inches thick. The ends were milled to provide means for holding the block on the table of the milling machine. In all tests a spiral cutter with nicked teeth was used, 3½ inches in diameter, 6 inches face, and for a 1½-inch arbor. The cutter was driven by a key, and made of high speed steel. All tests were made by driving the machine by an electric motor, belted to the machine. The object was to have all conditions as near as possible to those under which the majority of milling machines have to run, the only difference being that the belt was nearly horizontal instead of vertical. In testing the efficiency of machines in this way, the belt must be considered part of the machine. The power consumed was ascertained by reading of ammeter and voltmeter, the amount of metal removed, by measuring width and depth of cut, and the amount of feed per minute, was computed from the gearing.

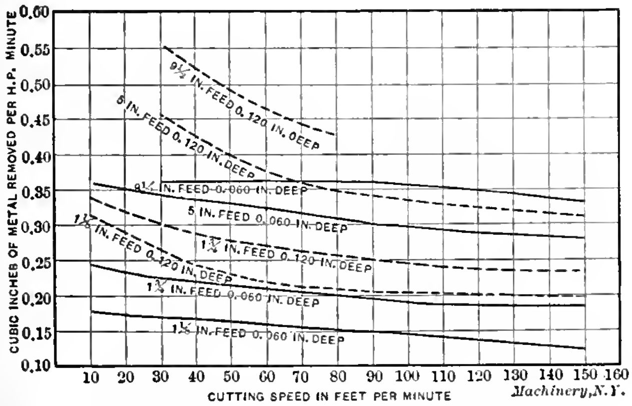

Fig. 3. Work of 1 H.P.-minute, measured in Cubic Inches of Metal removed, for Different Feeds and Cutting Speeds.

These preliminary tests showed considerable differences in the efficiency of different makes of machines; that is, one machine would cut considerably more material than another for a given amount of horse-power developed by the motor. They also showed that the efficiency of these machines was relatively low as compared to the lathe. This latter might have been expected considering the nature of the cutting tool. As the main problem in a machine shop is not to save power, but to get the greatest possible output, this lack of efficiency cannot be held up against the milling machine as a type, for its other peculiarities make it highly efficient as a producer of work. The fact that one make is so much more efficient than another is of great importance, however. It shows that the less efficient machines:

a. Use a needlessly large amount of power.
b. Have less capacity than they might have for removing metal.
c. Use a large amount of power constantly for the purpose of breaking down the machine.

It follows that it should be the aim of the designer to produce a machine of the highest possible efficiency as a power transmitter, because

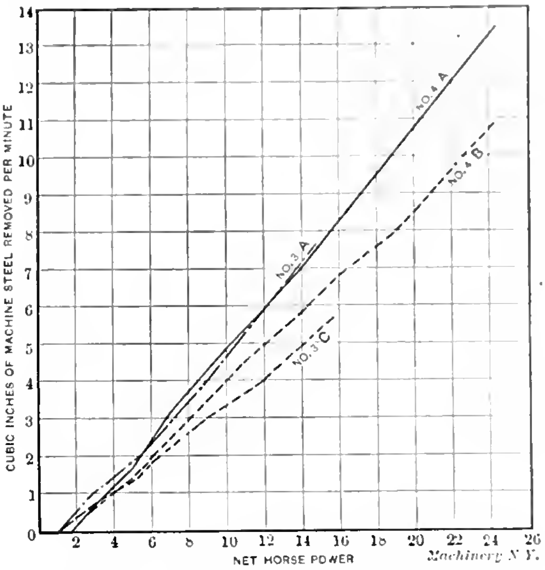

Fig. 4. Diagram showing Relation between Horse-power required and Metal removed.

a. This increases the capacity of the machine.
b. It insures long life and freedom from repairs.
c. It is economical in the use of power.

This high efficiency requirement stands by itself. It must be supplemented, however, by other good features, such as convenience, etc. The main features aimed at, and considered essential to high efficiency, were the following:

a. Absence of combined torsional and bending stresses in shafts.
b. Absence of torsional stresses in shafts subjected to heavy loads.
c. Moderate gear speeds.
d. Moderate shaft speeds.
e. Minimum number of gears in action.
f. No gears rotating, which are not required for the transmission.
g. Tumbler bearing anchored solidly, and not merely hung from a lever.
h. Pulley shaft relieved of belt pull.

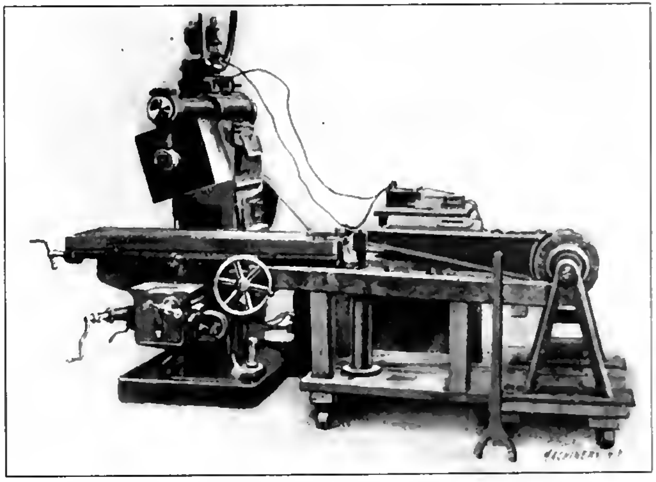

Fig. 5. Apparatus for Testing Efficiency of Feed Mechanism.

Final Tests.

More complete tests were made when the machine designed along the lines mentioned was completed. These tests were of three kinds:

a. Tests determining the amount of metal removed per horse-power.
b. Tests determining the efficiency of the feed mechanism.

b. Tests determining the efficiency of the feed mechanism

c. Tests determining the efficiency of the driving mechanism.

Power Required to Remove Metal.

The same motor and belt were used for all cutting tests. A series of tests was made with a depth of cut of 1/16 inch; then with a depth of 1/8 inch; then 3/16 inch, 1/4 inch, and 3/8 inch. This complete test was repeated four times. The cutter was sharpened in the ordinary way before starting a complete series of tests, and not resharpened during the test. The same cutter, resharpened, was then used for the next machine. For each depth of cut, a number of different feeds were used.

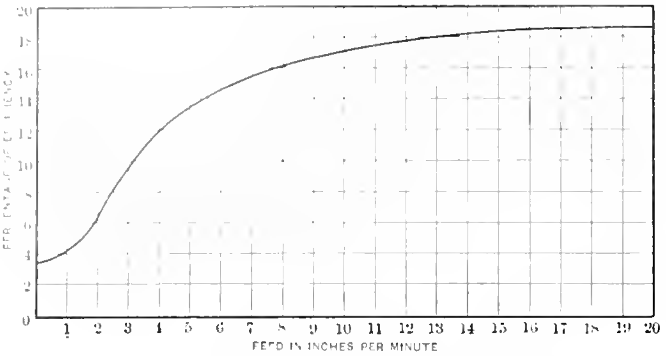

Fig. 6. Curve showing Efficiency of Feed Mechanism.

The amount of power required to remove a given amount of metal varied with the speed, depth of cut and feed per minute, and seemed to have a tendency to the minimum when the section of the chip removed per tooth approached most nearly a perfect square. Figs. 1, 2, 3, and 4 show curves giving relation between power required and metal removed under different conditions of speed, feed and depth of cut. The fact that the power required changes with these conditions of feed, speed and depth of cut made it impossible to plot a single curve giving relation between power and metal removed. The curves were extended to the zero point, but the high point of all curves is the actual highest average obtained, so that in a certain sense the curves also show the comparison of the greatest possible capacity of these machines. This should be taken as significant, however, only when remembering the conditions under which the machines were tested, and then only as a measure for the maximum driving power.

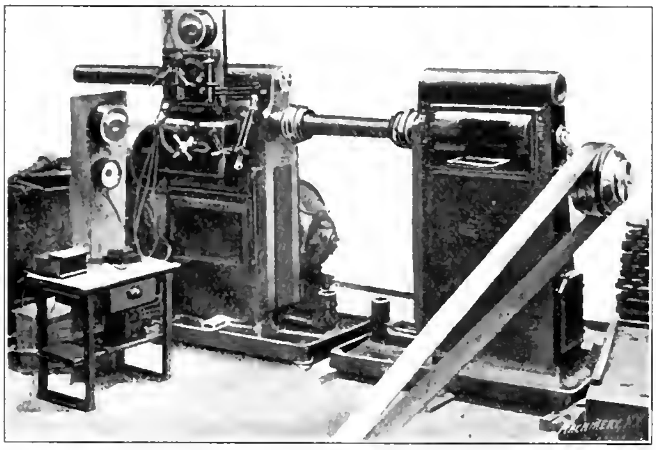

Fig. 7. Apparatus for Testing Efficiency of Driving Mechanism.

Efficiency of Feed Mechanism.

Fig. 5 shows the manner in which the machine was rigged up for testing the efficiency of the feed mechanism, and Fig. 6 shows the curve of average values plotted from the tests; each ordinate is the average of the ordinates corresponding to a certain amount of feed. The results of these tests justify again the precaution taken to obtain an efficient feed mechanism in the new line of milling machines. It may be mentioned here that these precautions consisted in avoiding idle running gears, high gear velocities, combined torsional and bending stresses in shafts, and ill supported and floating bearings, and above all, the use of quick pitch screws.

Tests upon Efficiency of Driving Mechanism.

The third series of tests relates to the efficiency of milling machines as power transmitting devices: that is, the ratio of "input" and "output" of power. Some preliminary tests were made by observing the power at the spindle by means of an absorption brake of the Weston type. This gave fairly good results at the higher speeds, the torque being small; but at the lower speeds and with greater torque the action of the brake became jerky and it was practically impossible to obtain reliable readings. The tests were carried on with the apparatus shown in Fig. 7. This consisted of two machines of the same type, make and size placed opposite each other and connected by a stout shaft. The feed works were removed, as were also knee, saddle and table, so that nothing was left but the bare frames and driving works. The machines were placed with the spindles approximately in line. A flange was screwed to the nose of each spindle; each flange was provided with a tongue engaging the groove in a similar flange opposing it, and keyed to the stout connecting shaft. There was plenty of clearance between tongue and groove and also endwise so that the connection could behave as a universal joint shaft in case the spindles were not exactly in line. It must be remarked here that the motion in this universal joint shaft was exceedingly small. Flat pieces of steel bolted to the first mentioned flange prevented the connection from coming apart.

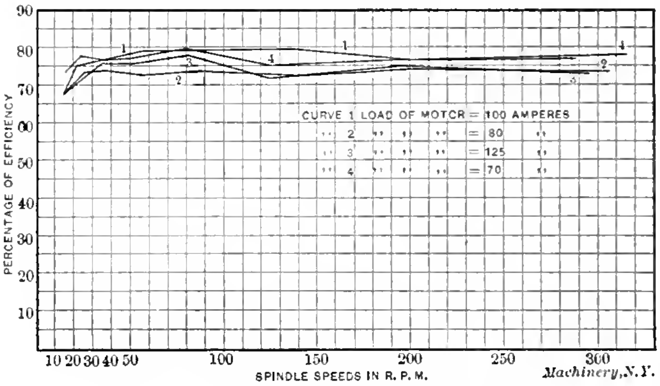

Fig. 8. Diagram of Efficiency of Drive of Milling Machines.

One of the machines was driven by a motor while the other drove a generator. The current thus generated was dissipated in a water rheostat, by means of which the amount of current could be closely regulated. There was a set of electric instruments for motor and generator each, so that all readings could be taken simultaneously. Both machines were driven by belts. A tachometer was used to determine if one of the belts slipped excessively. If the generator voltmeter showed considerable drop and the tachometer showed about the proper speed at the first driving shaft of the first machine (motor machine), then the belt to the generator must have slipped. If, however, the tachometer showed a drop, then the belt from the motor to the first machine must have slipped. The speed controlling levers of both machines were always in corresponding positions—that is, both were set for the same speed, so that at whatever speed the spindle was running, both driving pulleys were always running at the same speed, and that is the speed at which they are supposed to run under working conditions. The results of the tests are shown in Fig. 8. It will be seen that the efficiency of the machine varies from 67 to 79.7 per cent.

Efficiency of Cutters of Different Types.

The milling machine is not essentially less efficient as a power transmitter than any other machine tool, but the amount of metal removed per horse-power per minute is low; much lower in fact than for the lathe or planer. Were it not for other properties, the milling machine could not compete with either of these two machines. Still it cannot be denied that the milling machine would be esteemed higher if its power consumption could be brought down to the level of

the lathe. It is obvious that this cannot be done by increasing the efficiency of the mechanism, as the margin is not large enough to allow of any material improvement. Any substantial increase of efficiency must therefore be found in improvements of the cutting tool. With this consideration in mind, some tests were made as to the power required to remove a given amount of metal with different styles of cutters.

Cuts made with a spiral cutter with nicked teeth showed a best efficiency of 0.48 cubic inch of metal per net horsepower per minute, and this efficiency was obtained only in a few isolated cuts and with a very sharp cutter. Cuts made with a 14-inch face cutter with inserted teeth and on a No. 4 Cincinnati high power miller showed a production of 0.64 cubic inch per net horse-power per minute, an increase of 33 1/3 per cent over the spiral cutter. This result confirms the general belief that a face cutter cuts freer than a spiral cutter. The teeth of this face cutter were radial, as it is customary to make them. Tests made with the cutter shown in Fig. 9 showed an efficiency of 0.96 cubic inch of metal per net horse-power per minute, and a few isolated cuts even higher. This is an improvement of 100 per cent over the spiral cutter and 50 per cent over the face cutter with radial teeth. The cutter shown in Fig. 10 showed the same efficiency. Both cutters have the blade set tangent to a circle concentric with the cutter, thus giving them a rake angle of 15 degrees. The clearance was 7 degrees. The points of the cutting blades were rounded to prevent injury by burning or chipping, and this reduced the effective rake near the horizontal tangent to this curve. It was for this reason that the blades were set leaning backward as in Fig. 10. But for this curvature at the point of the blades, the simpler construction of Fig. 9 would be perfectly satisfactory. The leaning back of the blades is rather a refinement than a necessary improvement.

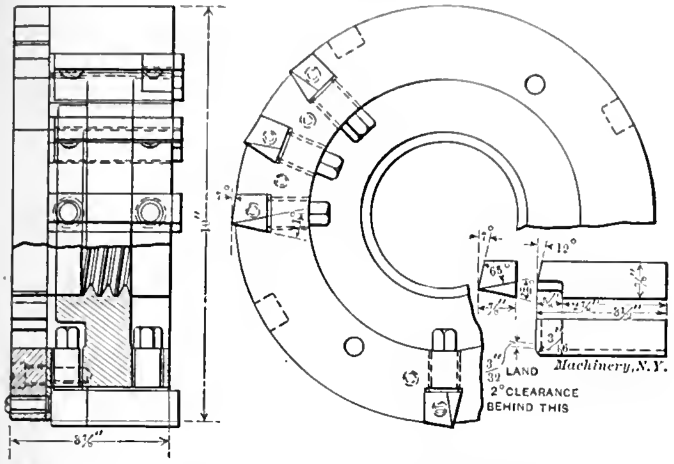

Fig. 9. Ten-inch, 16-blade Cutter used in Experiments on Milling Cutters.

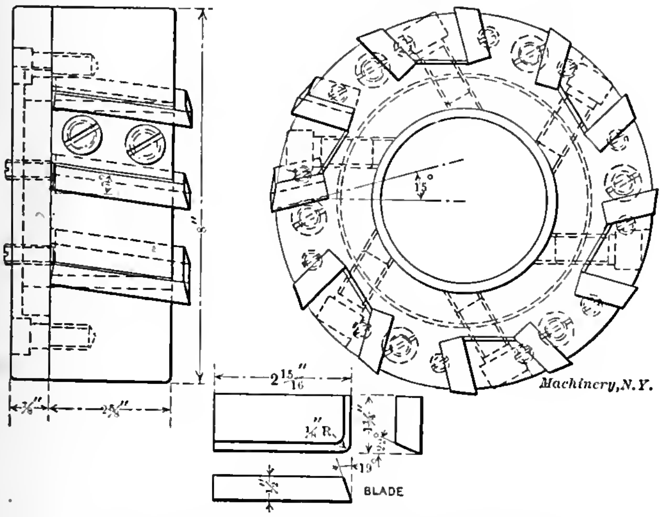

Fig. 10. Inserted-tooth Cutter showing High Efficiency.

It should be borne in mind that the tests made with these cutters were made on a vertical machine which had the same driving parts as a horizontal machine of the same size, and besides an additional two shafts and four gears, so that it is safe to say that its mechanical efficiency must be less than that of the No. 4 horizontal machine used with the spiral cutter with nicked teeth. The action of the feed on a machine using this cutter may be somewhat different from that on a machine using spiral cutters. Whether there is such a difference and what it amounts to, has not been ascertained by tests, and might be a promising field to explore. The fact that, generally speaking, the face cutter with rake removes double the amount of metal with the same amount of power as compared to the spiral mill, is significant, and places the vertical machine in the front rank for slabbing work wherever it is possible to use this type. Equally significant is the fact that a cutter with rake removes 50 per cent more metal than a cutter without rake. It may be mentioned here that many of these cutters, especially for so-called rotary planers, are being made and have been made for a great many years with the teeth leaning backward as in Fig. 10 but without rake; the makers and users apparently believing that this leaning constitutes rake.

[In the May, 1906, issue of MACHINERY, Mr. DeLeeuw commented on the subject of making milling cutters without front rake. It is interesting to note how correctly the results of actual experiments bear out the opinions then expressed.—EDITOR.]

CONSTANTS FOR CALCULATING HELICAL GEARS.

C. W. PITMAN.*

The calculation of helical gears always is a time-consuming operation, and any short-cuts or labor-saving methods, proposed from time to time, are eagerly accepted by designers. The working out of a table of constant factors which can be applied directly to the various requirements of the design, opens up one of the easiest and shortest roads to the solution of helical gear problems known to the writer, and such a table has therefore been computed and is presented in the accompanying Supplement. The use of this table will reduce very materially the time necessary for the computation of the angles, dimensions, etc., of helical gears, as well as greatly simplify the calculations.

The body of the tables in the Supplement gives constants C_t for center distances of shafts for each speed ratio given, the shafts being at right angles, while the factors U, F, and L are equally applicable to gears on shafts at any angle. The constants for unit diameter of gear per tooth, U, and for unit center distance per tooth of fast gear, C_t, are calculated for gears cut with spur gear cutters of 1 diametral pitch; for any other pitch divide the constant by the diametral pitch of cutter used. The factors C_t given in the body of the tables, are, it should be noted, per tooth of fastest running gear, or gear having the smallest number of teeth. All factors are given for each degree (from 12 to 78 degrees) of angle of tooth helix. For angles including a fractional part of a degree, while strict accuracy would require the use of interpolation formulas, test calculations have shown that the proportional value between factors, as used in the examples given later in this article, is sufficiently accurate to meet all practical requirements.

The simplicity of the operation of calculating a pair of spiral gears will be apparent from an example: Required the number of teeth, diameters, and center distance, for a pair of gears, helix angle of pinion 60 degrees, of gear 30 degrees, speed ratio 2 to 5, and teeth of 6 diametral pitch. The following notation will be used in the formulas:

N_a = number of teeth in pinion (gear having the smallest number of teeth),
P_d = diametral pitch,
C_t = center distance per tooth (1 diametral pitch) of pinion, as given in tables in Supplement,
U = unit diameter per tooth (1 diametral pitch), given in the Data Sheet Supplement,
L = lead of tooth helix per inch pitch diameter, given in Supplement,

---

* Address: 3519 Frankford Ave., Philadelphia, Pa.

D = pitch diameter,

F = cutter factor, as given in Supplement.

From Table II in the Supplement, we find the factor C_t for this angle and speed ratio to be 2.4435, and by the formula $N_a = \frac{C_t}{P}$ center distance, and disregarding for the moment the number of teeth, we have $\frac{2.4435}{6} = 0.40725$.

If we wish a center distance of approximately 5 inches, we will use a value of $N_a = 12$; this gives us $0.40725 \times 12 = 4.887$ inches center distance; 12 teeth in pinion; and $12 \times \frac{5}{2} = 30$ teeth in gear.

For the further calculations, using the formulas given below, and the factors for the angles stated, we have:

$\frac{U \times N_a}{P_d} = \frac{2 \times 12}{6} = 4$ inches pitch diameter of pinion,

$L \times D = 1.814 \times 4 = 7.256$ inches lead of tooth spiral of pinion,

$F \times N_a = 8 \times 12 = 96$, thus requiring No. 2 cutter for pinion.

Using the same formulas for the gear gives us:

$\frac{1.1547 \times 30}{6} = 5.774$ inches pitch diameter of gear,

$5.441 \times 5.774 = 31.416$ inches lead of spiral of gear,

$1.54 \times 30 = 46$, requiring No. 3 cutter for the gear.

From the above it will be at once apparent that the tables giving as they do constants for finding all data necessary for the sizing and cutting of the gears, permit a great saving of time over any other method, whether graphic or by calculation. In fact, by their use the task is rendered practically as easy and as simple as the figuring of a pair of spur gears, and the novice can do this work as well as the expert.

The above solution meets the conditions involved in probably nine out of ten spiral gear problems, that is, where the center distance of shafts is adjustable, and the helix angle can be taken at will. Occasionally, however, it becomes necessary to calculate the gears to suit a fixed center distance, in which case the helix angle must be made to suit the other conditions. This has always been a tedious and time-consuming operation, but the use of the table cuts out the drudgery, and reduces the time required to a minimum.

For instance, suppose in a machine having the above gears, it were required to replace them with others having a speed ratio of 1 to 2, without changing the position of the shafts. Transposing the formula for center distance and solving, we have

$$C_t = \frac{P_d \times \text{center distance}}{N_a}$$

and using for trial the same number of teeth in the pinion as before,

$$C_t = \frac{6 \times 4.887}{12} = 2.4435.$$

Inspection of the tables in the supplement shows that this corresponds to an angle lying between 68 and 69 degrees; this might do, but a smaller angle is preferable; trying 14 teeth, we have

$$C_t = \frac{6 \times 4.887}{14} = 2.0945.$$

This gives an angle of 55 degrees 15 minutes for the pinion, and is much better; for the gear we have 28 teeth, and a helix angle of 34 degrees 45 minutes, and using the proportional value between factors U for these angles, gives by the formula for pitch diameters,

$\frac{14 \times 1.7546}{6} = 4.094$ inches, pitch diameter of pinion,

$\frac{28 \times 1.2171}{6} = 5.679$ inches, pitch diameter of gear.

While the range of speed ratios given is sufficient to meet nearly all requirements, gears can be as readily calculated, and the center distances then found, for any other ratio. Thus, for a pair of gears of 4 pitch, 19 and 20 teeth, helix angles 45 degrees, we have, by the formula for gear diameters:

$\frac{19 \times 1.4142}{4} = 6.717$ inches, pitch diameter of pinion,

$\frac{20 \times 1.4142}{4} = 7.071$ inches, pitch diameter of gear, and

$\frac{6.717 + 7.071}{2} = 6.894$ inches, center distance.

For shafts at other than a right angle the factors C_t do not apply, and for fixed centers the proper helix angles can be found only by repeated trials. Where the center distance can be made to suit diameters, however, as is usually the case, the process is very simple. Thus, for shaft angle 65 degrees, speed ratio 1 to 4, gears 8 pitch, we have:

Pinion, 8 teeth, 30 degree helix angle;

Gear, 32 teeth, 35 degree helix angle.

$\frac{U \times N_a}{P_d} = \frac{1.1547 \times 8}{8} = 1.1547$ inch, diameter of pinion;

$\frac{1.2208 \times 32}{8} = 4.8832$ inches, diameter of gear.

Center distance $= \frac{1.1547 + 4.8832}{2} = 3.0189$ inches.

The lead of spiral and the cutter to use for milling the teeth will be found as in the first example.

For helical gears on parallel shafts the table will also be found a great convenience, as it reduces the necessary calculations to a minimum. The constants given in the body of the table do not apply for these gears, since the helix angle of both gears of a pair is the same, and their diameters are therefore proportional to their velocities. For example: suppose a speed ratio of 1 to 5, helix angle 15 degrees, 8 diametral pitch. Using 14 and 70 teeth for pinion and gear respectively, we find by formula

$\frac{U \times N_a}{P_d} = D$,

$\frac{1.0353 \times 14}{8} = 1.812$ inches, diameter of pinion,

$\frac{1.0353 \times 70}{8} = 9.059$ inches, diameter of gear, and

$\frac{1.812 + 9.059}{2} = 5.436$ inches center distance.

If it were desired to replace these with gears of 6 pitch, speed ratio and center distance the same, the diameters would obviously be the same, and the helix angle must be found; transposing our formula, we have

$$\frac{D \times P_d}{N_a} = U.$$

For N_a we must assume a value, but as the helix angle for these gears is generally kept as small as possible, the number of teeth in the smaller gear of the pair will always be taken at the nearest whole number less than $D \times P_d$; therefore

$$\frac{1.812 \times 6}{10} = 1.0872 = U.$$

Consulting the table we see that this value of U will give an angle of 23 degrees 6 minutes. The leads and cutter to use are found as follows:

For the pinion, 10 teeth,

$7.367 \times 1.812 = 13.338$ inches lead of tooth spiral,

$1.28 \times 10 = 13$; use No. 8 cutter.

For the gear, 50 teeth,

$7.367 \times 9.059 = 66.737$ inches lead of tooth spiral,

$1.28 \times 50 = 64$; use No. 2 cutter.

METAL-CUTTING TOOLS WITHOUT CLEARANCE.*

The principles of a turning tool intended to cut without clearance, consisting of a cutter and a holder so constructed as to allow the cutter a slight oscillatory freedom in the holder, are discussed in the following: The center line on which the cutter oscillates is substantially coincident with the cutting edge. The oscillation of the cutter about the center line does not affect the position of the edge, but allows the face of the cutter to swing around to conform to the face of the metal from which the chip is being severed. The objects of this construction are to make possible the use of more acute cutting edges to reduce the cutting stresses; to wholly or partly equalize the unbalanced side pressure on the cutting edge; and to obtain a rubbing contact to prevent lateral vibration.

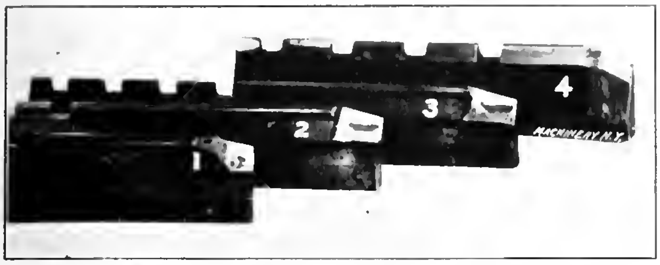

Fig. 1. Illustration showing the Abrasive Contact of Chip on the Top Slope. Nos. 1, 2 and 3 were used in Tool-holder illustrated in Fig. 3. No. 4 shows one of the Earlier Forms.

In order to make clear the reasons for the construction of the tool shown, it will be necessary to briefly analyze some of the conditions under which metal is worked in a lathe, dealing particularly with cutting angles, clearance of cutting edges, and the importance of minimizing the tendency of the work and tool to separate under cutting stresses. The subject has been approached from the standpoint of a designer and manufacturer of lathes, and particularly lathes of the "flat turret" lathe type.

The generally accepted cutting angle of greatest endurance under high speed is about 75 degrees, and the angle of least resistance, according to some of Dr. Nicholson's tests, is about 60 degrees. The cutting angles of the tool illustrated and discussed may be varied from the present orthodox angles down to 30 degrees or less, according to the nature of the work. The results obtained by Dr. Nicholson, which showed an increase in cutting stress for tools more acute than 60 degrees, may have been due to the cuts having been taken without suitable cutting lubricant. Furthermore, the comparative lack of durability of the more acute edge below 70 degrees, may have been due either to heat or lateral vibration, or both. The heat would have been greatly reduced by a liquid cooling medium, especially one having some suitable lubricating qualities, and the lateral vibration may be eliminated by means to be explained. The thin edge of an acute tool is obviously the least suited to carry off heat or to withstand the vibration incident to cutting.

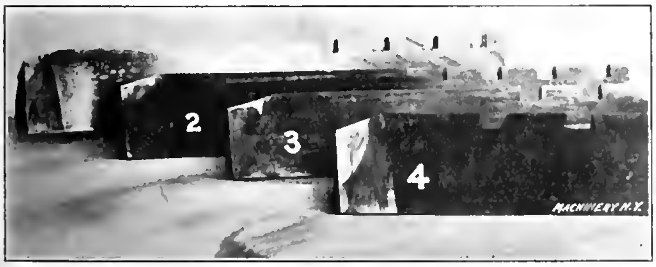

Fig. 2. Reverse Side of Cutters shown in Fig. 1. Illustration shows Rubbing Contact of the Tool against the Shoulder of the work. Each Tool bears Same Number in Both Engravings.

Class of Work Considered.

The tool illustrated should be considered from the standpoint of one who sees nothing but lathe work under 20 inches in diameter, and of the kind usually found in any machinery building plant, not that the means may not be of value in larger work, but simply that this is out of the author's range of experience, and such work was not considered in designing the tools described. A more exact description of the range of work for which this tool is intended may be stated as follows: Lathe and turret lathe work under 20 and over 4 or 5 inches in diameter, and less than 8 or 10 inches in length, also work up to 2 and 3 feet in length of diameters under 3 to 3½ inches and generally over ¾ or 1 inch in diameter. This includes three classes of work: (*a*) chuck work, having diameter generally exceeding length, held wholly by a chuck or face-plate; (*b*) bar work, which is held in chuck and steadied by back rests; (*c*) work having dimensions similar to bar work, but which must be turned on centers, with or without following and fixed steady-rests. The material dealt with is regular open hearth machinery steel of about 20 points carbon.

In work supported on centers and in chucking work, the connection between the work and tool includes a number of joints, both for sliding the tool in relation to the work, and for the rotation of the work. Each of these joints has more or less slackness, and each of the slides and other members are more or less frail in structure. With a mounting of this kind, the cutting edge of the tool does not pass through the metal without swerving and flinching.

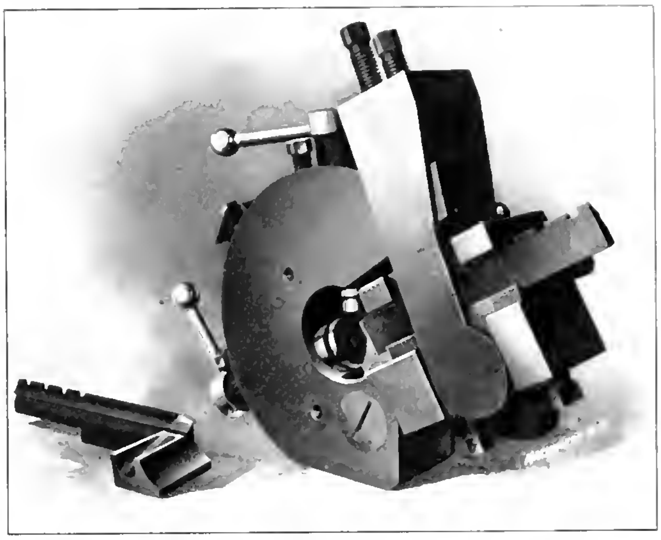

Fig. 3. The No-clearance Turning Tool for the Flat Turret Lathe.

Means for Improving Efficiency.

A machine's efficiency is proportional to its strength to resist its working stresses. There are two ways to increase this efficiency: (*a*) by strengthening the machine, and (*b*) by reducing the stresses for a given result. In the author's previous work the strengthening of the machine has been accomplished by the elimination of unnecessary features, and placing the necessary joints for obtaining the various motions in the least objectionable positions. The next step was to devise a means for minimizing the stresses at the cutting edge, and the object in view is to explain how this result has been obtained. This reduction of stresses may not be important in roughing work in which a flinching of the work or machine may be disregarded so long as the machine continues to crush off the metal, but for the kind of work mentioned above it must be considered of first importance.

Analysis of Conditions.

In the class of work under consideration each piece has several diameters, with shoulders which should be accurately spaced and formed. Nearly all the shoulders required in this class of lathe work are the so-called square shoulders. In engine lathe practice these shoulders are "squared up" by a side tool after the other turning has been done by a round nose or diamond point tool, but in the turret lathe, for bar work, these shoulders are produced by the same tool that takes the stock-removing cut. The tool used in turners for bar work cuts on the same principle as the engine lathe side tool; that is, its rake or top slope is almost wholly side

---

* Abstract of paper by Mr. James Hartness read before the American Society of Mechanical Engineers, December meeting, 1908.

[The lathe tool, the principles of which are here discussed, has been developed by Mr. Hartness of the Jones & Lamson Machine Co., Springfield, Vt., for special application to the flat turret lathe manufactured by this company. It is strictly a special turning tool, and will not be furnished as a part of the regular equipment of this machine.—EDITOR.]

slope, and its cutting edge stands at an angle of 90 degrees to the axis of the work.

In the engine lathe a tool of this character has generally been unsatisfactory for rapid turning, yet in the turret lathe this very tool seems to be universally used for all bar work. The difference in performance seems to be due to the difference in mounting. It works well where there is no chance of vibration, but trouble begins when it is used in a machine like the engine lathe or turret chucking lathe in which the work is supported by one part of the machine and the tool by another, and the true path of the cutting tool through the metal is dependent on the entire structure of the machine, there being nothing to prevent vibration. The no-clearance tool to be described is a side tool without clearance. Its under face bears flatly against the work, thereby preventing lateral vibration.

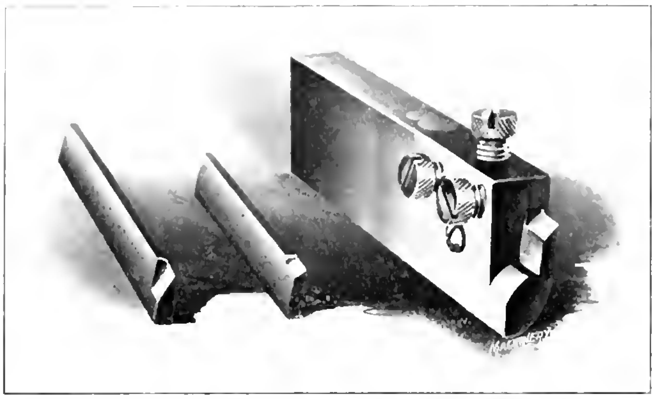

Fig. 4. No-clearance Tool for Standard Engine Lathe Tool-post, showing Three Cutters of Different Angles.

For the purpose of analysis the cutting stress may be divided into three elements; the direct cutting stress, the separating stress, and the tendency to vibrate.

Direct Cutting Stress.

By direct cutting stress is meant that part of the stress that is directly downward in a lathe. With all other conditions unchanged, we should expect to find an acute edge tool offering the least resistance, and that the difference in direct cutting stresses for tools of varying cutting angles would show a marked reduction in favor of the more acute tools. Dr. Nicholson's experiments, already mentioned, showed an increase in cutting stresses and a marked loss in endurance, below 60 degrees, but these tests were on dry cutting without the benefit of a lubricant or cooling solution. Thin edge tools are undoubtedly benefited more by lubricant or cutting medium, than blunt edge tools. Just what cutting angle would be the best under conditions of most efficient cooling medium may not yet be fully known.

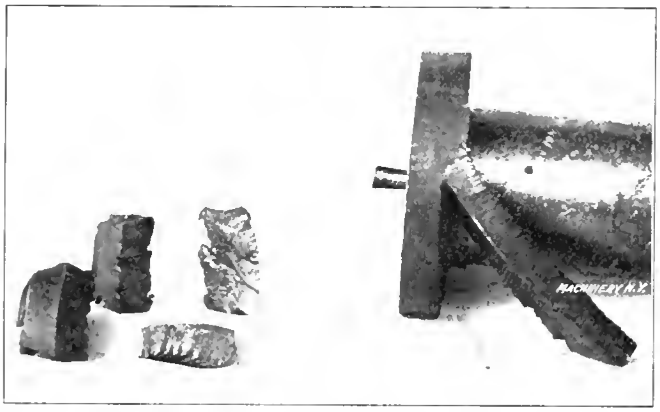

Fig. 5. Sample of Broken Chips and Work with an Unbroken Chip. This View is nearly Full Size. The Exact Dimensions of Sample are 1 3-4 Inch Diameter turned down to about 1 Inch; feed about 7 per Inch; Cutting Angle of Tool about 38 Degrees; Extreme Edge 1-32 Inch Flat. These Chips were broken by a Chip Breaker.

It is obvious that the least direct cutting stress for a given depth and feed should be obtained by a straight edge tool, and one that would take a chip in which there is the least molecular change. Crushing and partially or wholly shearing the chip into chunks which are three or four times the thickness of the feed undoubtedly increase the working stresses and heat.

A flat top slope should have a straight cutting edge. The more the edge is rounded the greater the conflict of the metal crowding onto the edge. The flow of metal on the top slope of the round nose does not move in one direction wholly, but tends to travel towards the center of the curve. The conflict of currents of metal which approach the center from various parts of the curved cutting edge, increases the direct cutting stress. The crushing process of the usual method of turning is due both to the bluntness of the cutting angle and the shape of the edge.

Separating Stress.

By separating stress is meant that stress which, in turning a shaft, forces the tool outward radially. Increasing this stress causes the work and tool to move apart, and results in variation in diameter, also in irregular and generally inaccurate product, particularly when the rough stock runs eccentric or irregular. Although this separating stress may be decreased by giving the tool more back slope, this is only possible in tools taking light depth cuts. A lathe tool, however, which takes a cut like a side tool, shows little or no tendency to separate radially. With the side tool set at an angle of 90 degrees to the travel of the feed, the feeding stress does not tend to force the work and tool apart; in fact, this tool may be set so as to produce a slightly beveled shoulder either side of the 90-degree angle so as either to draw the work and tool together when making an overhanging shoulder or to force the work and tool apart when producing an external bevel.

Vibration Stress.

The quivering stress which is due to the nature of the chip is affected by the cutting angle of the tool. The chunks which make up the parts of a chip are less firmly united in a chip taken by a tool of 70 degrees cutting angle than by a tool of 50 degrees, and, of course, the more firmly united chunks give a more continuous chip with the least vibration

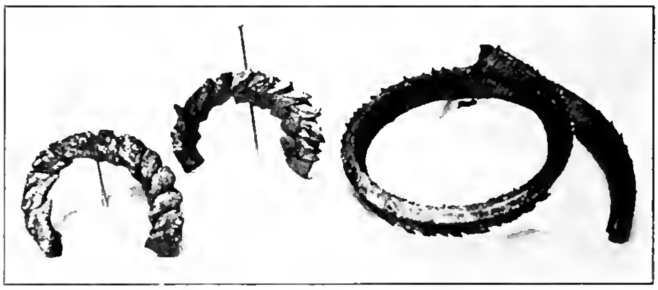

Fig. 6. Chips taken by Diamond Point Tool, 75-degree Top Slope and Slightly Rounded Nose.

Fig. 7. Chip taken by 40-degree No-clearance Tool at same Feed and Depth. Illustrations about Full Size.

In turret lathe practice, especially in bar work, the tool and work are held together by a back rest which follows on the surface produced by the cutter, and in some kinds of turret chucking work the tools for interior work are mounted on boring-bars which take bearing either in the work or in the chuck which holds the work. When tools get this steadying support directly on or in the work, they are freed from the chattering due to the machine mounting, but not free from that due to their own frailty or to the intermittent flow of the chip as it is taken off in chunks.

Relative Destructive Effect of Heat and Lateral Vibration.

Attention should be called to the effect of heat in the destruction of the cutting edge, and no amount of care in the mounting of the work and tools will prevent destruction of the cutting edge of the tool by heat. Heat is undoubtedly most destructive when roughing at high speeds, but the vibration plays a very important, if not the greatest part in edge destruction when finishing at the usual speeds. As the speed is reduced, the vibration gains in relative importance, which should be taken into account in considering the no-clearance tool. With the slower speeds, tools should be used that give the best results at slow speeds.

The failure of the keen edge under normal cutting conditions, and its surprising endurance under some abnormal conditions, seemed to indicate great possibilities open to any scheme that would maintain the best conditions. For instance, the edge of a diamond point may be broken off by an

ordinarily heavy chip, at one time, and at another time a similar tool becomes deeply imbedded into the metal without breakage. Under some conditions a cutting tool will actually sharpen itself in the process of cutting, yet neither of these results is regularly maintained. They suggested, however, the possibility of supplying a means by which they could be maintained in regular work.

Clearance.

Since the birth of the slide rest lathe in which the tool was first guided by mechanism, turning tools have been given clearance and it has been assumed that they would not cut without clearance. Of course, it is well known that the orthodox lathe tool goes out of commission after losing its clearance, but that does not demonstrate that a tool cannot cut without clearance. It only proves that the ordinary tools require clearance as they are now formed and mounted. A tool which has been ground for clearance and set in such a position that its under face is at an angle to the shoulder produced, presents but a small area to the shoulder of work when the clearance of the extreme edge has given way. The area is so small, compared with the stress of the abrading metal passing it, that it rapidly scores and wears into a rough surface standing at a negative clearance angle.

The tool which has been set by chance in an engine lathe, so that a comparatively large area of the under face rides on the wall of metal, does not wear away, because its surface is not subjected to as great abraiding pressure per unit of area. Its area is sufficient to withstand abrasion. It was therefore assumed that increasing the contact of the under face of the tool against the face of the work would make it possible to cut without clearance. The advantage of a no-clearance tool is that its face rides on a good area and supports the under edge against the pressure of the chip, thus relieving the edge from the one-sided pressure which must be borne by a tool having clearance.

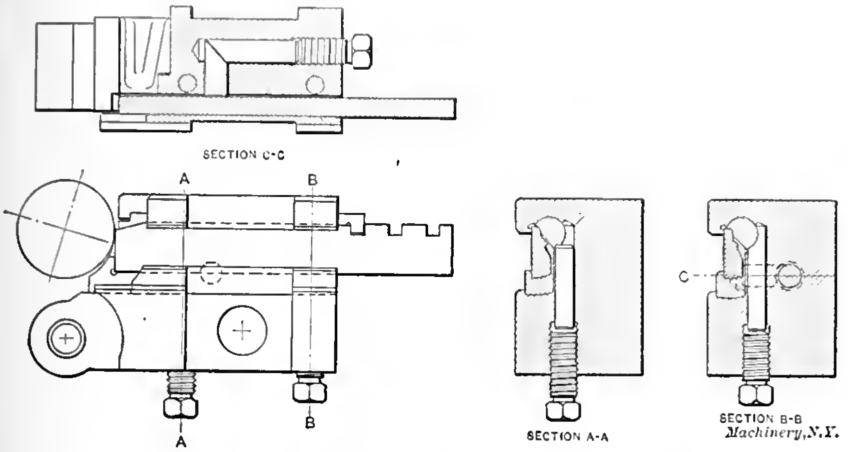

Fig. 8. Holder for No-clearance Tool in the Flat Turret Lathe.

No-clearance Tool.

In order to enable the tool to ride flatly against the wall of metal from which the chip is being removed, it must be mounted so as to allow a comparatively free swiveling action on a center line that is substantially coincident with the cutting edge of the tool. When the tool is so mounted, the pressure of the chip on the top slope tends to throw the so-called clearance face against the shoulder, for the mounting allows the tool to swing around to any angle that may be necessary to fit any work form, from a straight surface in planer work and the nearly straight surface in work of large diameter down to the angle of a helix obtained by the coarse feed on work of relatively small diameter. A tool so mounted either swings automatically to adapt itself to angularity of feed, or may be swung by hand as soon as the cut is started. Its natural tendency holds it snugly against the metal, but the force may be varied from one that equalizes the stress on each side of the cutting edge down to a very slight stress which only holds the tool in no-clearance position. An important feature is that the tool is free to swing around to offset the unequal wear on the "clearance" face.

The swivel mounting of the tool allows the cutter to swing around to take care of not only the feed, but the changing surface of the tool due to wearing action. In the early experiments, cutters were used which were clamped rigidly in a holder, which, in turn, was pivotally mounted on a fixed holder. The cutting edge of the tool was so located as to stand exactly on the center line of the swiveling holder.

In the later experiments the scheme has been simplified by loosely mounting the cutter itself, providing it with a round bottom struck from a center line which is near the cutting corner of the tool. The cutting edge is usually standing at an angle to its center line of swivel, giving the tool a front slope. The scheme of inclining the cutting edge to the line of swivel was adopted for the purpose of using a bar-shaped tool in which its shape could be maintained by grinding, for with this shape grinding back, the end provides for the wearing down of the top edge. This gives the tool a front slope when the swiveling center is kept horizontal. In some cases it may be well to tilt the holder to an angle that brings the cutting edge horizontal. This departure from the ideal center position of the line of swivel is not sufficient to cause any trouble. In fact, the pivotal line need not be exactly parallel to the cutting edge, neither is it necessary to have it very near the center line of swivel. It is probable that, under some conditions, the cutting edge may advantageously be located either above or below or on either side of the cutting edge. The exact location of the cutting edge relative to the center of oscillation partly determines the pressure with which the tool rides against the wall of metal from which the chip is taken.

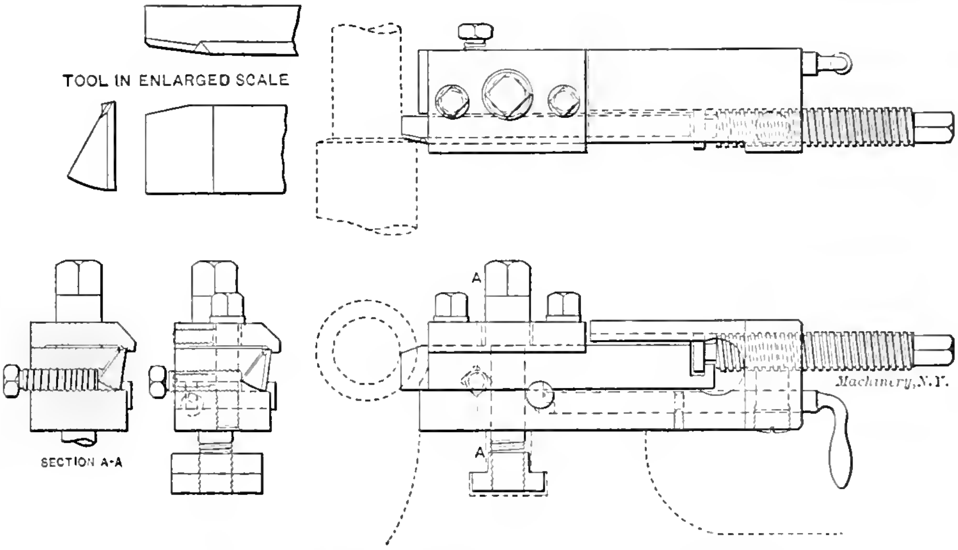

Fig. 9. Holder for No-clearance Tool when used in the Engine Lathe.

The extreme top edge of the tool, in some instances, has been slightly flatted on the more acute angles, the flat measuring from about one-sixty-fourth to one-thirty-second inch, and standing either 90 degrees from the so-called clearance face or sloping in either direction. Very good results were obtained by giving it a negative side slope of a maximum of from 10 to 15 degrees from the horizontal. This top flat seems to make a good resting place for the false edge, and it may be that its successful operation is dependent on the false edge.

One interesting phase of these experiments has been the

comparative willingness on the part of the tool to relieve the carriage of the duty of feeding. This first became apparent when the carriage continued to advance after the feed had been "thrown out." This self-feeding feature, of course, cannot apply to the action of planers, boring mills, or work of large diameter. It is only mentioned here to indicate the absence of resistance to the feeding motion under some conditions. The ultimate outcome of the use of acute angle tools may lead to allowing each tool taking a heavy cut on small diameters to determine its own feed. In the turret lathe this would be a distinct advantage.

Chip Lifter and Chip Control.

The chip produced by the acute angle tools possesses great lateral strength. The continuous chip is preferred by any operator who has had experience with hot chips which are thrown off by the tools of blunter angles, but while this particular feature enables him to closely observe the action of the tool without risk, the continuous chip in itself becomes troublesome, if allowed to run too long without breaking. In some of the first experiments with this tool, chips having a depth of about three-eighths of an inch, and produced by a feed of six revolutions of the work to the inch, were found exceedingly troublesome, especially when allowed to run out to lengths of five to fifteen feet.

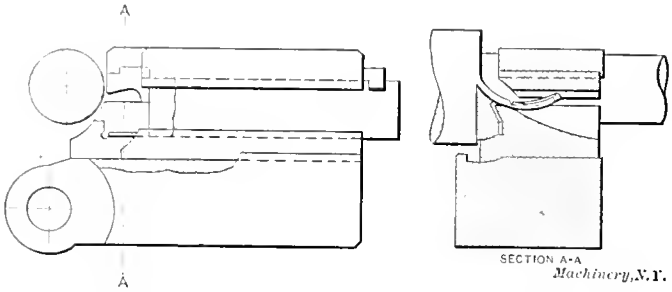

Fig. 10. Chip Breaker used in the Flat Turret Lathe.

The lateral stiffness of the chip of the more acute tool made it possible to increase the tearing open or splitting effect. In order to increase the tearing action of the chip it is necessary to allow the chip, after it has passed from the edge of the tool, to pass over a lifter in the form of a wedge, either formed integral with the tool or placed in the path of the chip near the tool, having an angle that not only assists in tearing the metal ahead of the tool, but will also relieve the slope of the tool near the edge from an important part of the work. Although this chip lifting effect may be produced by a top slope having a curved surface, it has seemed best for the convenience of grinding the tool on an ordinary wheel to keep the top slope of the cutter a flat surface, and introduce this chip lifter as a separate member, either as a part of the toolholder or in conjunction with the chip breaker described below.

Although it is a satisfaction to be able to stand near the cutting tool, and to know that the chips will not shoot out in hot chunks at all angles from the tool point, there remains the fact that a continuous chip is troublesome. Even with the blunt tools, the curling chips which are sometimes used to illustrate ideal working conditions of a machine, require constant attention of the operator, and either a very large receptacle which doubles the floor space required for the machine, or the almost constant attendance of an extra man for removing the chips from the room. The use of the more acute angles increases the chip trouble, and may in some instances make it advisable to retain the blunt cutting angles, or at least, tools which produce tolerable chips.

For turning bar work in the turret lathe it has seemed best to adopt a chip breaker which produces a fracture by placing an obstruction in the path of the chip at such an angle that the chip, shortly after it has left the tool, is bent beyond its breaking point either by lifting or depressing, or both. It is preferred to use a chip breaker which depends on depressing the chip after it passes over the chip-lifting incline. A breaker of this kind breaks the chip in lengths varying from one-half to three inches.

Conclusions.

The conclusions of the investigations may be summarized as follows: The no-clearance cutter relieves the edge from the one-sided pressure; it prolongs the life of the cutter by allowing abrasion on its face without producing negative clearance; it prevents lateral quivering; it converts the lip angle into cutting angle which for a tool of given form constitutes a gain of from 5 to 10 degrees in cutting angle; it has extended the working range of the side tool which gives the minimum separating stress; it has made possible the use of acute angle tools which reduce the cutting stress, thereby increasing the output of machines which have been limited by lack of pulling power; the reduction of the cutting and separating stresses has increased the accuracy on nearly all lathe work; this reduction also increases the output which has been limited mostly by the frailness or the slenderness of the work.

* * *

CUTTING WORMS AND HOBBING WORM-WHEEL SEGMENTS.

The two illustrations shown herewith explain the practice of the Garvin Machine Co. in making worms and worm-gear segments, such as are used for automobile steering gears. The cutting of the worm, as shown in Fig. 1, is done entirely by standard methods, the attachment shown in place in the machine being the regular spiral gear and worm milling attachment made by the builders. The use of an attachment of this kind permits the milling of spirals of very short lead, such as required for worms. It would not be possible to mill them with a cutter on the regular cutter arbor, as the table of the universal machine could not be swiveled to a great enough angle to permit this.

The hobbing of the worm segment requires special apparatus, the construction of which is plainly indicated in Fig. 2. The segment is mounted on an arbor with a worm-wheel of the same pitch and number of teeth as would be contained in the segment to be cut. On the cutter spindle is mounted a taper hob and a spur gear, the latter meshing with a corresponding gear of the same size, keyed to a worm supported in supplementary bearings fastened to the overhanging arm at the outer end, and to the machine columns at the inner end. This worm meshes with the worm-wheel on the arbor, on which is the work. This work arbor, with the worm-wheel and the work, is free to revolve when driven by the worm just described, being loosely mounted on the centers.

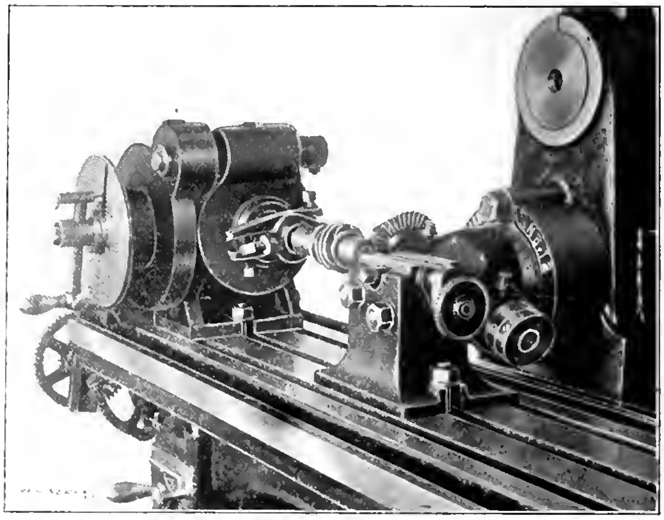

Fig. 1. Milling Worms with the Universal Attachment.

The principle of the hobbing operation is identical with that described in connection with Fig. 128, of the article entitled "Gear Cutting Machinery" in the June, 1908, issue of MACHINERY. The cutting operation starts with the saddle moved in toward the column until the work is beyond the hob at the small end, the knee being raised to the proper height so that the large or finished diameter of the hob will cut teeth of the desired depth. At this adjustment the driving worm and worm-wheel should be properly in mesh with each other. The saddle is fed outward, so that, with the ma-

chine in operation, the work is fed to successively larger diameters of the hob, which thus cuts deeper and deeper until finally the work passes out through the large end, as shown in the illustration. This finishes it to the proper depth. The work and the hob do not get out of step with each other, as the cross motion rolls the master worm-wheel on the master worm in just the proportion that the work should roll on the hob. Since the driving members do not get out of step with each other, the driven members do not.

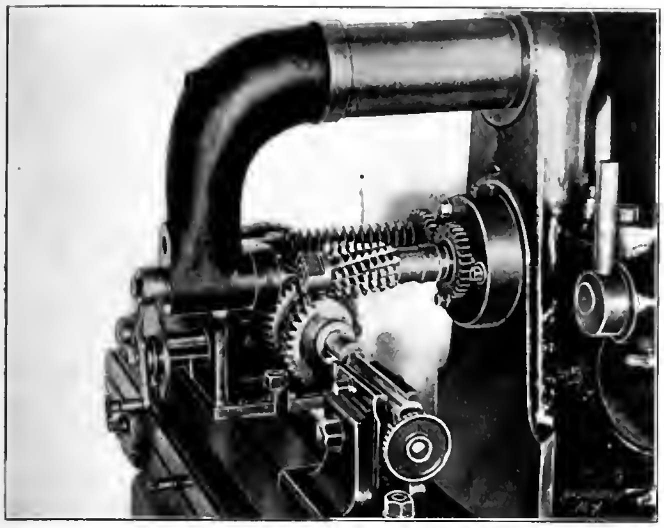

Fig. 2. A Positive Hobbing Attachment, employing a Taper Hob.

Of course the reason for making the worm-wheel in this way, aside from the question of time involved, is that the ordinary method of gashing and hobbing on a freely running arbor could not be employed in this segment worm-wheel. The apparatus would be fully as useful, however, with regular worm-wheels, doing the work in one operation instead of two.

MACHINE SHOP PRACTICE.*

MACHINING INTERNAL COMBUSTION ENGINE DOUBLE-CYLINDER CASTING.

When castings, such as the one shown on the Shop Operation Sheet accompanying this issue, are to be machined, fixtures to facilitate setting the work are essential to economical production. If only one or two castings were needed, the extra time required for setting them for the different machining operations, without fixtures, would not be great enough to justify the expense of such equipment. We shall assume, however, that in this case a sufficient number of castings are to be machined to warrant such expenditure, and in the following a description of the fixture for holding these castings will be given, and the way the various parts to be machined are set in proper relation with the tools in the turret, explained.

It will be understood, of course, that the layout and construction of a fixture for holding work of the kind illustrated, will depend entirely upon the shape of the casting and location of the surfaces to be machined. The dot-and-dash lines in Fig. 2 represent a plan view of the casting shown on the Shop Operation Sheet. As will be seen, there are, in this particular case, four valve ports and the openings *V* and *X* to be machined on one end of the cylinder, and the two cylinders to be bored from the opposite end. If the fixture which is to hold the casting is to be efficient, it must be so constructed that the four valve ports and the openings *V* and *X* can be brought in line with the axis of the lathe spindle without resetting the casting, and also so that the cylinders may be bored with a minimum amount of trouble and the distance between their centers kept uniform. The fixture, which is shown in Fig. 2, consists of a base-plate *A*, and a cylindrical plate *B* having a boss which fits into a recess in *A*, upon which the plate revolves to change the position of the work. Obviously, if the casting is centered upon plate *B*, the four port openings may be made to coincide with the axis of the spindle by revolving *B*, if the base-plate *A* is properly located upon the face-plate of the turret lathe, and means provided for setting plate *B* so that the centers of the port openings coincide with the axis of the spindle.

In laying out the base-plate *A*, the recess for the boss on plate *B*, and a hole for plug *C* which fits the hole in the spindle, are located upon a center line *a—b*, the distance between them being equal to radius *r*. After the boss on *B* has been fitted into the recess in *A*, the four dowel pin holes *k*, *l*, *n*, *p*, in plate *B*, should be located. The exact position of the centers of the four valve port holes are first laid out, and center lines drawn through them. Upon these lines and at points equi-distant from the center *J*, the four dowel-pin holes are drilled, and a hole to coincide with them is drilled in the base-plate *A* on center line *a—b*, at a point *k*. These holes are reamed with a taper reamer and a dowel pin fitted to them. It will be apparent that if the casting is centered on plate *B* so that the centers of the valve openings will come on the center lines *a—b* and *c—d*, each valve opening can be centered by revolving *B* and inserting a dowel pin in one of the four locating holes at a point *k*. For example if the valve seat *S* is to be machined, plate *B* would be revolved until dowel hole *l* coincided with the hole in base-plate *A* at *k*. The seat *S* would then be directly over locating pin *C* which fits into the hole in the lathe spindle.

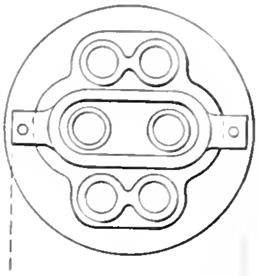

Fig. 1. Special Form of Clamp for the Fixture.

In order that the openings *V* and *X* be machined without resetting the casting, a second hole for the plug *C* is drilled and tapped in the base-plate *A* at a point corresponding with the center of *V*. When the four valve seats have been machined, straps similar to *Q* (see Shop Operation Sheet) are placed across the seats and *Q* removed, so that the holes *V* and *X* can be machined. The base-plate *A* is then removed from the face-plate, and the locating pin *C* shifted to the hole under opening *V*. When the base-plate *A* is again clamped to the face-plate, obviously, opening *V* will be centered. To center *X* it is only necessary to remove the dowel pin at *k* and turn plate *B* one-half a revolution. The removal of clamp *Q* and the substitution of others for this last machining operation, can be obviated by the use of the clamp illustrated in Fig. 1, which will not interfere with the movements of the tools and which will grip the work more firmly.

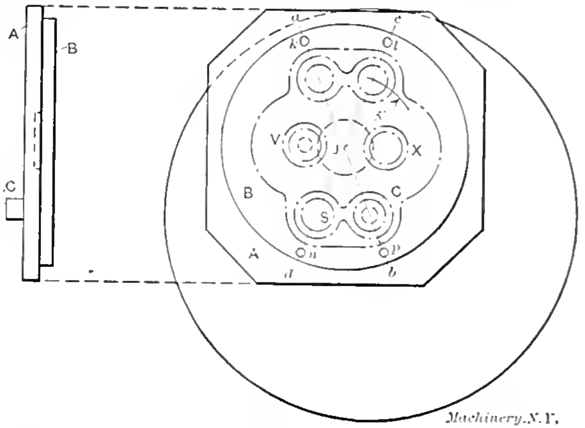

Fig. 2. Diagram of Fixture for Holding Double-cylinder Casting.

The next operation consists in boring the two cylinders. As the holes *V* and *X* are to be concentric with their respective cylinders, means must be provided for setting these holes true when the casting is inverted. As the work has remained in the same position with relation to plate *B*, this may be accomplished by locating two plugs, which fit the valve openings, at points on the center line *a—b* corresponding with the centers of the openings. When the position of the casting on plate *B* is then reversed, one cylinder will be in a position to bore and the other may be centered by revolving *B* one-half a revolution, using the dowel at a point *k* as before.

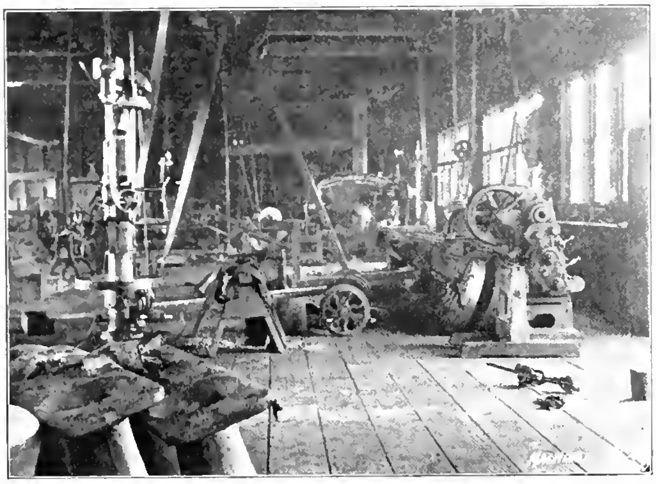
SHOP PHOTOGRAPHY.[*]

H COLE ESTEP [†]

It is the purpose of this article to give a few practical, pertinent hints on the taking of shop and engine-room photographs. If pictures are taken of ingenious hurry-up repairs, of the original appliances installed in the plant, or of new methods of setting up or handling work in the shop, supplemented by descriptive matter and drawings where necessary, it will be surprising to find how soon a complete, original, and valuable set of notes and data, which will be of constant service, can be collected. Furthermore, these data can be made useful to one's fellow craftsmen by publication in technical journals. Scale drawings and descriptive data are often essential, but usually, to get a clear understanding of an apparatus as it actually appears when in use, a photograph is indispensable.

The art of taking good photographs is not difficult, nor is expensive apparatus required. The writer has taken hundreds of pictures, which have been published in a score of technical magazines, all of which were made with a $20 folding hand camera. The prime requisites for a shop camera are flexibility and compactness. Pictures must be taken in all conditions of light and weather, indoors and out, for which an adaptable camera is necessary; odd angles, mazes of piping and cramped quarters require a compact construction. The lens for this work should have good definition (sharpness) and depth, should be reasonably, but need not be excessively, fast. The shutter should have a wide range of control and should work without jar. The bellows should be of such length as to permit the taking of small objects full size. The back of the camera, carrying the plate or film holder, should be reversible, so that it is not necessary to unscrew the camera from the tripod and turn it over, should a change from a horizontal to a vertical view be advisable. Ground glass is necessary for focusing, and, as will be seen later, a good, accurate view finder is often useful. Contrary to the experience of some, I have found the 4 x 5-inch size to be the most suitable; enlargements can be made, if necessary. This size combines features of economy of operation with a light and compact apparatus. I therefore use a 4 x 5-inch folding plate camera, the box, when closed, measuring 6 x 6 x 3 inches. This apparatus has a bellows, which can be extended to 13 inches, a good double rectilinear lens, giving sharp pictures with a wide open diaphragm, an automatic shutter working from 1/100 to 1 second, a reversible back, and ground glass focusing screen. The camera complete with case and one plate-holder cost $20. I discarded a roll film kodak, because it would not permit focusing subjects en ground glass; this focusing must always be done when possible, if uniformly accurate results are desired.



Photograph taken on a Film, thus Obviating the Halations Common to Interiors made on Plates.

At an expense of $1.50 I produced a "film-pack adapter," enabling me to use daylight-loading film-packs, thus combining all the advantages of the plate and roll film cameras, with none of the drawbacks of either. I have used film-packs for two seasons, and find them admirably suited to shop picture making. Using films, I have often taken pictures directly against the strong light from adjacent windows, without the slightest blur, or any of the evil effects of halation, inevitable with plates. An example of this is shown in the accompanying half-tone, where a good picture is presented in spite of the poor light of the shop.

After selecting the proper apparatus, the next thing, in order to secure good results, is the proper lighting of the subject. The over-zealous amateur often reasons, to his subsequent undoing, that since light makes the picture, one cannot have too much of it, forgetting that it is the contrast of light and shadow and the shading of light into shadow that really makes a good photograph. Unfortunately, the matter of lighting in work of this kind is usually absolutely beyond the control of the operator. About all he can do is to select the point of view best suited to the subject and take the light as it comes. Reflectors and screens are used by some, and although they are of service, my experience has been that they are usually more bother than good. Wherever possible, the light should be from the side, striking the floor at an angle of 45 degrees from the horizontal. But these are "laboratory" conditions with which we are not concerned. Machinery, lathes, etc., that are not too large, can be set in relief by a white background. In taking pictures in boiler rooms, I have often made pipes, practically invisible at first, stand out by an application of whitewash or whitelead.

Much of the evil in shop photographs, due to the unavoidably poor lighting, can be ameliorated by proper exposure. As in all kinds of picture taking, accurate exposure is the key to success in shop photographs. The question of exposure brings with it the one of diaphragm or stops. The lens of the camera is supplied with an iris diaphragm, by means of which the hole through which the light enters can be varied in diameter from about 1/16 inch to the full diameter of the lens. Except where extreme sharpness is required, I have found that a U. S. No. 16 stop (diameter ¼ inch) is the best lens opening for all around work. The question of proper exposure is one of experience entirely, by the aid of which one feels what is right without going through any definite reasoning process. However, as a guide, I have established what I call "a standard exposure under standard conditions, using a No. 16 stop." It is defined as follows: With clear weather outside, the standard exposure, using films, in the interior of the *average* shop or engine room is 35 to 40 seconds. In hazy weather, double this time; in dull, cloudy weather, quadruple it.

Often one cannot focus on the ground glass and must depend upon the scale of distances on his camera-bed for focusing, and upon his view-finder for properly placing the subject. A very little practice will enable one to judge distances accurately and focus with the scale. The view-finder should be tested by focusing some object on the ground glass and observing its position in the finder. It is rare that an object in the center of the plate will also appear in the center of the finder. The error must be determined and allowed for when using the finder alone. Use a light, stiff tripod and do not straddle one leg while focusing. A gossamer focusing cloth is best. At a small extra expense, a supplementary wide-angle lens can be obtained, which will be found very useful in tight corners.

Unless one is experienced, it is best to have the developing done by an expert. To obtain the best results in this class of work, the negatives should be printed on glossy silver-chloride paper, toned to a deep brown, almost verging on a blue, and giving a high polish in a burnisher or on a ferrotype plate.

LARGE COLLET MADE ON AUTOMATIC SCREW MACHINE.

Fig. 1. Collet, 4 5-8 Inches in Diameter, finished from 40-point Carbon Steel in 70 Minutes on an Automatic Screw Machine.

In the November issue of MACHINERY some interesting work produced on a large sized Cleveland automatic screw machine, manufactured by the Cleveland Automatic Machine Co., Cleveland, O., was illustrated. This work consisted of a cast iron piston provided with a stem, practically finished all over, and a drill chuck with taper shank. The size of the parts made, and the rapidity with which the operations were performed, gave special interest to this article and illustrated in a clear manner how the automatic screw machine has during the last few years proved itself capable of performing a great many operations, which but a short time ago were considered as belonging to the province of the engine lathe. In the half-tone accompanying the present article is illustrated a piece of work the dimensions of which are larger than those of the parts shown in the previous issue. The work illustrated is a collet used in the Cleveland automatic screw machine, made from 40 points carbon steel; it is made from the bar in one hour and ten minutes. The full significance of this will be better appreciated by referring to the dimensions of the collet as shown in the line-engraving, Fig. 5. It will be seen that the largest diameter of the collet is 4⅝ inches and that the length is 7 1/16 inches. The size of the bar, as indicated in Fig. 2, is the same as the largest diameter of the collet when finished.

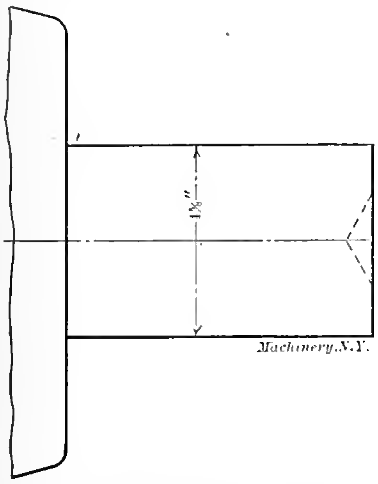

Fig. 2. Bar fed forward and Centered.

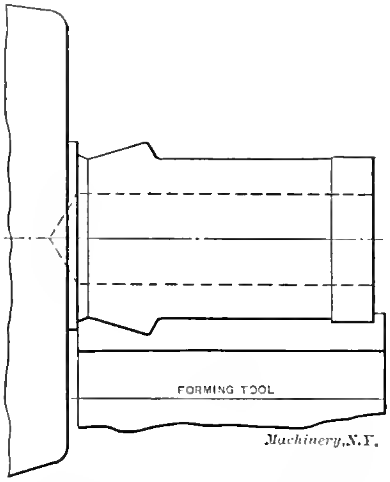

Fig. 3. Hole drilled and Outside formed.

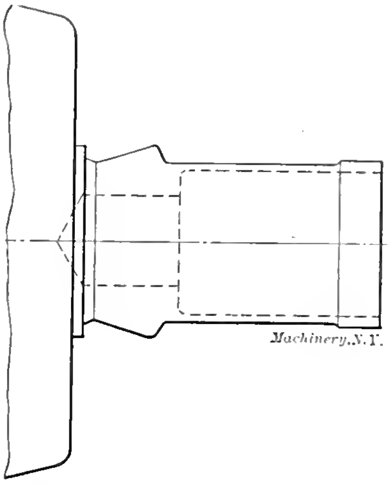

Fig. 4. Hole in Collet counterbored.

The operations performed on the bar are shown in the four line-engravings, Figs. 2 to 5. In Fig. 2 the bar is shown fed forward to the proper position and centered. In the second operation the small hole through the bar is drilled as shown in Fig. 3 and the outside of the collet is formed by a forming tool as indicated, the whole length of the cylindrical surface of the collet being formed at once. The diameter of the hole drilled is 2¼ inches. In the third operation this hole is counterbored to a diameter of 3⅝ inches and to a depth of 5 inches, as shown in Fig. 4. Finally, in the fourth and last operation, this counterbored hole is reamed to the exact size and the collet is cut off from the bar.

The weight of the stock from which this collet is made is 34½ pounds before machining, and the weight of the collet when finished and cut off is 8½ pounds. It will thus be seen that the stock removed in seventy minutes is 26 pounds and that the metal has been removed at the rate of nearly 0.4 pound per minute. Taking into consideration the expense of producing this piece of work, it will be noted that inasmuch as the operating expense of the automatic screw machine employed is only a mill a minute, the actual labor cost for this collet chuck blank is only seven cents. The same piece could be produced from machine steel of about 10 or 15 points carbon in about fifty minutes, or at an actual labor cost of about five cents, which is a remarkable performance if compared with the time required to perform this work either in a lathe or in a hand-operated turret machine. It is not only the size of the work in this case which is of interest to the mechanic, but also the accuracy with which it is performed. Thus the front end of the collet is provided with the correct taper required, when it leaves the screw machine, and the outside diameters are of correct dimensions. The forming operation employing but one single forming tool for a surface over seven inches long and of a shape requiring considerable more metal to be removed at some places than at others, is also very remarkable. In the past it has usually been considered impossible, or at least impracticable, to attempt to take forming cuts of such width; and the present example gives one an entirely different idea of the possibilities of forming operations with forming tools of broad face, than has been generally entertained by mechanics.

The size of the machine in which the work illustrated was performed is, of course, of large dimensions, it being known as a 6-inch automatic, and handling bars weighing from one thousand to twelve hundred pounds. There are, doubtless, many mechanics working in shops where small and medium-sized work is being done, who will be surprised to learn that such large automatic screw machines are being built, which are capable of producing work of the size here illustrated.

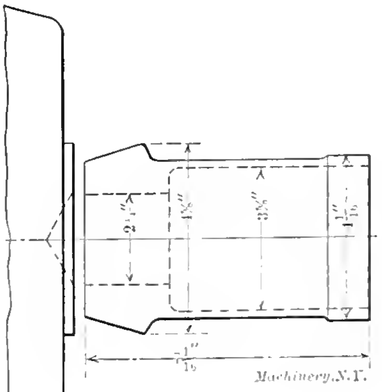

Fig. 5. Collet cut off, after Counterbore is Reamed

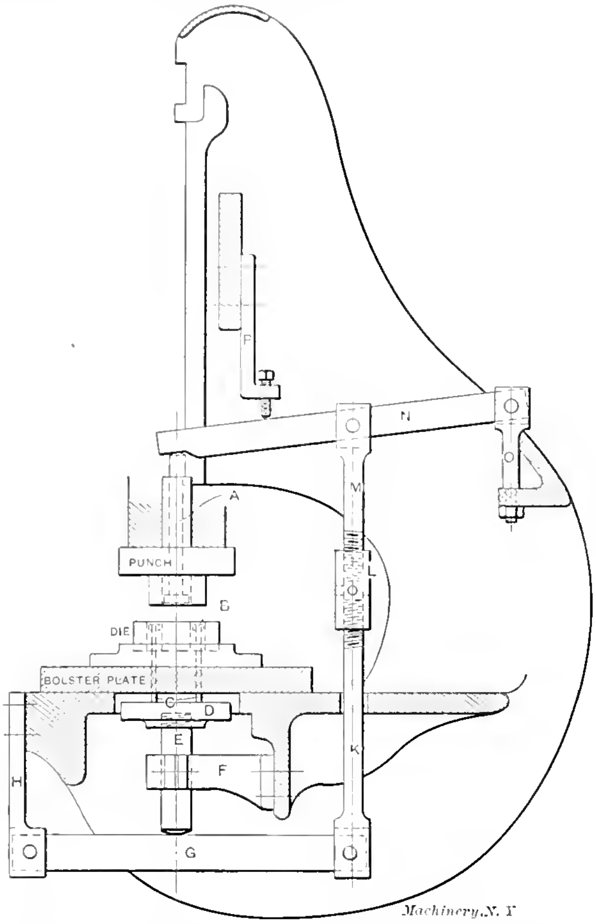
LETTERS UPON PRACTICAL SUBJECTS.

Articles contributed to MACHINERY with the expectation of payment must be submitted exclusively.

STRIPPER ATTACHMENT FOR PUNCH PRESS.

It happens frequently in a great many shops that the punch presses do not give half the results they are intended to give; for example, the inclinable presses are not used inclined, and the tools put on them are provided with the "spring and rubber" type of stripper, with all the annoyances belonging to this type, *viz.*, only one-half of the stripper working, the springs breaking, the dies split by the rubber, etc. In a shop within the writer's experience, where these conditions prevailed, it was finally decided to design a stripping arrangement that would work right, and the device shown in the line engraving was installed. The illustration shows a section through the inclinable part of the press and indicates the position of the ribs. The tool shown is of the washer type, *i. e.*, the punch is a ring, cutting both on the outside and inside. Inside of the punch is fitted a stripper plunger *A*. This plunger is longer than the punch, so that its end extends beyond the shank of this tool.



Machinery,N.Y.

View showing the Way in which the Stripper is attached to a Press.

The die has a circular stripper *B* to which are attached rods *C* descending under the bolster plate. The ends of these rods bear on a circular plate *D* supported by a shank *E*. This shank moves freely through the bracket *F* bolted to the press frame. The lower end of shank *E* rests on a lever *G* held in a support *H* fixed in the front of the table of the press. At the other end, this lever is attached by rods *K* and *M* to the lever *N* which bears on one end on the top of the stripper plunger *A* and is pivoted at the other in a support *O* fixed on a cross rib of the machine. The combined length of rods *K* and *M* is regulated by the turnbuckle *L*.

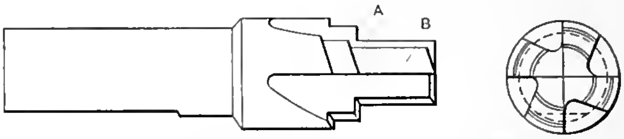
This attachment works as follows: Let us suppose the press ram is in the lower position, the tool cutting the blank. As the whole stripping device is supported from plunger *A*, all parts are in the lowest position. When the ram starts upward the weight of all the moving parts of the stripper is supported by the blank in the punch, this being generally enough to strip the punching. The plunger *A* is prevented from coming too low down by a collar, not shown. Going higher up, the press ram carries along, through the levers, the plate *D*, thereby stripping the lower blank. If the upper blank did not give way at first, it is stripped when the lever *N* encounters the stop *P*, the lower punching being then already stripped.

In making such an arrangement, one should not be afraid of putting too much strength into it. We had Bliss No. 21 presses, that is, presses with about 8 inches opening and a crank-shaft 3 inches in diameter, and we used 3 × ¾-inch machine steel for lever *N*, 4 × ¾-inch for lever *G*, the rods *K* and *M* being 1 inch. All the small pins were ¾ inch, and the guide *E* 1½ inch in diameter.

New York. E. FULBER.

RELIEVING SPECIAL REAMERS.

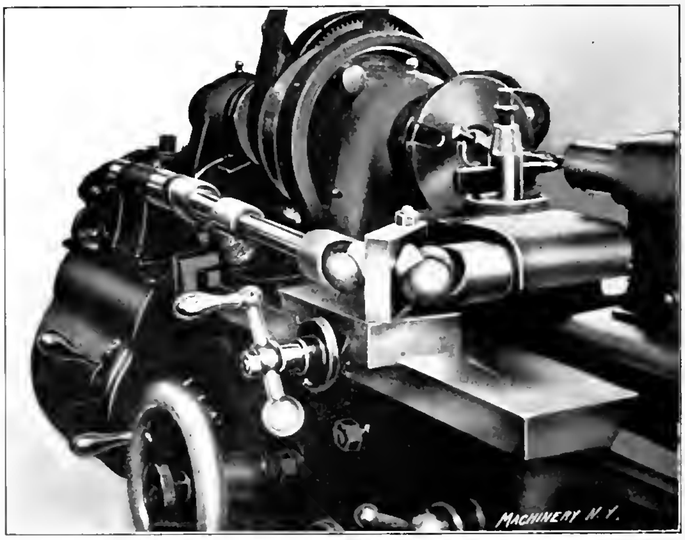
In making many forms of special drills and reamers, used in valve work or for other irregular forms, the relieving attachments usually furnished with the Pratt & Whitney or Hendey-Norton lathes, will not cut all angles of relief. This necessitates hand work where it is least desirable, as inaccuracy will cause chattering or rough and oversized holes. For the class of finishing reamers shown in Fig. 1, relief at *B* is easily cut with the standard relieving attachments, but relief at points designated by *A* is not so easily obtained, especially if it is desired to undercut the corner slightly.



Machinery,N.Y.

Fig. 1. Class of Reamers to which the Relieving Attachment is adapted.

Not long ago, in a shop where thousands of special reamer and drill forms are turned out each year, I saw an attachment made to use in conjunction with the regular relieving mechanism, that enabled the tool-maker to cut relief at any desired angle, with as much ease and certainty of accurate results as in relieving plain work in the regular way. This attachment is shown applied to a Hendey-Norton lathe, in Fig. 2. It consists, primarily, of an additional universal joint mounted on a sliding base or carriage of its own. This double joint taking the place of the regular single joint, allows the compound rest or tool carrriage to be operated at any angle within an arc of 90 degrees, or even more if needed. The usefulness of this attachment will be apparent, at once, to anyone having use for a relieving mechanism. It was designed by a local tool-maker, and all the parts made by him, except the universal ball joints which were made by the



MACHINERY N.Y.

Fig. 2. The Relieving Attachment in Place on a Lathe.

Hendey Machine Co. The device has been in use about two years, and has given satisfaction on all classes of work.

Referring to Figs. 2 and 3, the base of the device *A* is made a nice sliding fit in the cross-slide ways, and is left free to move out or in with the tool-post mechanism. The upright part *B*, which carries the two universal ball joints, is clamped at any desired angle by means of the bolt *E* which engages a nut sliding in the slot *C*. As the motion of the cam shaft and universal joints is oscillating, the bearing in the upright part *B* is simply a bored hole with a well-fitted pin inserted in it to hold the two ball joints together. The rod *F* is the regular cam shaft connecting with the cam and gearing at the left of the lathe, while part *D* connects with the tool-post mechanism.

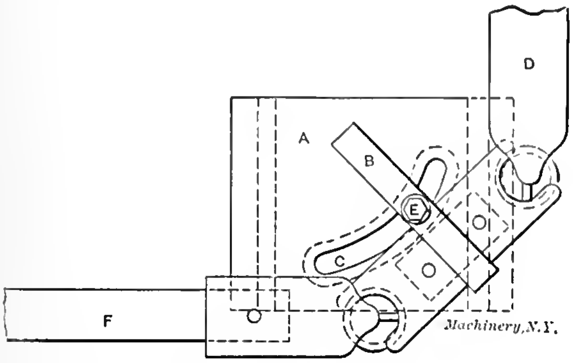


Fig. 3. Plan of the Attachment showing its Construction.

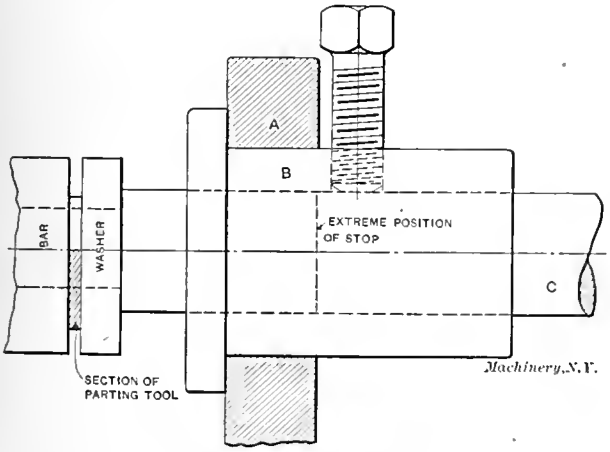
The beauty of the device lies in its simplicity and the ease with which it is placed on the lathe and set at the desired angle. It is also useful for relieving many forms of special and irregular, formed milling cutters, and it is the only device that I know of that enables one to relieve the cutting edges on the *inside* of the hollow mills or "outside reamers," that are so convenient for sizing various parts used in brass valve work, but which are not usually used on account of the difficulty of obtaining accurate inside relief. Everyone knows that relief is absolutely necessary for tools of all kinds, used for brass cutting, especially the brass usually used in a manufacturing plant. Ethan Viall.

Decatur, Ill.

STOP FOR JONES & LAMSON TURRET LATHE.

The accompanying engraving shows a stop for work up to, say, six inches long, to be used in the Jones & Lamson turret lathe, in place of the regular swinging stop. When the latter is used, it is necessary to run the turret slide of the machine back against a stop fixed at a predetermined point on the bed. This consumes a certain amount of time. When turning up bushings, washers, etc., which are cut off from the bar, a stop such as illustrated will be found advantageous on account of its convenience. The sectioned part *A* is that part of the regular cross-slide through which the bar ordinarily passes when cut off, and which is provided with a hole for the bar. In this hole the bushing *B* is inserted, which, in turn, holds the stop rod *C*. This stop rod can be pulled back inside of the bushing, as indicated by the dotted line in the engraving, leaving only a sufficient amount to the binding screw to bind against. When the work is comparatively short it can be passed up against this stop, and cut off to proper dimensions, without making use of the regular swinging stop provided. It is clear that the longest length of stock that can be gaged in this manner is determined by the location of the cutting-off tool in relation to the location marked as the extreme position of the stop in the engraving. Frank L. Immler.



New Form of Stock Stop for Jones & Lamson Turret Lathe.

Pilot Knob, Mo.

MACHINING PLANE SURFACES TRUE WITH BORED HOLES.

When small castings, etc., are to be bored in a lathe, so that the hole will be true with another surface, a very quick and accurate method of doing this is as follows: Bolt the piece to the face-plate in such a manner that the hole can be bored first; then take the face-plate off the lathe without disturbing the setting, and clamp it to a milling machine or planer table, and machine the surface, using the edge of plate to measure for center distance. Recently I had two castings (see Fig. 1) to bore and finish on the bottom. The center distance *A* had to be about right, and the holes in line with the bottom. I proceeded by clamping both castings on the face-plate, as shown in Fig. 2, and boring and threading the holes, after which I took the plate off the lathe, and clamped it to the milling machine table. By measuring the diameter of the face-plate and subtracting the center distance *A* from the radius I obtained the right distance to feed in after touching the edge of the plate with the end mill. This was a very quick and accurate way of doing the job. It will be understood that the outside diameter and back edge of the face-plate must be true when on the lathe spindle.

Providence, R. I. R. C. Scholz.

SOME USES FOR WROUGHT IRON PIPE.

Wrought iron pipe may be used to such good advantage in many emergencies that it is only necessary to show a few examples to prove how widely useful its application may be. In cutting round holes in brickwork, masonry, or concrete, it has become quite common practice to discard the old star chisel, and use instead the common form of the so-called "brick drill," which is nothing more or less than a piece of pipe with teeth filed across one end similar to saw teeth. Repeated case-hardening in prussiate of potash gives sufficient hardness to penetrate even the most stubborn concrete walls. To provide slight clearance for the body of the drill as it enters into a deep hole, the teeth should be mushroomed out slightly with a round taper plug. To avoid splitting the pipe by the repeated blows of the hammer, a malleable iron cap should be screwed tightly to the end, thus furnishing a good head for striking blows. Chips do not retard the cutting action of this form of drill, because they crowd down into the hollow core, and are removed when the drill is withdrawn from the hole.

An extension for a 5/16-inch twist drill can easily be made of a piece of ¼-inch pipe of suitable length, by tapping out the hole in one end with a standard 5/16-inch tap and running a die over the shank of the drill for a distance of about ¾ inch. When pipe and drill are thus screwed together, the drilling operation has the tendency of making it hold tighter in the extension, but if the drill should hap-

pen to break before the seam in the pipe splits open it is an easy matter to replace the broken shank with a new drill. We hear so much about positive-drive drill chucks, double-tang drills, oval sockets, etc., that I wonder why we do not drive all drills by means of a standard thread on the shank the same as a lathe chuck. If the only objection is the added cost of the thread, it seems as though we might have quite an interesting discussion on all the merits and demerits of the various positive-drill drives. On some of the larger sizes of drills the standard pipe may not be strong enough to stand the pressure of driving the drill after being tapped out, the end may then be covered with a reducing coupling and then tapped out, or better still, extra strong or double extra strong pipe may be used if it is on hand.

When cutting off heavy stock in the circular cutting-off saw or in the hack-saw, it is advisable to support both the overhanging ends. A cheap and serviceable stand having no loose parts and able to stand hard usage may be made as follows: A standard cast iron flange 8 inches in diameter, tapped for $\frac{3}{4}$-inch pipe, is used as the base. An upright piece of the right length is screwed into the base, and to the upper end is fastened the support upon which the bar rests. This support consists of a tee having two elbows screwed up close into the ends by means of close nipples. When all is tightly screwed together, the top of the tee should be the same height from the floor as the bed of the saw. Two or more of these stands at each saw do away entirely with blocking up, prevent heavy bars from crashing into the floor, and enable one man to cut with safety any bar he is able to lift.

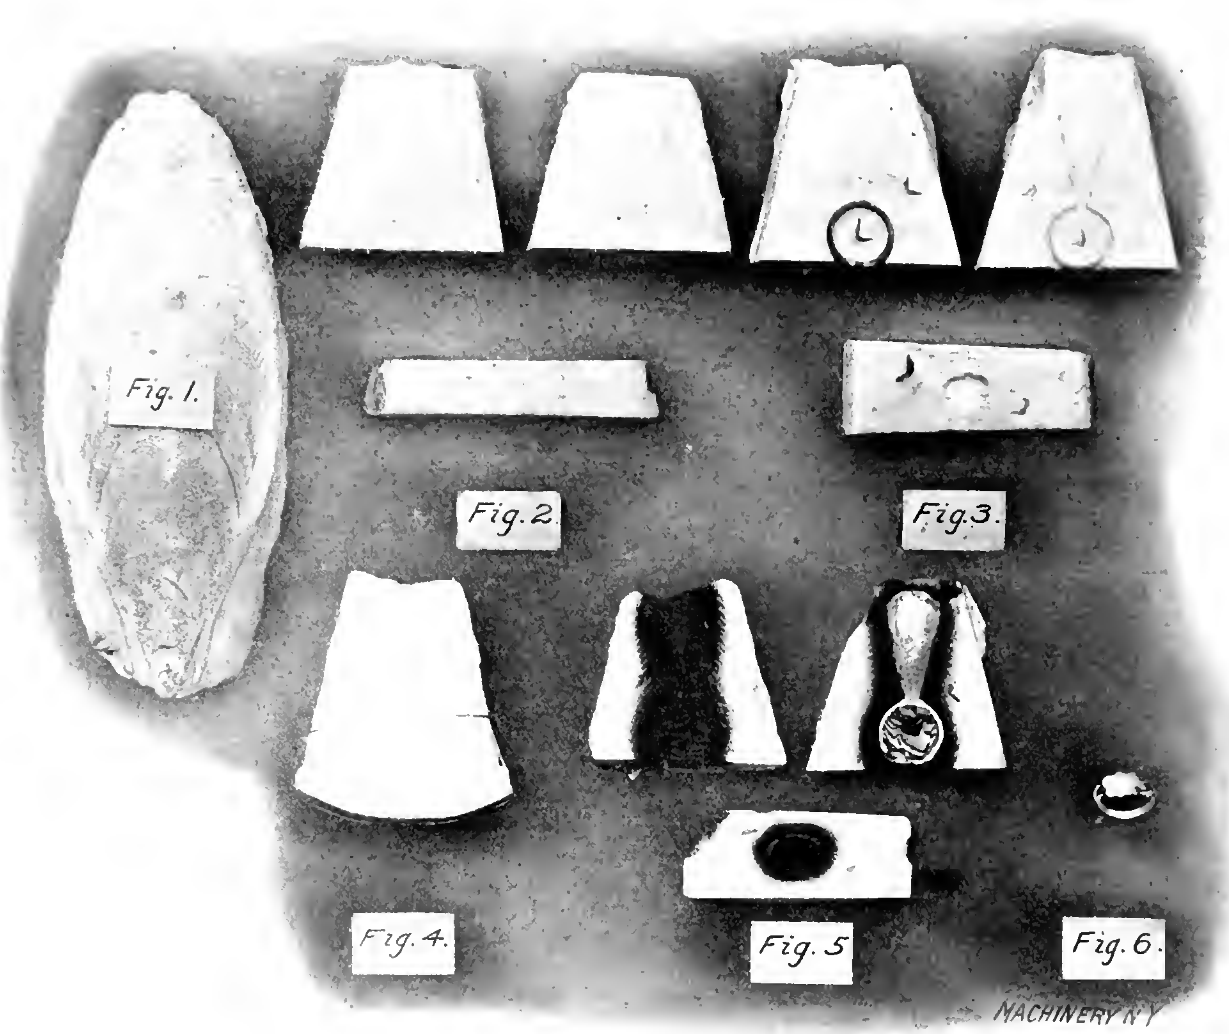
H. J. Bachmann.

New York City.

[The light weight relative to its strength, and comparative cheapness of pipe, has made it a very valuable material in many constructions in the shop. The common usage for bannisters, railings, etc., is well known. Adjustable stands for electric lights are often made from gas-pipe, and we have seen the frames of plumbers' work benches built up entirely from pipe fittings. For many of these purposes discarded pipe is as good as new, and, of course, very much cheaper.—Editor.]

INTERESTING MOLDS FOR FINGER RINGS.

The accompanying half-tone engraving illustrates a phase of metal working which no doubt will interest men who are used to working in the cruder materials, but unfamiliar with the handling of precious metals. The illustrations show molds for casting finger rings, as used by jewelers. The material of which the molds are made is simply cuttle-bone.



Cuttle-bone, and Molds which are made from it for Casting Finger Rings.

Fig. 1 shows the rough bone in its familiar form, while Fig. 2 shows three parts of a mold ready to receive the impressions of the pattern. It is in the matter of making the impressions that one of the most valuable properties of the cuttle-bone is exhibited. A metal pattern slightly larger than the ring is to be, is employed. This pattern is simply placed between the parts of the mold shown in Fig. 2, and the parts are pressed together, the cellular structure of the bone permitting the pattern to indent the surface, producing a mold as shown in Fig. 3, where the pattern is still embedded in one part of the bone. It will be noted that the "seal" part of the ring is formed in the lower piece of bone, and the circular portions in the two upper halves. The pattern is now "drawn," and the gate cut as indicated. The mold is then wired together, as shown in Fig. 4, the alignment being preserved by the V-shaped metal pieces indicated in Fig. 3, which are pressed into the bone at the same time as the impression of the pattern is taken. The molten metal is

now poured; the effect of the heat is shown in the coloring of the bone, in Fig. 5. In one part of the mold in Fig. 5, the ring is shown in place after casting, with the sprue attached, and the completed ring is shown in Fig. 6. After casting, the rings are filed and engraved.

Some rings are cast in sand molds and some in metal molds, but cuttle-bone makes a very simple mold and does not require any venting, on account of its porosity. The writer is indebted to Mr. M. Lichtenstein, of 19 South 48th Avenue, Chicago, for the set of molds from which these photographs are taken.

Chicago, Ill. W. E. Morey.

UNIQUE TURRET LATHE TOOL.

It is required to finish a number of castings, as shown in Fig. 1. These castings are 10¼ inches in diameter, and provided with steps or recesses as shown. The castings are to be finished all over, and as turret lathes have only six holes in the turret for tools, the question presents itself how to finish the stepped face in one operation, if possible. The tool shown in Fig. 2 was constructed for this purpose, and is used in connection with the guide *C* in Fig. 3. The cutter shown in detail at *D*, Fig. 2, is made of high-speed steel, and the guide *C* of machine steel and case-hardened on the faces *B*. When machining the casting, two boring-bars are used, one for rough boring and the other for finishing the hole preparatory to reaming. These tools, together with the reamer, occupy three holes in the turret. In the fourth hole is inserted the stem of the stop *C* against which the end *E* of the cutter *D* rests when taking the cut. The holder for the cutter is held in the tool-post on the cross slide, and when the guide *C* is brought up against the end of the cutter, the spring *A* is compressed. The deepest recess of the work is now finished. It will be seen that as the end *E* of the cutter *D* moves outward on the guide *C* it will reach the first step, and, actuated by the spring, will slide down this step and finish the intermediate recess in the work. It then slides down to the lowest step on the guide, finishing the outside face or side of the work. The fifth and sixth holes in the turret are used for holding flat cutters for finishing the surfaces *F* and *G*, at the same time removing the rounded corner between the steps which is caused by the previous operation. In Fig. 4 is shown a gear blank faced on the hub and rim with the same tool in combination with a corresponding guide. The illustration shows plainly the manner of operation. This tool is particularly commendable in cases where the turret has not enough holes to receive all the tools required if a separate tool were provided for each surface. To be able to turn two surfaces by the same tool is therefore very essential in many cases, and is made possible by the tool construction shown.

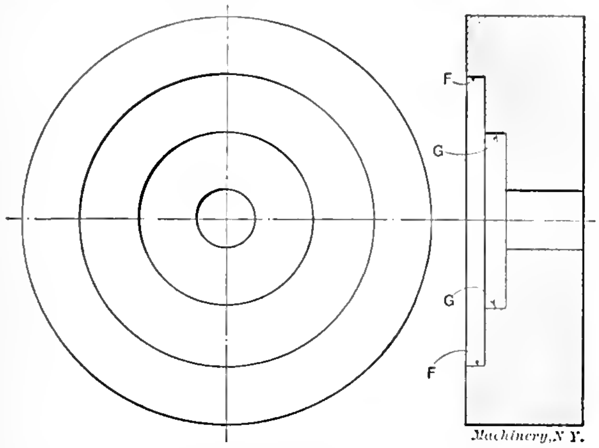


Fig. 1. Casting to be Finished.

Lowell, Mass. J. S. Scott.

RAPID STEEL ARMOR PLATE PLANING.

Some good planing was recently done in the shops of the Witkowitzer Bergbau und Eisenhütten Gewerkschaft. The piece was a hardened steel armor plate of Krupp's best make, 5.81 inches thick. In three hours and fifteen minutes, without re-sharpening the tool, there were removed 115.94 cubic inches of steel. The cutting speed was 16.76 feet per minute; the feed 0.12 inch; and the depth of cut 0.512 inch. The establishment mentioned, reports that this is the best work in this line yet done therein. It was, of course, performed by one of the numerous rapid-cutting steels which have sprung up all over Europe after the introduction of the Taylor-White process in 1900. G.

THE ACKNOWLEDGMENT OF ADVERTISING MATTER.

As you are doubtless interested in anything contributing to the efficiency of trade paper advertising, we take the liberty of suggesting a matter that is often brought to our attention by clients.

Advertising in the trade and technical papers brings inquiries of various sorts, some from people who are interested in the purchase of apparatus, others from persons who wish to inform themselves about the subject in question, and still others from people who appear to apply merely through curiosity, or the desire to get something for nothing. Now, the majority of manufacturers, while they often spend considerable money in the preparation and printing of their catalogues and other trade literature (the bare cost of printing alone often running up to 50 cents or 60 cents per volume) do not, as a rule, object to filling the requests of all three classes.

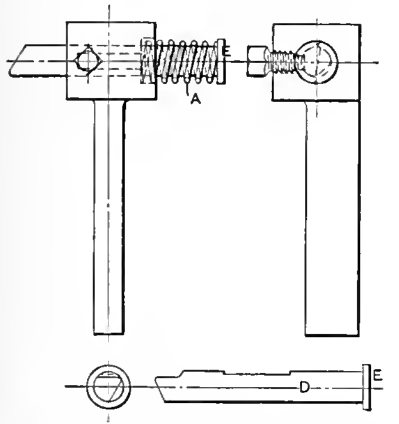

Fig. 2. Tool held in Tool-post on Cross-slide in Turret Lathe, for Finishing Casting in Fig. 1.

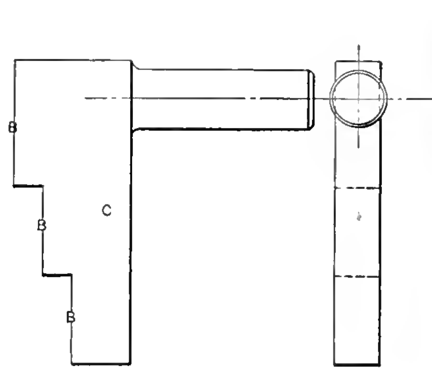

Fig. 3. Guide for Turning Recess in Casting, Fig. 1, used in Combination with Tool in Fig. 2.

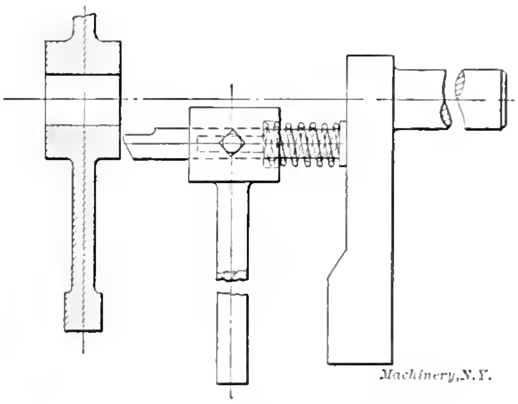

Fig. 4. Facing Hub and Rim of a Gear Blank by the Tools shown in Figs. 2 and 3.

However, the publication of advertising literature is only one step in the selling campaign, and once the prospect has been opened, the organization of selling forces is such that other steps should follow, as it were, automatically. The next thing, therefore, for the salesman to do after receiving an inquiry and sending the literature requested, is to call upon or write to the inquirer to find out what his needs may be. This frequently leads to much waste of time and money. The man who asks for a catalogue may not, as suggested above, be in the market, and if he is located in some out-of-the-way place, it costs a good deal to find this out by means of a personal call.

The point that we wish to bring out is that people who ask for catalogues should at least acknowledge receipt of the

printed matter, and of the letter which usually accompanies it, stating whether or not they expect to purchase in the near future. They rarely ever do this, thereby putting not only the manufacturer, but often themselves also, to some inconvenience and annoyance, inasmuch as the manufacturer has gone to the expense of printing this matter and of mailing it, a simple acknowledgment would seem to be in order, especially as many manufacturers now enclose return postal cards, oftentimes stamped, for this very purpose.

If you could consistently take this matter up in your reading columns and say something which would lead to a more general understanding of the situation on the part of the public, we believe it would lead not only to a lessening of the expense and labor involved in selling machinery, but also to the higher efficiency of trade and technical paper advertising.

New York. THE GEO. H. GIBSON CO.

SIMPLE WIRE-BENDING TOOL.

The accompanying half-tone engravings illustrate a piece bent from plain steel wire, and the appliance used in performing the various bending operations. The straight wire shown in Fig. 1 is 8 inches long, No. 6 gage.

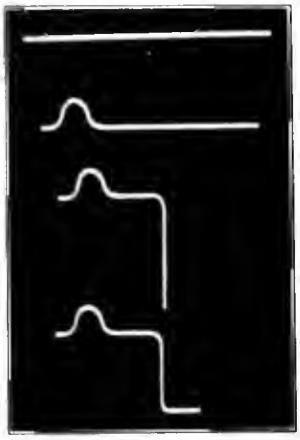

Fig. 1. The Successive Steps in the Bending Operation.

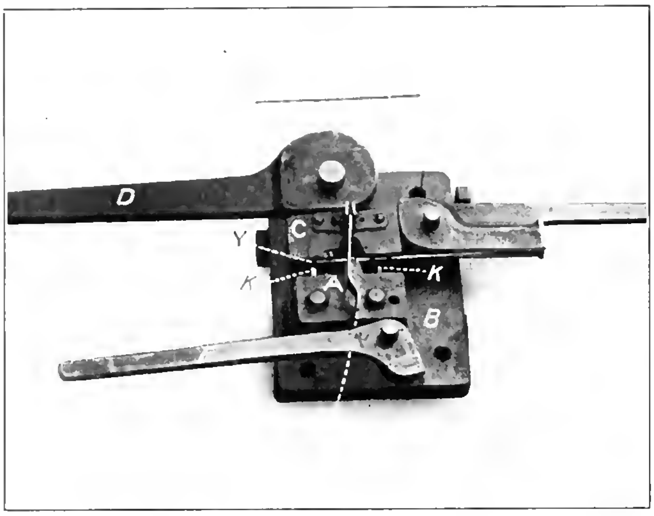

Fig 2. Jaws A and C, which form the First Bend, opened and Wire inserted.

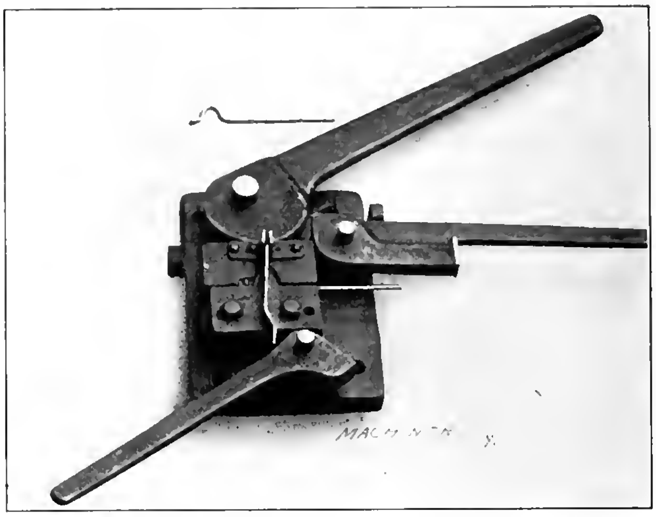

Fig. 3. Jaws closed by the Upper Lever, and First Bend made.

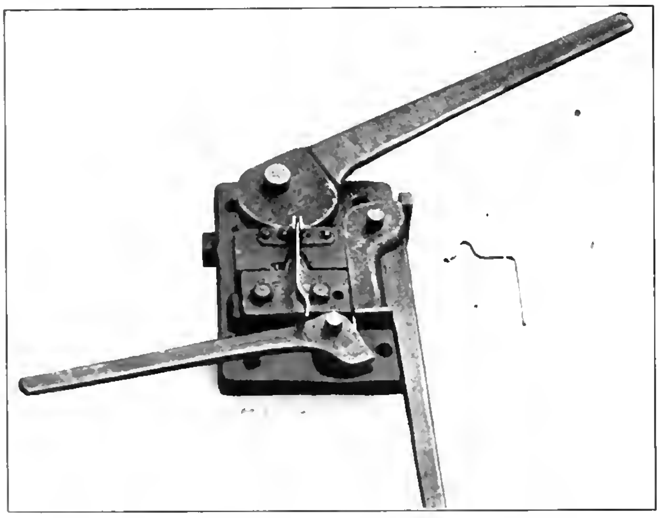

Fig. 4. First Right-angle Bend made by the Lever to the Right.

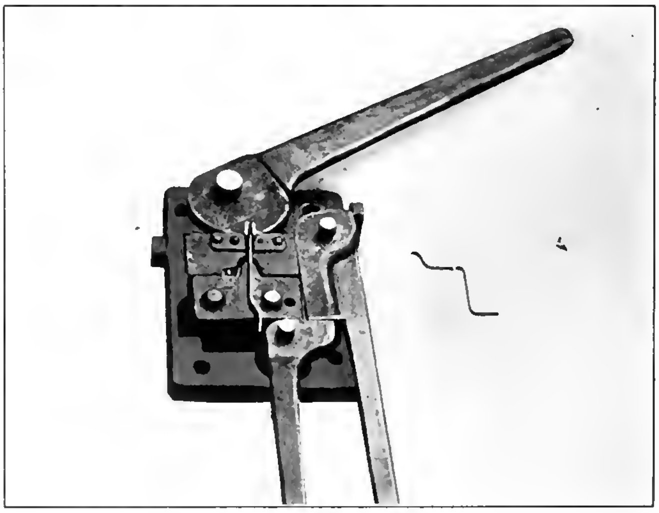

Fig. 5. Second Right-angle Bend made by the Lower Lever.

The shape of the wire after it has passed through the consecutive operations, is plainly indicated in the same illustration. Fig. 2 shows the appliance for performing the work, which is here shown in the position where the straight wire is placed in the opening between the jaws *A* and *C*. The inside former or jaw, *A*, is bolted to the bottom plate *B*, while the outside former slides back and forth on the pins *K*. A spring between the two jaws keeps them apart when the levers are in the position in Fig. 2. The two pins *K* also support the wire when placed in the tool by the left hand of the operator, and a small pin located at *Y*, in the sliding jaw *C*, acts as a stop for laying the wire at its proper place for bending. The lever *D* is now swung around by the right hand of the operator, to the position shown in Fig. 3. This brings the jaws together and produces the first bend. The part of the wire, which extends beyond the jaws, is now in position for the second bend. The operator takes hold of lever *E* with his left hand, and swings this lever downward against the fixed jaw *A*, making a second bend, as shown in Fig. 4. The operator now removes his right hand from lever *D*, and grasping the lever *F*, produces the third or last bend, as shown in Fig. 5. The latch on hook *G* holds the two jaws together after lever *D* is released, as shown quite plainly in Fig. 5. The direction of motion of lever *F* is now reversed. The end of the latch or hook *G* is beveled, so that when lever *F* is swung back, the hook is raised and disengaged from the jaw, thereby permitting the jaws to open. At the same time, springs, not visible in the illustrations, act on the levers *D* and *E*, causing them to return to their original positions, as shown in Fig. 2. The action of the device is very rapid and safe. The operator's hand is never in danger of being injured, because at no time does the operator place his fingers where they are liable to be hurt by the action of the mechanism. The simplicity of the tool and the safety of the device is a factor which should not be overlooked. It should be remembered that the output of a tool should not be the only consideration.

Yonkers, N. Y. G. P. CAMPBELL.

TO SET OVER THE TAIL-STOCK TO TURN A TAPER.

Referring to the article "To Set Over the Tail-Stock to Turn a Taper" in the September issue, if the only error is that caused by the depths of the center holes, these can be measured and subtracted from the length of the piece.

Another way would be to clamp a T-square or its equivalent in the tool-post or holder, set it against the foot-rule (see Fig. 1, ante) and clamp it there at the required angle; then put the work between the centers and set the foot stock over until the square bears along the side of the piece. (This is of course for pieces already turned cylindrical and truly centered.) The square must be at the height of the centers.

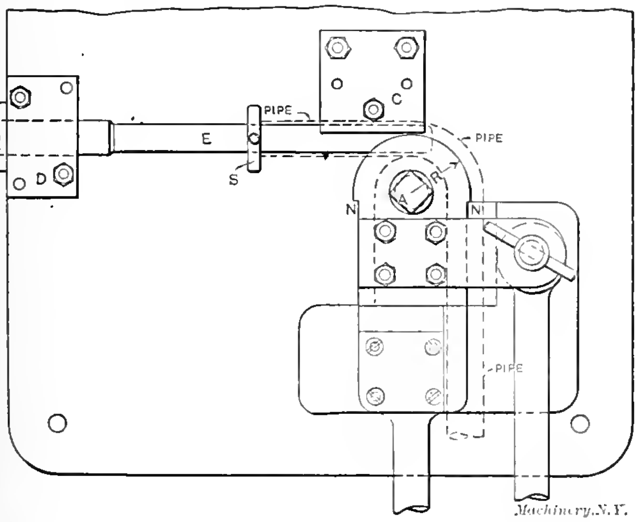
Dresden, Germany. ROBERT GRIMSHAW.

[Our correspondent doubtless knows that a correction made for the depth of the center holes, when figuring the set-over of the tail-stock for turning a taper, can only be approximate. The reason is that the location of the bearings of the piece on the centers always is uncertain, and unless the precise location of the bearings can be ascertained the calculation will be inaccurate.—EDITOR.]

PIPE BENDING DEVICE.

The writer read with interest the article in the September, 1908, issue of MACHINERY, entitled Pipe Bending Device. Having designed and followed the construction of this fixture myself, I wish to make a few suggestions which may be helpful to anyone wishing to construct a device of this kind. The success of the fixture depends entirely on the shape of the end of the horn or mandrel *E*. To get the correct shape requires a great amount of patience and experimenting, and it is not possible to give definite figures or dimensions for this shape. The pipe, in making the bend, must spin off the end of this horn, and a little too much or too little in the curvature of the end will prevent good results.

In the engraving shown in the September issue, the stop collar *S* was omitted. This collar acts as a stop for the end of the pipe, and is adjustable on the mandrel *E*. By means of this collar the bend in the pipe may be located at any required distance from the end. Backing-block *C* and mandrel *E* should be so placed that the pipe fits quite snugly between them. The mandrel should also be a good sliding fit inside of the pipe.



Plan of Pipe Bending Device, showing Position of Parts after making a Right-angle Bend.

The radius *R* of the swivel block *A* should project at least ⅛ inch beyond the center line of the pipe, and the block should be notched at *N*, bringing the outline back to the center line. The backing-block *C* then, of course, extends only to within ⅛ inch of the center line. With a fixture made in this way, the pipe may be bent to a complete return bend. It appears that the pipe needs some extra support beyond the center line, and only short bends can be made successfully without this support.

The distance which the end of the mandrel *E* extends beyond the center line of the swivel block *A* should be experimented with very carefully. After bending a few pieces with the end of the horn placed at various distances beyond the center of the swivel block, the preferable position of the mandrel is easily determined. When finally established so that the pipe bends without buckling, the collar and the mandrel are drilled and reamed in place, and a taper pin driven in. When once located, this collar should never be tampered with. R. B. LIBBY

Lansing, Mich.

A BIT OF RADIAL DRILL DESIGN.

Two methods of driving the spindle of a universal radial drill are shown in the accompanying engravings. Fig. 1 is the usual way, and Fig. 2 an improved method which has, in my opinion, sufficient advantages to warrant its universal adoption. Both Figs. 1 and 2 are sections through the center of the arm; *F* is the spindle, *G* the driving shaft in the arm, and *E* the face of the arm.

One of the worst features of the ordinary universal radial, is the short bevel gear shaft *H* (Fig. 1), upon the center of which the drill head swivels. It is impossible to make this bearing of good proportions, because as the distance *C* is lengthened the distance *B* is increased. Now it is an axiom in designing a radial drill, that the spindle must be as close to the arm as possible to minimize the twisting action, so that the designer is placed between the devil and the deep sea—he must sacrifice either rigidity or durability, or else compromise. He generally does the latter and evolves a machine that is neither rigid nor durable.

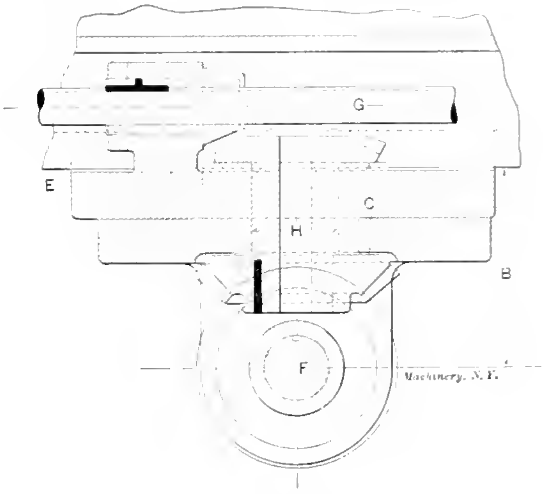


Fig. 1. A Common Form of Drive for Radial Drill Spindles

The new Bickford universal radial was designed to overcome these difficulties, and, as far as can be judged from illustrations and printed descriptions, a fairly satisfactory solution seems to have been attained. Long before I heard about the new Bickford machine I had been puzzling my brain for a more satisfactory method of driving the spindles of universal radials and my solution is shown in Fig. 2. On the arm shaft *G* is mounted the miter gear *J* which drives the miter *K*, the latter being forged solid with its shaft *P*. Keyed to the shaft *P* is the spiral pinion *L* which meshes with a spiral gear *M* keyed to the socket *N* in which the spindle *F* slides. The drill head swivels on the bush *O* which forms one bearing for the shaft *P*. Now let us compare Fig. 2 with Fig. 1 which represents actual practice. The length *C* of the bearing *H* is 3¾ inches, while the over-all length *D* of the bearings for shaft *P* is 11 inches, or nearly three times as long. The dimension *B*, which represents the distance from the center of the spindle to the face of the arm, is 8 inches, while *A* is only 6 inches, so that we are 25 per cent "to the good" here. Summing up, then, we find that the new type is practically 300 per cent more durable and nearly 25 per cent more rigid.

The end of the shaft *P* lends itself very conveniently for driving the feed motion, either by belt cones, as shown, or a gear box. Another advantage is that the spindle, being offset to the left of the fulcrum *D*, will go very close to the column and thus give a greater horizontal movement of the head on

the arm, though, of course, this extra length will have to be put onto the outer end of the arm. The only objection to this arrangement, so far as I know, is that the drill head will have a tendency to swivel on the fulcrum *D* under the pressure of the cut. Personally, I think that the clamping bolts will take care of this, because the twisting moment tending to swivel the drill head is only one-twelfth of the moment which tends to twist the arm around the column when the machine is drilling horizontally at a radius of 60 inches, and most firms find that a V-clamp is sufficient to resist this.

In our practice, we provide a worm and worm gear for turning the arm around the column. This arrangement provides a positive stop for the column, which I think is necessary for universal radials, because if the spindle is at the outer end of the arm and swivelled to drill horizontally, the turning moment on the column clamp is enormous, and a friction clamp, in my opinion, is utterly inadequate for the work. Where very heavy cutting is to be done, it may be necessary to provide a similar arrangement for this form of drill head; but even if this had to be done, it would be very convenient for adjusting the angular position of the spindle.

Racquet.

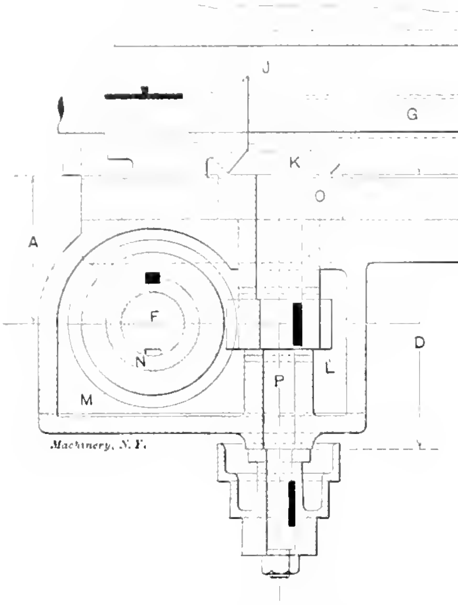

Fig. 2. An Improved Drive giving Greater Rigidity and Durability.

SETTING WORK ON THE FACE-PLATE.

A much more satisfactory way of setting the die-blank illustrated on Shop Operation Sheet No. 76, than that which is there given, is as follows:

When laying out the blank, inscribe a circle the size of the hole to be bored, heavy enough to be seen plainly. After the blank has been approximately trued up, and balanced as explained in steps 1 to 6, fasten a sharp scratch in the tool-post on a line with and facing the prick-punch mark. Bring this point (with the cross-feed) to the circle inscribed and adjust the blank until, by turning the face-plate, the circle will follow the point. The advantage of this method is a more accurate job, and if the work moves while being machined (as it is liable to do), it will be seen at a glance, and can be easily adjusted again. In truing up with a prick-punch mark, you have no way of telling if the work moves, and no way of truing it if it did. Prick-punch marks are never satisfactory for accurate work.

A Subscriber.

[It is doubtful whether the method of setting work advocated in the foregoing, has any advantage over that given in the Shop Operation Sheet referred to. If a circle the size of the hole to be bored is first scribed and the blank set by it, it is probable that the setting will not be as accurate as when the datum or central point from which the circle is scribed, is used, provided, of course, that a center tester is available. The die-blank in question, however, was laid out from a master templet, and the circular ends might have been set with a pointer without locating a central point. This method could also be employed in case the work shifted; or, assuming that part of the hole had been trued, a test indicator could be used instead.—Editor.]

LOCK-NUTS USED IN ENGINEERING PRACTICE.

The engraving shows two forms of nut-locks. I use the term advisedly, for most of the devices illustrated in the September Data Sheet are means for locking nuts rather than lock-nuts proper. The nut shown in Fig. 1 is made from a coil of square steel bar; it is shaped by punching and finished by milling. The hole is tapped a little below nominal size.

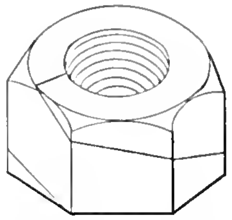

Fig. 1. Helicoid Lock-nut.

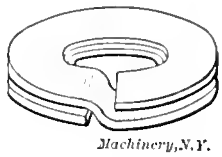

Fig. 2. Spring Washer.

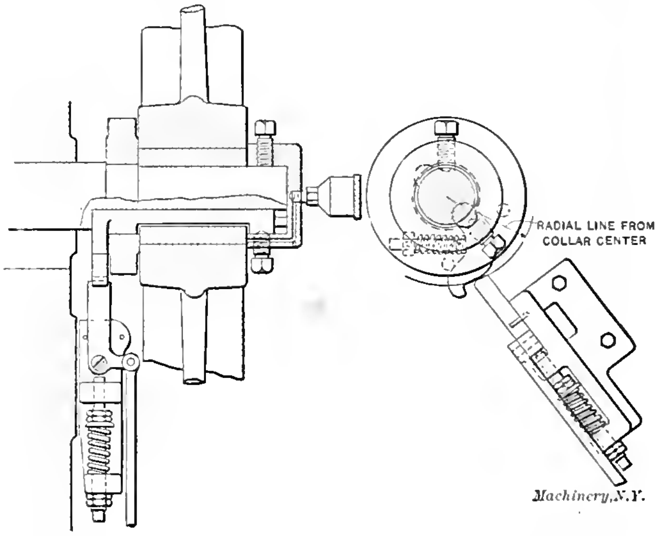
Screwing the nut on a bolt expands the coil which grips the bolt tightly. These nuts are employed, in many cases, for engine connecting-rod bolts. If properly fitted, they never work loose.

The spring washer shown, is used on rough, cheap work, as, for instance, on the ends of bench vise screws, with an ordinary nut, to retain the screw in position and to automatically take up wear on the front collar of the screw.

Nutlocks.

BLISS POWER-PRESS CLUTCH.

In the November issue of Machinery, engineering edition, we find an article entitled "Clutches for Power Presses," by Mr. Frank Mossberg (being an abstract of his discussion of the American Society of Mechanical Engineers' paper by Mr. Henry Souther, on clutches). In this article is illustrated the Bliss clutch, Fig. 4, and we wish to call attention to the fact that the illustration does not properly show the Bliss clutch, being wrong in several details. The accompanying illustration correctly shows the Bliss clutch, and by comparison with Fig. 4 in the article referred to, several differences will be noted. A few of these are as follows:



Bliss Power-press Clutch.

The wheels are all fitted with bronze bushings. The construction of the end collar is not correctly shown in the previous illustration, the wheels in all regular fly-wheel presses being fitted with two locking points and not three; three locking points are used only when the press is geared. The end collar is fitted with a set-screw by which the clutch can be locked, in which position it is impossible to trip the press. This has been found of service when setting dies in the press. Instead of the cap bolt, shown in the illustration referred to, for holding the end collar in place, there is a grease cup by which the shaft bearing is oiled.

Brooklyn, N. Y.

Joseph B. McCann,
E. W. Bliss Co.

HOW AND WHY.

A DEPARTMENT INTENDED TO CONTAIN CORRECT ANSWERS TO PRACTICAL QUESTIONS OF GENERAL INTEREST.

Give all details and name and address. The latter are for our own convenience and will not be published.

TURNING SOFT RUBBER SAWING CAST IRON UNDER WATER.

The following questions are submitted to the readers for answers:

L. M.—What is the best method of turning soft rubber in a lathe, and what form of tools are required? Is a lubricant necessary, and if so, what is best?

H. M. Co.—We have been doing some experimental work sawing cast iron under water with a regular hack-saw. The cast iron surface seems to become glazed and the saw blades refuse to attack the metal, simply sliding upon it as though it were a hardened surface. Can you suggest any way of avoiding the difficulty when it is necessary to saw under water?

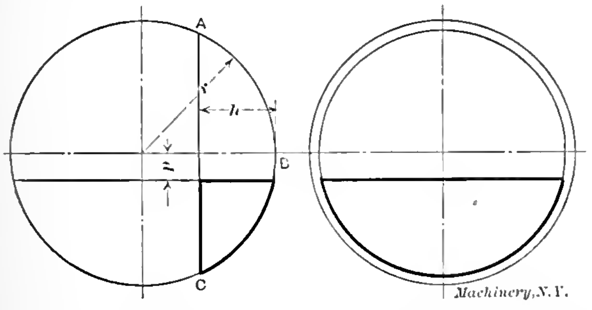
MULTIPLE THREAD SPECIFICATIONS.

P. G. and T. W.—An order came to our shop for a job in which the instructions for a square thread were as follows: "Double square thread, two per inch." We cut the thread ½ inch pitch and 1 inch lead. Our customer contends that it should have been cut ½ inch lead, or two threads per inch, then doubled. Which is correct?

A.—The customer's instructions were indefinite and could be interpreted either way. The case illustrates the confusion that arises from the indiscriminate use of the terms "lead" and "pitch." What the customer evidently desired was a double square thread, ¼ inch pitch and ½ inch lead, and if the order had specified this the mistake could not have been made. In all specifications for multiple-thread screws it is highly essential to specify both lead and pitch to avoid confusion and mistake.

OBTAINING VOLUME OF PART OF A SPHERICAL SEGMENT.

F. M. S.—I would like to submit the following problem to the readers of MACHINERY. Given the volume of a spherical segment, to determine the volume of the portion obtained by placing a plane through the segment perpendicular to its base, as indicated in the accompanying engraving. Here the volume required is that of the portion shown in the heavy lines; the values known are *r*, the radius of the sphere, *h*, the height of the segment *ABC*, and *p*, the distance of the cutting plane from the center of the segment.



CAUSE OF DIMINUTION IN VOLTAGE FROM A GENERATOR.

J. T.—We have a direct-current 10-kilowatt, 125-volt, 80-ampere Westinghouse generator running at 1,350 R.P.M., which we used occasionally last winter. On starting up the machine, the voltage would keep steady at 120 volts for perhaps thirty minutes, then it would gradually fall to about 110 in the course of thirty minutes more. Then, if we turned the rheostat to bring up the voltage, it would gradually fall again the same as before. In the meantime the whole machine would warm up a little, but the longer it ran the weaker the voltage became. If the machine was stopped long enough to let it cool off, it would start off with the voltage strong as usual, but the longer it ran the weaker the voltage became. We carry about 75 lights, and have tried cutting out the lights when the voltage dropped, but it would not rise to normal until the machine had been stopped for some time. We know that the trouble was not caused by a slipping belt or loss of speed. What is the cause?

Answered by Wm. Baxter, Jr.

A.—The action of your generator is normal, and does not indicate that anything is out of order. When the machine starts up, the current flowing through the wire heats it, and the rise in temperature increases the resistance, so that less current passes through the field coils and as a result the magnetic strength is reduced, and this causes the voltage to drop. When you turn the rheostat to cut out resistance, the current is increased and the voltage rises. The proper thing to do to save unnecessary adjusting is to set the rheostat, at the start, so as to develop a voltage a trifle higher than the normal; then the field coils will heat up faster, and will have to heat up more before the voltage is reduced to a point where it has to be increased again. It after the machine has run long enough to get warmed up to the normal running temperature, the voltage cannot be raised to the required point by cutting out all the rheostat, it indicates that the speed is too low, and the remedy is to speed up. The increase in velccity should be made a trifle more than the increase in voltage that may be desired; thus if the voltage can only be run up to 120, and you want 125, increase the speed five or six per cent.

SPIRAL GEAR PROBLEMS.

C. K.—Kindly work out and illustrate the following problems: 1. Find the essential dimensions for a pair of spiral gears, velocity ratio 3 to 1, center distance between shafts 5⅛ inches, angle between shafts 38 degrees. 2. Find the essential dimensions of a pair of spiral gears, velocity ratio 8 to 3, center distance between shafts 9 5/16 inches, angle between shafts 40 degrees. 3. Find the essential dimensions for a pair of spiral gears, velocity ratio 5 to 2, center distance between shafts 4 1/16 inches, angle of shafts 18 degrees. 4. Give rules for calculating the change gears for connecting the dividing head and lead-screw of the milling machine table, when cutting leads that are not given on the tables furnished by the builders.

A.—1. All three of the spiral gearing problems you have given us can be solved by a simple modification of the plan described in the May, 1906, issue of MACHINERY, in an article entitled "A Method of Procedure in the Design of Helical Gears." This article, which is also reprinted in MACHINERY'S reference series No. 20, should be referred to in connection with this description.

The following reference letters will be used:

C = center distance between the axes of the gears,
D_a = pitch diameter of the pinion,
D_b = pitch diameter of the gear,
N_a = number of teeth in pinion,
N_b = number of teeth in gear,
P'' = diametral pitch of cutter,
α_a = tooth angle of pinion,
α_b = tooth angle of gear,
γ = angle between the axes of gear.

First obtain a preliminary solution by the diagram shown in Fig. 1. Draw lines AG and AG_1, making an angle with each other γ equal to 38 degrees, the angle between the axes. Locate the ratio line AE by finding any point such as O_1 between AG and AG_1, that is distant from each of them in the same ratio as that desired for the gearing. In the case shown, it is 6 inches from AG_1 and 2 inches from AG, which is in the ratio of 3 to 1 as required. Through O_1 draw line AE which may be called the ratio line. Select a trial number of teeth and pitch of cutter for the two gears, such, for instance, as 36 teeth for the gear and 12 for the pinion, and with 5 diametral pitch for the cutter. The diameter of a spur gear of the same pitch and number of teeth would be $36 \div 5 = 7.2$ inches. Find the point O on AE, which is 7.2 inches from AG_1. This point will be 2.4 inches from AG, if AE is drawn correctly.

Now apply a scale to the diagram, with the edge passing through O and with the zero mark on line AG, shifting it to different positions until one is found in which the distance across from one line to another (DD_1 in the figure) is equal to twice the center distance, or 10.25 inches. If a position of the rule cannot be found which will give this distance between lines AG and AG_1, new assumptions as to number of teeth and diametral pitch of the gear and pinion must be made, which will bring point O in a location where line DD_1 may be properly laid out. DD_1 being drawn, the problem is solved graphically. The tooth angle of the gear is B_1OD_1, or α_b, while that of the pinion is BOD, or α_a. OD_1 will be the pitch diameter of the gear, and OD the pitch diameter of the pinion.

To obtain the dimensions more accurately than can be done by the graphical process, the pitch diameters should be fig-

ured from the tooth angles we have just found. To do this, divide the dimensions as OB and OB for gear and pinion, by the cosine of the tooth angles found for them. If they measure on the diagram, for instance, 21 degrees 50 minutes and 16 degrees 10 minutes respectively (note that the sum of α_b and α_a must equal γ) the calculation will be as follows:

$$
\begin{aligned}
7.2 \div 0.92827 &= 7.7563 = D_b\\
2.4 \div 0.96046 &= 2.4988 = D_a\\
\hline
&10.2551 = 2C
\end{aligned}
$$

The value we thus get, 10.2551 inches, for twice the center distance, is somewhat larger than the required value, 10.250 inches. We have now to assume other values for α_b and α_a, until we find those which give pitch diameters whose sum equals twice the center distance. Assume, for instance, that α_b = 21 degrees 43 minutes, then α_a = 38 degrees — 21 degrees 43 minutes = 16 degrees 17 minutes. We now have:

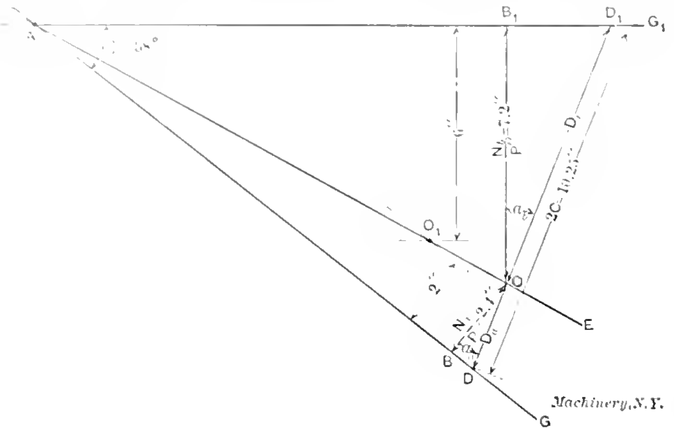


Fig. 1.

$$
\begin{aligned}
7.2 \div 0.92902 &= 7.7501 = D_b\\
2.4 \div 0.95989 &= 2.5003 = D_a\\
\hline
&10.2504 = 2C
\end{aligned}
$$

This value for twice the center distance is so near that required that we may consider the problem as solved. The other dimensions for the outside diameter, lead, etc., may be obtained as for spiral gears at right angles, and as described in the article previously referred to.

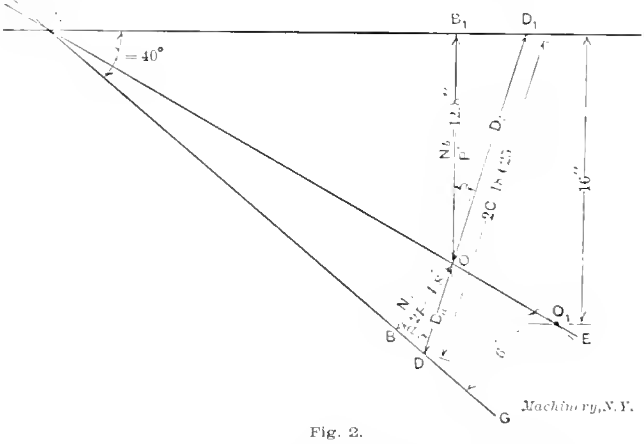

Fig. 2.

2.—The diagram for solving this problem is shown in Fig. 2. The axis lines AG_1 and AG are drawn as before and the ratio line AE is drawn in the ratio of 8 to 3, or 16 to 6, by the same method as just described. A point O is found having a location corresponding to 64 teeth and 5 pitch for the gear, and 24 teeth for the pinion. This gives distance OB = 12.8 inches and OB = 4.8 inches, by which position O is so located that a line DD_1 can be drawn through it at a convenient angle, and with a length equal to twice the center distance, or 18.625 inches. We measure the angles for a preliminary graphical solution as before, and then by trial find the final solution as follows, in which angle α_b is 17 degrees 45 minutes, and α_a is 22 degrees 15 minutes:

$$
\begin{aligned}
12.8 \div 0.95240 &= 13.4397 = D_b\\
4.8 \div 0.92554 &= 5.1862 = D_a\\
\hline
&18.6259 = 2C
\end{aligned}
$$

This gives the value of twice the center distance near enough for gears of this size.

3.—The diagram for solving this problem is shown in Fig. 3. The axis lines AG_1 and AG are drawn as before, and the ratio line AE is drawn in the ratio of 5 to 2, by the same method as just described. A point O is found having a location corresponding to 45 teeth and 8 pitch for the gear, and 18 teeth for the pinion. This gives distance OB_1 = 5.625 inches, and OB = 2.250 inches, in which position O is so located that line DD_1 can be drawn through it at a convenient angle, and with a length equal to twice the center distance, or 8.125 inches. We measure the angles for a preliminary mathematical solution as before, and then by trial find the final solution as follows, in which angle α_b is 16 degrees 45 minutes and α_a is 1 degree 15 minutes:

$$
\begin{aligned}
5.625 \div 0.95757 &= 5.8742 = D_b\\
2.250 \div 0.99976 &= 2.2505 = D_a\\
\hline
&8.1247 = 2C
\end{aligned}
$$

It is often a matter of great difficulty, when the center angle γ is as small as in this case, to find a location for point O such that standard cutters can be used, and that line DD_1 can be drawn of the proper length through O without bringing D to the left of B, or D_1 to the left of B_1. It will be noticed in this case that to make the center distance come right, angle α_a had to be made very small, so that the pinion is practically a spur gear. In some cases, to get the proper center distance, it may be necessary to so draw line DD_1 that one of the tooth angles is measured on the left side of BO or B_1O. Such a case, for instance, is shown in the position of d_1Od. When a line has to be drawn like this, the tooth angles α'_a and α'_b are opposite in inclination, instead of having them, as usual, either both right hand or both left-hand. In Fig. 4 are shown gears drawn in accordance with the location of line DD_1 of Fig. 3, while Fig. 5 shows a pair drawn in accordance with dd_1 of the same diagram, which will illustrate the state of affairs met with in cases of this kind. This expedient of making one spiral gear right-hand and one left-hand should never be resorted to except in case of extreme necessity, as the construction involves a very wasteful amount of friction from the sliding of the teeth on each other as the gears revolve.

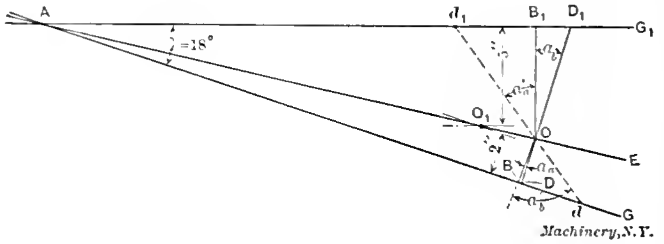

Fig. 3.

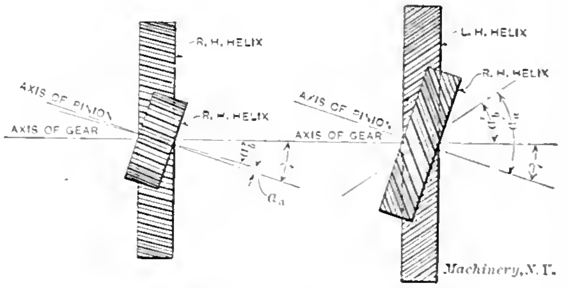
4.—Your request for information relating to the figuring of leads for cutting spirals in the milling machine was quite fully answered in the "How and Why" Department of the June issue of MACHINERY. The same subject is also discussed on page 36 of MACHINERY'S Reference Series No. 18. You will also be assisted in selecting gearing which very closely fits the required ratios by studying the article entitled "How to Obtain Approximate Fractions by the Method of Continued Fractions," by Mr. Mitchell Dawes in the August, 1908, issue of MACHINERY.



Figs. 4 and 5.

INSTRUCTION OF APPRENTICES IN THE CINCINNATI MILLING MACHINE CO.'S SHOPS.

The need of a more systematic method of training apprentices than that in vogue during the last decade, has been keenly felt by all manufacturers of machines, because of the growing lack of skilled and properly trained workmen. A great deal has been written about industrial education and about apprenticeship schools, but most of what has been said of the latter has been applicable to very large shops where it was possible to devote a special department to the instruction and training of apprentices. The medium and small-sized shop would encounter the difficulty of heavy expense, if the systems followed in very large establishments were inaugurated. For this reason, any method which will successfully solve the problem of apprenticeship instruction in a medium-sized shop, will undoubtedly be of interest to all who have given this subject attention, and the following outline of the system in use in the works of the Cincinnati Milling Machine Co., Cincinnati, O., may prove suggestive to those who are contemplating the inauguration of some instruction for apprentices in their own plant.

Fig. 1. One Section of the Cincinnati Milling Machine Co.'s Apprentice School in Session.

The apprenticeship school of the Cincinnati Milling Machine Co. was organized in May, 1907, and has thus been established long enough to make it possible to form an opinion about the results obtained. The apprentices work the larger part of the time in the shop under the supervision of the regular department foremen, but receive instruction along more theoretical lines, having practical application, for two hours once a week. Forty apprentices are enrolled and divided into two sections of twenty each. Each of these sections receives instruction Tuesday and Thursday mornings, respectively, from ten to twelve A. M. The boys are paid their regular contract wage during the school hours. A large room in the main office building is utilized as a school room, and is equipped in a manner as shown in the accompanying half tone Fig. 1.

The phase of this particular system of instruction which is of the most interest, is the manner in which the knowledge is imparted to the boys. It would seem at first that two hours a week is entirely too short a time to obtain adequate results, particularly when twenty boys are to be instructed. This difficulty made it important for the instructor to devise some method by means of which all the boys could be kept employed, working on individual problems, leaving the instructor free to devote himself to each of them in turn; the difficulty was overcome by designing so-called "jig sheets," of which two are shown in Figs. 2 and 3. As will be seen from the illustrations, these sheets cover practical subjects, and are made up in such a form as to outline for the boy where to place the answer which he is required to obtain, and, in a general way, the manner in which it is to be arrived at. The name "jig sheet" has been adopted for the reason that the original instruction sheet contains simply the statement of the problem and spaces to be filled in by the student. The "jig," with its explanatory drawings, is drawn on heavy bristol board and is intended to serve as a guide from which the boy is to work—hence the name. The boy places a thin bond paper sheet over this jig and traces all the lines and the illustration on the jig, on this bond paper, the paper meanwhile being attached to the bristol board by means of paper clips. The size of the bristol board is 11 by $8\frac{1}{2}$ inches, so as to permit using regular typewriter letter-size paper for the tracing. When the boy has traced the jig onto the letter paper, he carries out the required calculations,

---

* For additional information on this subject see the following articles previously published in MACHINERY: Evening School of Trades—Rindge Manual Training School, Cambridge, Mass., July, 1908; Can a Boy Learn a Trade in a School? April 1908; Promoting Industrial Education, May, 1907; Vital Needs of Industrial Schools for Industrial Workers, January, 1907; A Step Toward Increased Facilities for Industrial Education, December, 1906; An Experiment in Industrial Training, September, 1906.

placing the results of the whole calculation in the spaces provided. The method employed not only gives the boy an opportunity of acquiring the habit of neatness in copying from an original and an ability to copy simple drawings, but it also provides a neat and permanent record of his work.

Another important feature of this method of instruction is that there is no necessity of a definite outline of a complete course which is likely to fail to arouse the interest of the boy. On the contrary, each boy can be given a problem to work on which has some connection with his regular shop work, and his interest is thereby stimulated. Individuality is given full play, and the boy is permitted to select for himself out of a list of jigs the one that interests him, after which the instructor sits down beside him and endeavors to explain the principles involved. Should the problem require more knowledge of fundamental mathematics than the boy as yet possesses, it gives a good opportunity to instruct the boy in pure mathematics without making it tiresome or wearying to him, the boy realizing that the mathematics he is being taught are absolutely necessary for the solution of the practical problem which he has selected for himself. Thus, for instance, it was found that a boy who took but little interest in exercises in the division of decimals, worked contentedly for one full month carrying out divisions to six decimal places, calculating the angle of tapers, when the length and the diameter were given, and the tangent for the angle required.

The boys are given full liberty to ask any questions and also to propose any problems occurring in their regular work which they desire to have solved, and the instructor makes "jigs" for these problems in the order in which they are proposed, referring back to former exercises when required. It will be seen that in this manner mathematics, mechanics, strength of materials, machine design, drawing, etc., may be taught simultaneously with their practical application, the boy acquiring a working knowledge of these subjects in a way which makes it possible to arouse and continually hold his interest. Mr. J. Howard Renshaw, who is the instructor of the apprentices' classes referred to, states that the system works out very successfully in practice.

Figs. 2 and 3. Samples of Jig Sheets used in Apprentice School of Cincinnati Milling Machine Co. Designed by J. Howard Renshaw, Instructor. Sheets reduced from 7 1-2 x 9 1-2 inches.

In order to supplement the instruction and keep the interest of the boys, a branch library was secured from the public library of the city, numbering sixty volumes which circulate among the apprentices, the books being selected by the instructor. The cooperation of the public library has been valuable in that many books particularly adapted to apprentice education have been purchased by the public library since the inauguration of this apprenticeship school.

The president of the Cincinnati Milling Machine Co., Mr. Fred Geier, takes a personal interest in the apprenticeship school, receiving reports and information concerning each individual at regular intervals, and this has had the effect of making the boy feel that if he is successful and makes progress, his employer will know about it and take a direct interest in him. This feature is very valuable and of great importance in creating ambition and a desire for progress.

If the apprenticeship school is conceived with the object in view of not only realizing the possibility of education but with the wider view of creating mechanics who realize the full extent of their duties as well as their rights, then the inauguration of such a system of teaching apprentices as outlined above will create a different spirit among the boys. Instead of being antagonistic toward the firm, as many were when they started the course, they have come to realize that the fundamental principle of business is cooperation and that ultimately their progress and the success of the firm are closely connected. To prove a complete success, every apprenticeship school must connect the pure utilitarian studies with an understanding on the part of the students of the ethical side of their relation to their fellow-workers in the industry, whether the latter be high or low on the industrial ladder of success.

[A comprehensive selection of the "jig sheets," referred to above, will be compiled by Mr. Renshaw with full instructions, and published by MACHINERY. We believe this system fills a gap that has existed in industrial educational literature, and that it will be an important forward step in the instruction of apprentices and shop men generally who desire to better their condition. Full announcements of the plan will be given in succeeding issues.—EDITOR.]

Wireless telegraphic communication with balloons has successfully been maintained at Brussels where an air navigator exchanged signals with a station erected on a tower in the city. Signals sent from the French military station on the Eiffel Tower in Paris were also intercepted.

NEW MACHINERY AND TOOLS.

A MONTHLY RECORD OF APPLIANCES FOR THE MACHINE SHOP.

PEERLESS AUTOMATIC MULTIPLE-SPINDLE SCREW MACHINE.

A very interesting multiple-spindle screw machine (or automatic lathe, as the builders call it) has been placed on the market by the Peerless Automatic Machine Co. of Cleveland, Ohio. It follows the usual construction of such machines in being provided with a revolving spindle head, which indexes and rotates the several bars of stock, and in having a multiple tool slide and cross-slides which present cutting tools to the bars of stock in succession as they are indexed. Aside from this general plan, the machine incorporates a number of new and ingenious features in its mechanism, and is worthy of detailed study.

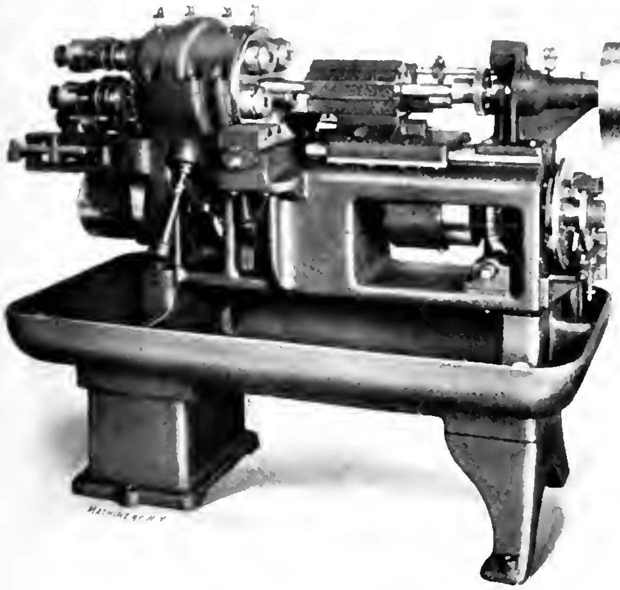

Fig. 1. The Peerless Automatic Multiple-spindle Screw Machine.

The Controlling Mechanism of the Machine.

Fig. 1 shows the front view of the machine, and Fig. 2 the rear view. The motions of the machine are all controlled by cams on a cam-shaft driven by the high-speed driving pulley shown near the base of the machine at the left of Fig. 2. This pulley may either be clutched directly to the worm driving the tool slide cam-shaft, or it may be connected with the worm through reducing gearing and change gears, mounted on the outside of the casing containing the change mechanism, as shown in Fig. 2. The change gears provide for ten rates of feed, varying from 0.004 to 0.026 inch of advance per revolution. This change of speed gives the cam-shafts, and therefore the operating mechanism of the machine, either a slow movement for feeding, or a rapid one for such operations as indexing and locking the spindle head, operating the collets and feeding the stock, withdrawing the tools from the work, bringing them up to a cutting position, etc. The change from fast to slow cam-shaft movement is effected by dogs adjustable to any position around the periphery of the plate mounted on the cam-shaft at the extreme right of Fig. 1, and the extreme left of Fig. 2.

Taking the parts on the cam-shaft in their order as seen at the right in Fig. 1, the disk just at the left of the speed-changing dogs carries cams controlling the threading mechanism, which will be described later. The worm-wheel on the shaft just inside the frame, drives the cam-shaft from the variable speed device previously described. The large cam in the base of the machine operates the tool slide for feeding the tools to the work. The spur gear at the left of the tool slide cam meshes with the one seen at the left of the rear cam-shaft in Fig. 2, thus driving the two sets of cams in unison. The plate seen under the rear cross-slide in Fig. 2 carries cams for operating the front and rear cross-slides. These cams operate through swinging sectors with teeth cut in their periphery, meshing with racks on the cross-slide. The next cam to the right operates the locking pin for locating the spindle head, which is indexed by the large sprocket wheel and chain shown. The cam at the extreme right opens and closes the collets and feeds the stock. As in all machines of this type, it will be seen that one revolution of the cams produces a finished piece of work, the rear cross-slide cutting off a finished piece for every indexing of the spindle head.

The Design of the Spindle Head.

Coming to a description of the details of the machine, one of the points of interest is the method of indexing and locking the spindle head. This is effected by the mechanism seen in Figs. 1 and 2, but is more clearly shown in the line drawing, Fig. 3. The sprocket-wheel *A*, as previously described, is directly connected by a chain with a sprocket-wheel fast to the spindle head *B*. Sprocket-wheel *A* is normally loose in its seat on cam *C*. In a slot cut in the latter is pivoted dog *D*. One end of this dog is adapted to engage a recess inside the hub of sprocket-wheel *A*, while the outer or projecting end is in position to be operated on by stationary cam *E*. Normally, dog *D* is out of engagement with sprocket-wheel *A*, but for a fifth of a revolution (there are five spindles in the head, which therefore has to be indexed a fifth of a revolution at a time) the cam throws the dog into engagement with the sprocket-wheel, thus revolving the latter and the spindle head to a new position. Cam *E* disconnects the dog when this new position has been reached.

The turret is locked in position by a decidedly novel arrangement of locking bolt and bushing. The bolt itself, *G*, is of the usual construction. It is forced into its seat by the spring shown, and is raised by cam *F*, operating lever *H*. The cam allows it to drop into place as soon as the indexing is completed. Bolt *G* is seated in a bushing *J* in the main casting of the machine, and its conical point engages plugs *K*, equidistantly spaced about the periphery of the spindle head. Bushing *J* and plug *K* are milled as shown in the small detail in Fig. 3, so that the tapered seat for the end of bolt *G* is formed half in one of them and half in the other. By means of this arrangement the accurate positioning of the spindle head does not depend on the closeness of fit of the cylindrical part of the locking bolt in bushing *J*. The seating of the bolt half in *K* and half in *J* insures a close fit at all times, even though the fit between *G* and *J* should wear. This combination of indexing and locking mechanisms is said to give a very easy and smooth engaging and disengaging action. This is due in part to the easy and smooth action of dog *D* in lock-

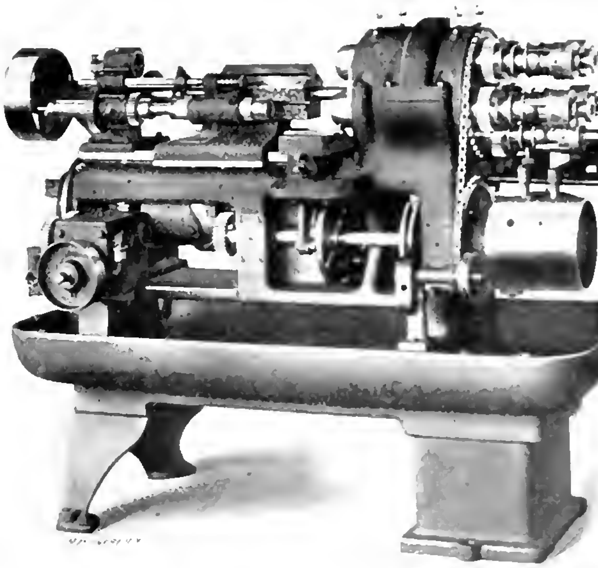

Fig. 2. Rear View, showing the Cam-shaft Drive, and the Operating Mechanism.

ing the sprocket to the cam drum, and is accomplished by the shape of engaging surface used, and by the shape given to the acting surface of cam *E*.

The collet-operating and stock-feeding mechanisms are of the standard construction, with the exception of the provision made for changing the length of feed of the stock. The adjustment for this is shown at the front of the machine, Fig. 1, at the left. It consists of a cam lever, connected to the stock-feeding lever by a slotted link, provided with an adjustment for increasing or decreasing the amount of lost motion thus allowed. When the lost motion is entirely taken up, the feed is at its maximum. The feeding of each bar of stock is effected when it reaches its lowest position. In this position the spindle is opposite the adjustable stop shown in the base of the tool slide in Fig. 1. The feeding is thus done accurately to length, and the feed cam needs never to be removed or adjusted. Since the stock feeding is done while the cutting tools are in operation, the lost motion device just described entails no loss of time.

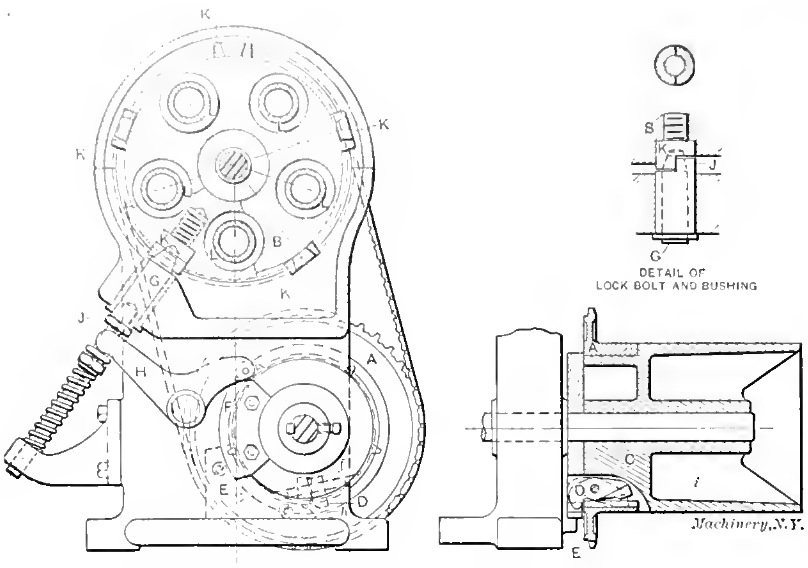

Fig. 3. The Method of Indexing end Locking the Spindle Head.

Ample provision has been made for oiling the spindle heads. The four oil cups shown in the various indexing positions of the head drop the oil into the spindle bearings. The oil flows from these bearings into oil ducts seen at *L* in Fig. 3, where it has no other escape than back through the bearings again. Oil may be independently introduced into these spaces, as well. The five main spindles are of crucible steel running in phosphor bronze bearings, the front bearing being of the taper construction with means of compensation for wear.

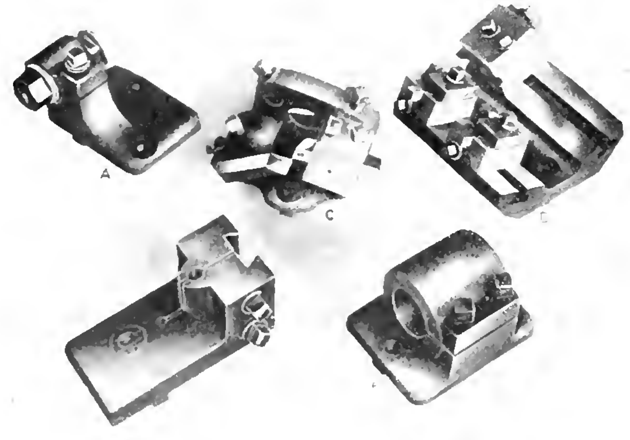

Fig. 4. A Set of Tools.

The Threading Mechanism.

The threading mechanism is best seen in the rear view, Fig. 2. The tap or die is secured to a revolving spindle carried by a tool-holder mounted on the tool slide. This revolving spindle may be connected, by either of the two pairs of gears shown, with the driving shaft of the machine, which is in turn positively geared to the spindles. The ratio of the two sets of gearing is such that one of them drives a tap or die at a slightly slower rate of speed than the work, but in the same direction, while the other drives the tap or die slightly faster than the work, and in the same direction. In the first case, the tap or die is threaded onto the work, and when the clutch connection is operated to connect the other set of gears, the higher speed releases or backs off the threading tool. With this arrangement it is possible to cut threads at about one-third the peripheral speed used for the other cutting tools, and it obviates as well the necessity for stopping and starting any of the revolving parts.

Facilities are provided for using two threading spindles, though but one is shown in the photographs. The second or auxiliary threading spindle is placed directly above the one shown and operates in the same manner, so that two dies, two taps, or a tap and die may be used. Both threading spindles can be independently adjusted and timed to cut any length of thread within the capacity of the machine. They are withdrawn from the work without reference to the movement of the tool slides. This threading mechanism is controlled, as previously mentioned, by cams on the disk at the outer end of the camshaft, just below the driving pulley.

Tools and Tool-holders.

Fig. 5 shows a close view of the machine, with the tool-holders set in position. A set of tools is shown in Fig. 4. As may be seen, the form of tool slide used does away with the necessity for holding the tools by shanks, as in the common form of turret. The long clamping surface provided at each station makes it possible to secure one or more tools on each tool-carrying face, and these may be adjusted backward or forward to suit requirements. In Fig. 5 it will be seen that the cross-slides are provided with an adjusting screw for setting the depth of cut independently of the height of the cams on the cam disk at the rear of the machine; a positive stop is also provided so that in forming down to a finished diameter, the tool slide is tightly held between the point of the cam and the stop, insuring accurate work. The two cross-slides are independent of each other in their movements.

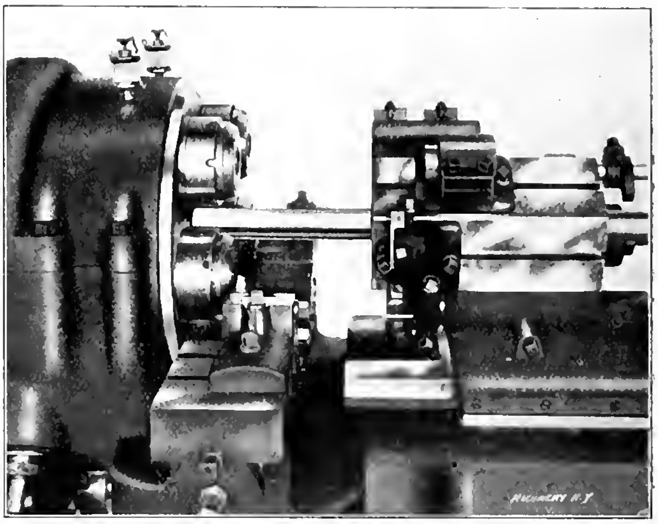

Fig. 5. Detail View of the Tool Slidee.

Of the tools shown in Fig. 4, *A* is a circular forming tool-holder for the cross-slide, and *B* is a straight forming tool-holder, also for the cross-slide. *C* is a roughing box tool; *D* is a finishing box tool provided with back rests and two blade holders (more may be used if desired), and *E* is a simple holder for such tools as drills, reamers, etc.

General Features.

As to the general features of the machine, it may be mentioned that the construction of the frame insures rigidity

and durability, as the spindle head bearing and the bed are cast in one piece. This bed is mounted on an oil pan base of large capacity, with a three point bearing, so that the machine is not thrown out of alignment no matter what the condition of the shop floor. A large oil reservoir is cast in the pedestal leg, into which the lubricant is strained, free from chips, and from which it is pumped back to the cutting tools. It will be noted that all the mechanism is accessible, the frame having been specially designed with this end in view. All the adjustments are made from the front. The inherent simplicity of the multiple-spindle machine is also plainly evident, and this simplicity has been preserved in the design. The machine illustrated has a capacity for work up to 1 inch diameter by 5 inches long. Machines of less or greater capacity can be furnished.

F. E. WELLS & SON CO. TAPPING AND THREADING MACHINE.

Fig. 1 shows a tapping and threading machine having a capacity for threaded diameters up to 5/8 inch, made by F. E. Wells & Son Co., Greenfield, Mass. This machine resembles the common type of light tapping machine in being provided with a friction forward and reverse drives, which may be engaged as desired by pressing in or drawing back on the work. It differs from the conventional type of machine, on the other hand, in being driven by a cone-pulley, allowing variations of speed to suit different sizes of taps; in obtaining the reverse by means of back-gearing contained within the cone-pulley; and in the improved facilities provided for holding and feeding the work. The machine is also provided with an oil pump and pan.

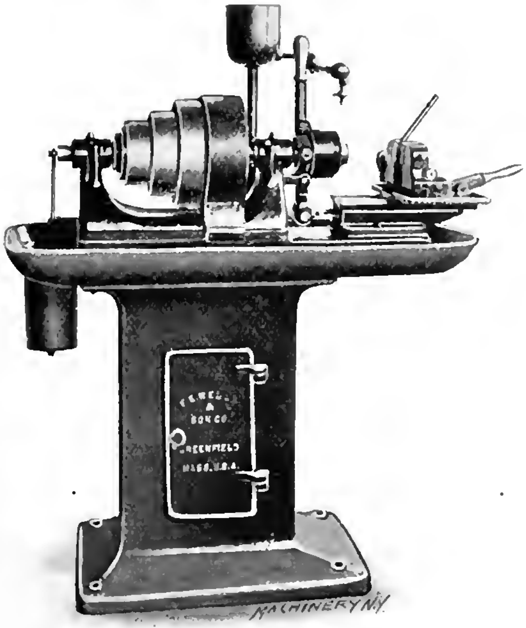

Fig. 1. A Combined Tapping and Threading Machine for Diameters up to 5-8 Inch.

The three-step cone-pulley carries an internal gear within its large diameter, which, through an intermediate rawhide pinion on a stationary stud, is connected with a smaller gear revolving freely on a spindle. A friction clutch arrangement, operated by shifting the spindle bodily, engages the spindle with the cone gear for the forward motion, or with this loose gear for the backward motion. The ratio of the gearing is such that the reverse is at a much higher rate than the forward movement. The shifting of the spindle for reversing may be effected by operating the lever shown at the front of the headstock, or by simply drawing back on the work, or stopping its further progress when its proper length or depth has been cut. A positive adjustable stop has also been provided for the work-slide, which throws the lever over and reverses the spindle at any length.

The work-slide is, as may be seen in Fig. 4, provided with two jaws operated by a right- and left-hand screw, thus making provision for centering the work. It will be noted that the bearing of the screw at the right of Fig. 4 is seated in a bracket, which is itself adjustable along the jaw guides. By shifting the position of this bracket the work may be held in any desired eccentric position, or the jaws may be brought up to the center again. The work slide is provided with a hand-lever as shown, for pressing the work against the tap in starting. This is only necessary for large tapping, up to nearly the capacity of the machine. For lighter work, the slide is pushed back and forth by hand directly.

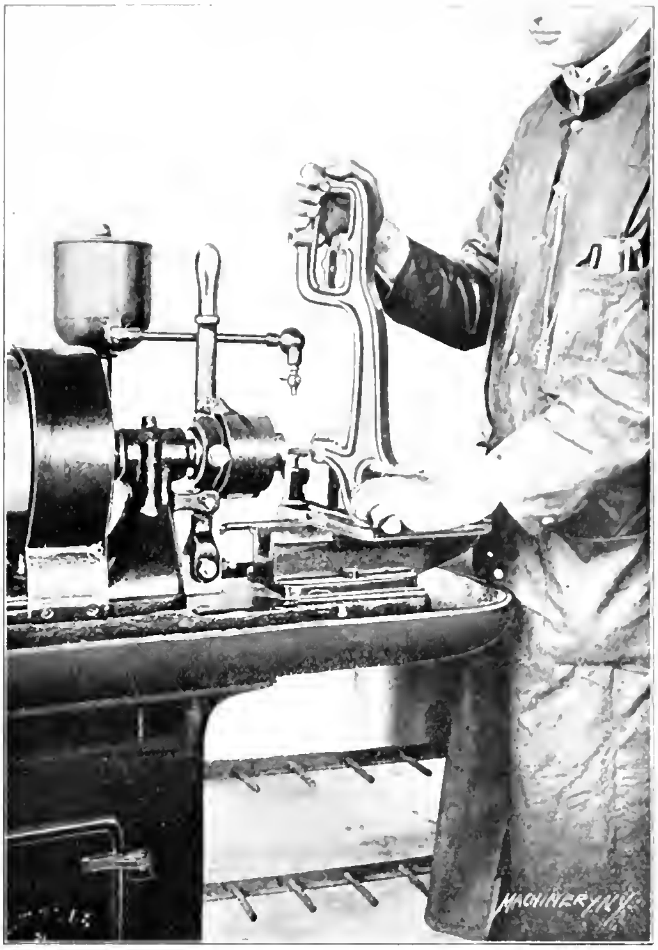

Fig. 2. Tapping a Casting held by the Hand.

Figs. 2, 3 and 4 show various operations for which the machine is adapted. In Fig. 2 a comparatively large casting is being tapped. The part of the casting operated on is backed up against the face of the vise jaws, and the whole slide is pushed by hand against the tap. When the proper depth has been reached, the adjustable automatic throw-out reverses the spindle and the tap is backed out. Smaller pieces are held by the fingers against the front end of the jaws, which are machined for the purpose. When operated in this way, the machine is as rapid on small work as the lighter machines commonly used for the purpose.

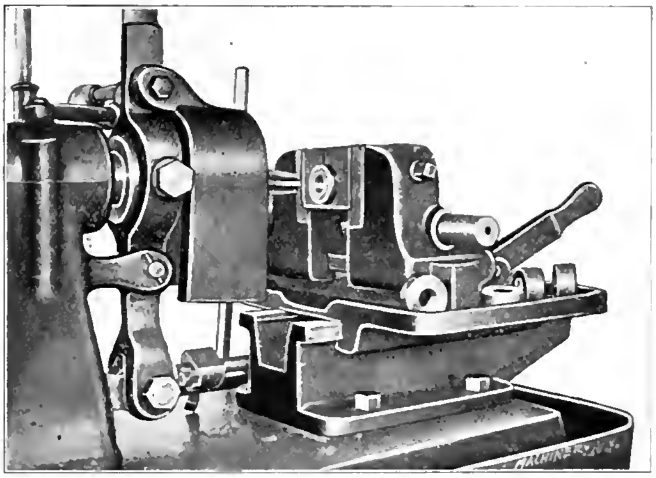

Fig. 3. Tapping a Finished Nut held in Special Soft Jaws.

Fig. 3 shows how special soft jaws may be used in the vise to suit special work. The piece in this case is a nut, smooth finished on the outside diameter. The jaws are machined to exactly fit the work and hold it without marring. There is movement enough in the work-slide so that a long shank taper tap can be used for threading nuts if desired, in which case they may be strung on the shank of the tap, from which they are removed without taking time to reverse the spindle. Fig. 4 shows how the machine may be used for external threading as well as for tapping. Arranged as shown, it makes a convenient and serviceable bolt threading machine.

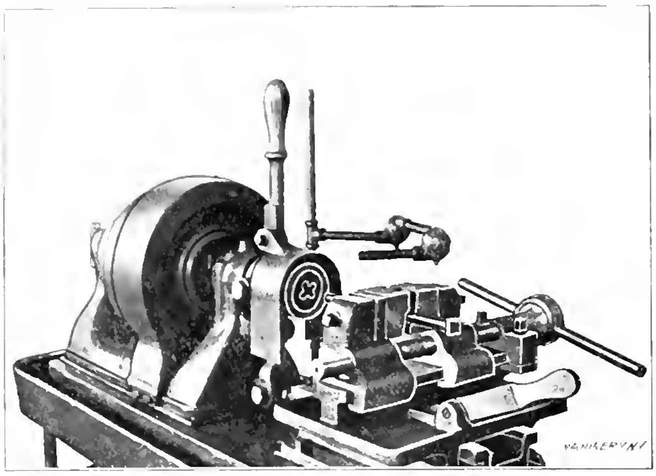

Fig. 4. Using the Machine as a Bolt Threader.

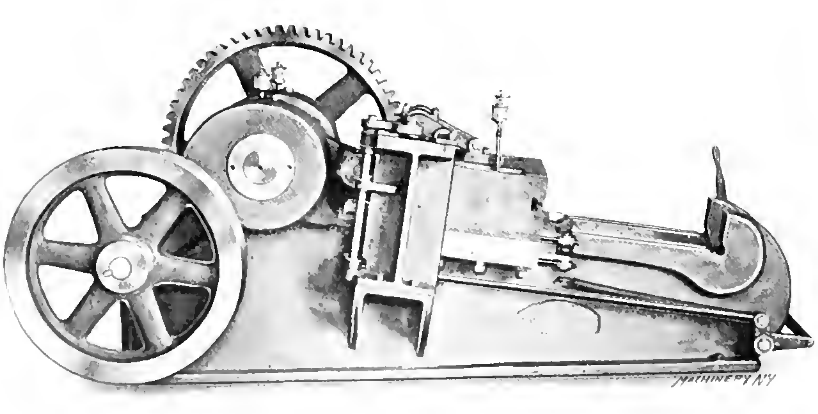
The oil pump is of the plunger type, driven directly from the rear end of the spindle. It feeds into the small tank shown at the rear of the machine, which gives a quiet, even flow of oil that does not spatter and is easily regulated. This supply tank is, of course, provided with an overflow back to the oil tank.

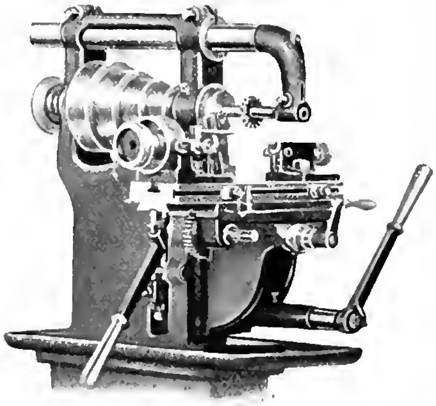
The capacity of the machine provides for tapping or threading up to 5/8 inch in diameter. As furnished by the builders, the machine is provided with a hardened steel vise for holding round or square stock, and a special positive drive tap chuck. This drives the tap by the squared part, and at the same time centers it by the shank.

AJAX HIGH-SPEED STOP-MOTION BULLDOZER.

An improved form of bulldozer, which is provided with a one-revolution clutch mechanism similar to that used on power presses, has been designed by the Ajax Mfg. Co. of Cleveland, Ohio. The use of a one-revolution clutch permits a much more rapid movement of the machine while still allowing the operator full control of its movements. For the No. 1 machine the movement of the cross-head takes place at the rate of 60 strokes per minute, while the time for a stroke of the largest or No. 6 size is at the rate of 45 strokes per minute. This rapid action allows a greatly increased output of work. The clutch is operated either by a foot pedal or hand lever, as may be most convenient for the operator.



Ajax High-speed Stop-motion Bulldozer.



Dalin No. 2 Hand Milling Machine.

The bed is a steel casting set on an angle to permit bringing the stock easily into place against the lower die. The cross-head is long, with ample bearing surfaces, and gibbed to take up wear in all directions while still keeping the cross-head in alignment. The gears are machine cut, and all the wearing parts and bearings are lined or bushed with bronze.

The machine is designed especially for bending work cold, and on stock which is of such material as to stand a cold bend a great saving of fuel is accomplished. The No. 3 machine will easily bend, cold, a 5/8 x 3-inch arch bar, with a pocket 8 inches deep, forming the four corners at a single operation. While it is primarily a bending machine, it can be arranged with dies to be used as a press or shear as well.

The No. 1, or smallest machine, has a cross-head travel of 5 to 8 inches (5 inches, standard); the face of the cross-head is 16 x 4 inches, and the machine weighs approximately 2,200 pounds. In the largest, or No. 6 machine, the corresponding figures are: 5 to 14 inches (10 inches, standard), 60 x 10 inches, and 24,000 pounds.

NO. 2 DALIN HAND MILLING MACHINE.

In the department of "New Machinery and Tools" of the September, 1907, issue of MACHINERY, we described the No. 1 hand milling machine built by Dalin Bros. of Rockford, Ill. A No. 2 machine of the same type has recently been designed by this firm. As may be seen in the engraving below, it differs from the older type in being provided with an over-hanging arm, and in having a larger base. It is also fitted with a small dividing head which materially increases its usefulness.

As in the older machine, stops are provided for the vertical movement of the knee on the column and for the traverse of the table on the saddle. Fine pitch screws are provided for the close adjustments of the stops, and the abutting surfaces are so placed that they will be free from chips. The spindle is regularly fitted with a draw-in sleeve and a ½-inch collet or chuck for straight shank arbors.

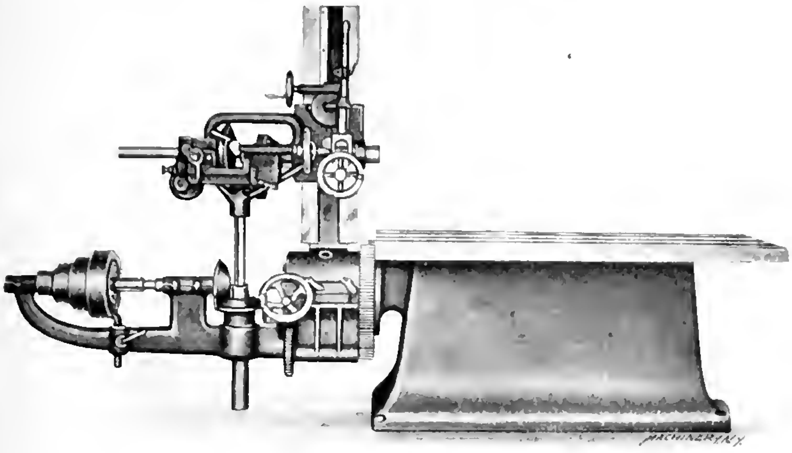
BARNES NO. 3 HORIZONTAL RADIAL DRILL.

W. F. & John Barnes Co., 231 Ruby St., Rockford, Ill., makes the horizontal radial drill shown herewith. This is similar in some respects to the builder's No. 1 machine of the same type, though it is of larger capacity, and has been provided with a number of new features which add to its usefulness and to the facility with which it can be operated.

The machine is, as its name indicates, a horizontal radial drill; that is to say, the spindle has all the movements and adjustments that a radial drill would have if the axis of its column were horizontal instead of vertical. The work table of the machine is, of course, left horizontal, and the only adjustment not provided for is that corresponding to the raising and lowering of the arm on the table. This is unnecessary owing to the fact that the horizontal table allows this work to be clamped in a position that will correspond to the vertical adjustment of the arm in the ordinary radial drill. The arm carrying the spindle head and all of the driving and feeding mechanism, is supported by a sleeve which swivels about a cylindrical stub cast solid with the base of the machine. This swiveling adjustment is controlled by a gear fast to the bed, meshing with a pinion, journaled in the sleeve and operated by a worm and worm-wheel, which allows the

swiveling adjustment to be obtained with great accuracy. The spindle head is adjusted up and down the column by a rack and pinion movement, also controlled by worm gearing and hand-wheel.

The driving shaft (with the four-step driving cone and the enclosed back gears used on all the Barnes back-geared drilling machines) is placed concentric with the axis of the swiveling adjustment, so that the belt center distance is not disturbed by any of the movements of the machine. This shaft is connected by gearing with the spindle, which thus is provided with eight speeds. A tapping device is also provided, permitting the operation of taps up to 3 inches in cast iron, or up to 2½ inches for pipe taps. Three rates of positively geared feeds are provided. The drilling capacity is for holes up to 3 inches in diameter out of the solid, in cast iron, or 2 inches in steel.



Barnes No. 3 Horizontal Radial Drill.

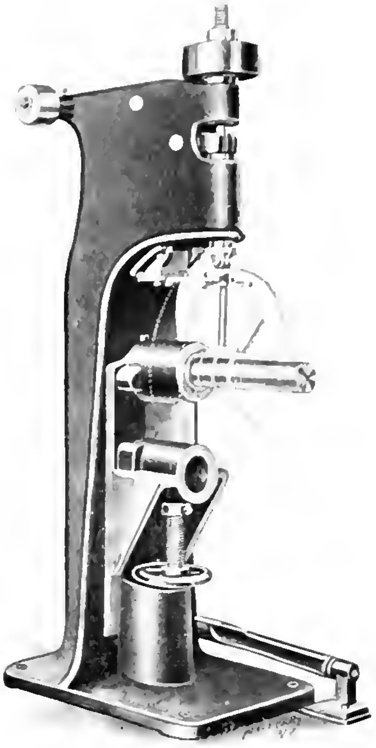
The maximum distance from the table to the center of the spindle is 29½ inches; the minimum is 2⅜ inches. The table is 24 inches wide by 65 inches long. The spindle is 1 15/16 inch in diameter and is provided with a No. 5 taper hole. It has a traverse of 18 inches. The machine weighs about 3,300 pounds. It is especially useful on work that can not readily be placed under an upright or radial drill, and is thus adapted to general machine shop use, as well as to such special lines as the manufacture of automobiles, safes, motors and engines. This type of drilling machine has been found particularly valuable for use with boring jigs, the horizontal table being much better adapted for chucking large irregular castings than a vertical angle plate.

GRANT RIVETING MACHINE FOR STEEL PULLEYS.

The Grant Mfg. & Machine Co., 80 Silliman Ave., Bridgeport, Conn., has designed the riveting machine shown herewith for the special work of riveting the spokes of steel pulleys to the rims. The spokes used in these pulleys are made of round steel, 1⅛ inch in diameter, with a shoulder at the end cut down to ⅞ inch in diameter where it enters the rim. When the shoulder is made of a length to project through the rim with the proper amount of stock for heading over, the action of the machine is such that the heading can be done with scarcely any surplus metal left to be removed by grinding when finishing the wheel. The action of the machine is uniform, and will give the same results continuously, if the amount of stock left for heading is uniform.

The pulley is placed on a projecting arbor in a seat bored in the adjustable knee of the machine. Two of these seats are provided, as shown, one for large and the other for small pulleys. A wide range of work is thus provided for. The hand-wheel and screw adjusts the knee to any intermediate position to cover the range from the smallest to the largest work. Several arbors are provided, ranging in size from 2½ to 4½ inches in diameter, to support the hubs of different sized pulleys.

In this machine, the rivet is headed by a pair of rollers mounted on a horizontal pivot in the end of a forked spindle, which, in turn, revolves about a vertical axis. When this forked spindle with the rollers mounted in the end is pressed down on the top of the work, the rollers spin over the end of the stock to form the head which holds the parts together. The action of the machine being purely rotary, it is noiseless. The character of riveting is the same as that produced on bicycle chain rivets, on which work the process has been generally used for years.



Grant Riveting Machine for Steel Pulleys, etc.

COLLIS HIGH-SPEED DRILLS.

The High Speed Drill Co. of Dubuque, Iowa, has spent two years developing a process of welding high-speed steel to a shank of low carbon steel. This has been considered a very difficult operation, but in the hands of this firm a process is said to have been developed that is commercially successful and uniformly satisfactory in its results. The specific use made of the process is in the manufacture of the Collis high-speed drills, having blades of high-speed steel and shanks of low carbon steel. The use of these two metals in this way combines the advantages of the high-speed steel for the cutting edge, while it allows the shank to be easily machined by ordinary processes to form a taper shank with a tang such as has proved to be the most satisfactory for driving drills. In samples of the work of this firm which we have seen, the welding is so well done that it is difficult, if not impossible, to see on the finished work where it is done. The details of the process are not made public.

Fig 1. Fig. 2.
Collis High-speed Drills.

Figs. 1 and 2 show a flat and a twisted drill, respectively, made by this process. They are especially effective when used in connection with air motors or electric drills, which often run at a higher rate of speed for a given size than would be allowable for drills of carbon steel. Under these conditions, the high-speed drill will work continuously for many hours without regrind-

ing, while a tool of the older material would fail at once. The flat drill is adapted for drilling iron and steel plate, structural steel and similar work. For regular machine shop work, the twisted drill is recommended. This is ground closely to size to compete in the matter of accuracy with the best makes of twist drills. Very severe service may be exacted of it, owing to its uniform section, and to the fact that the grain of the steel follows the twist.

These drills are made in a variety of styles of shanks for blacksmith's drills, bit-brace use, etc., as well as for the regular taper shank. It is thus necessary to have special holding chucks for them. The manufacture of these tools is the main business of the makers, and every care is given to the development of the processes of manufacture which tend toward accuracy and efficiency in tools. The matter of hardening and tempering is particularly looked out for, a very complete and highly organized hardening department having been installed for this work.

VARIABLE SPEED DRIVE FOR THE GRAY PLANER.

The demand for a variable cutting speed for the planer, coupled with a constant speed for the quick return, has resulted in the past few years in the designing of a great variety of driving mechanisms. The G. A. Gray Co. of Cincinnati, Ohio, to meet the need for a variable planer drive, built, about two and a half years ago, the arrangement shown in Figs. 1, 2 and 3. Since that time the drive has been thoroughly tried out in their own shops, with results so satisfactory that they are now placing it on the market.

As may be seen, the drive consists primarily of a pair of four-step cones, of which one is mounted on the constant speed shaft (which also carries the return pulley), while the other is mounted on the variable speed shaft with the forward driving pulley. The constant speed shaft may be driven either by a belt, directly from the line shaft through a pair of tight and loose pulleys, or, as shown herewith, it may be geared to the motor shaft, making a self-contained motor drive. The mechanism includes suitable means for shifting the endless belt over the cone pulleys, for making the changes in the forward speed, and for tightening the belt after the change is made.

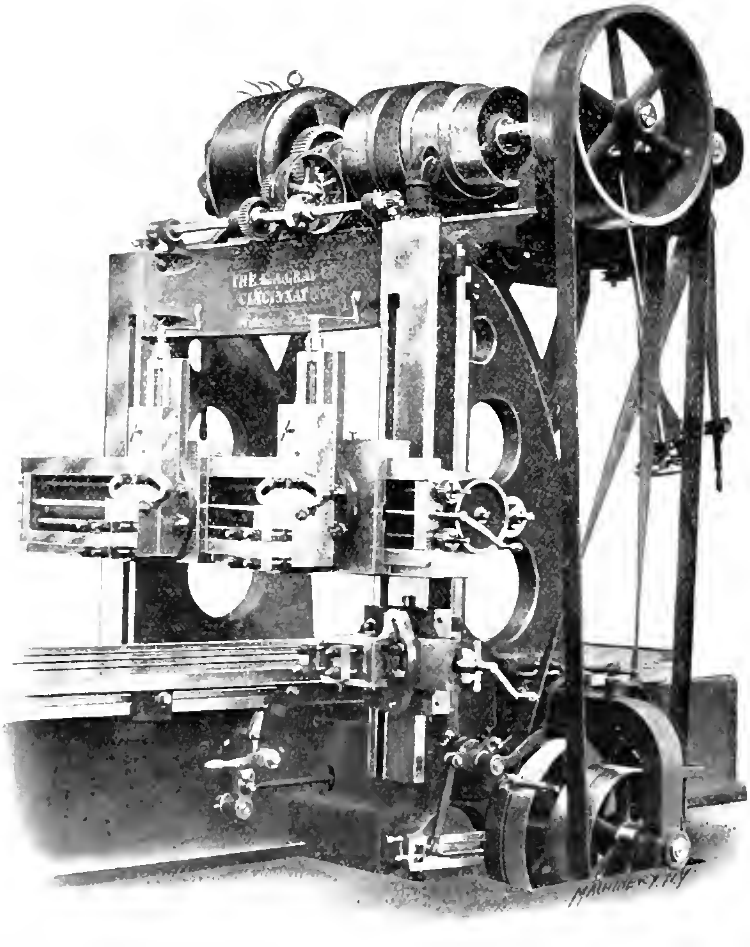


Fig. 1. Gray Planer fitted with a Four-speed Variable Forward Drive.

Fig. 1 shows a front view of the planer housings with this device mounted upon it. Fig. 2 shows a rear view, while Fig. 3 is taken from above the machine, to show the arrangement in detail. Referring to Fig. 3, the motor is geared to the constant speed shaft, which is the farther one of the two in this view. At the left-hand end this carries the heavy balanced-rim, reverse driving pulley, which thus always runs at constant speed. On this shaft is also mounted the 4-step cone shown, connected by an endless belt with the mating cone on the variable speed shaft in the foreground. This latter shaft carries the driving pulley for the forward movement, on its left-hand end. It is mounted in sliding bearings which are operated by links connected to levers on the rock-shaft shown. The long lever which depends from the rock-shaft at the left thus provides means for moving the variable speed shaft in or out, loosening or tightening the belt connecting the two cones. A clamp handle is provided for holding the adjustment at the proper tension when it has once been set. The proportions of the levers are such that it would be difficult to place a too severe strain on the belt, and the latter is of such proportions that it will transmit ample power for cutting without requiring an over-strain.

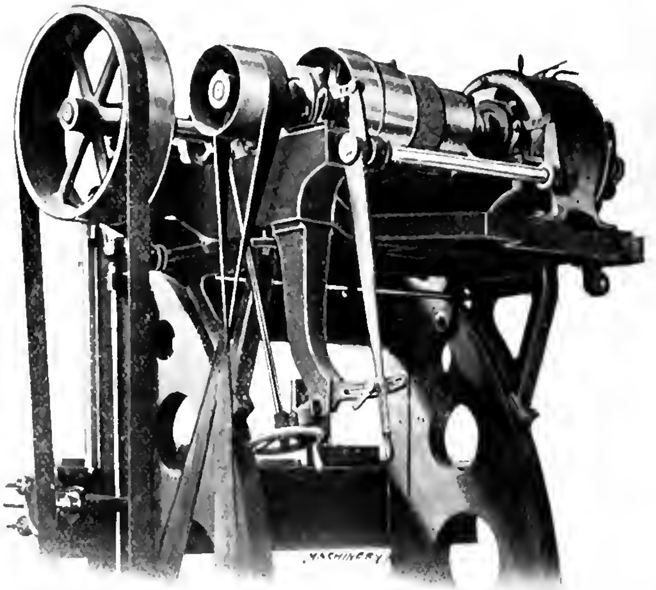

Fig. 2. Rear View of Housings, surmounted by Variable Speed Device.

In changing the forward speed, the belt is first loosened by the means just described, shifted to the desired step, and then tightened again. The shifting is effected by the hand-wheel seen just behind the lower end of the tightening lever in Fig. 3. It is also seen in Fig. 1, and more plainly in Fig. 2. This hand-wheel is connected by a shaft and bevel gears with a cam-shaft parallel to the two driving shafts. The cylindrical cam on this shaft controls belt shifters on both the idle and driving sides of the cone belt. The cam is so arranged that one end of the belt is shifted onto the smaller step of one cone before the other end is shifted onto the larger step of the mating cone. Owing to this arrangement, the shifting is effected without appreciable injury to the belts, the operation being identical with the movement of a trained mechanic in shifting a belt by hand. To further facilitate the shifting, the shoulders of the cone steps are beveled off as shown. The original belt placed on the first speed variator in the shops of the builders, two and

a half years ago, has been in use up to the present time. It has never been shortened, and has never been removed from the pulleys for any purpose since it was installed. It operates a 56-inch by 27-foot planer in the hardest kind of service.

The stationary pedestal bearings of the constant speed shaft are fitted with phosphor bronze bushings, automatically lubricated by ring oilers. The sliding pedestals for the variable speed shaft are provided with well-made ball-joint casings, also fitted with ring oiling phosphor bronze bearings. This arrangement forms a rigid universal swiveling bearing, insuring perfect alignment of the shaft bearings under all conditions. The whole device is rigidly built and, as may be seen from the illustrations, is simple and devoid of complicated or delicate parts.

The following advantages are claimed for this mechanism. There are no frictions to wear or require adjustment, and no clutches to be bruised or broken; there are no gears running loose on their shafts and thus liable to stick or cut; there are no sliding gears to be battered if carelessly shifted. The speed can be changed without stopping the motor, saving the considerable time otherwise necessary for allowing the armature and pulley to come to rest. The momentum of the two cones, supplementing that of the heavy fly-wheel pulley, reduces the strain on the motor at the moment of reversal. And, finally, the elimination of a complicated geared mechanism running at a high rate of speed, not only insures an almost noiseless drive, but does away, as well, with the vibration often met with in self-contained geared devices.

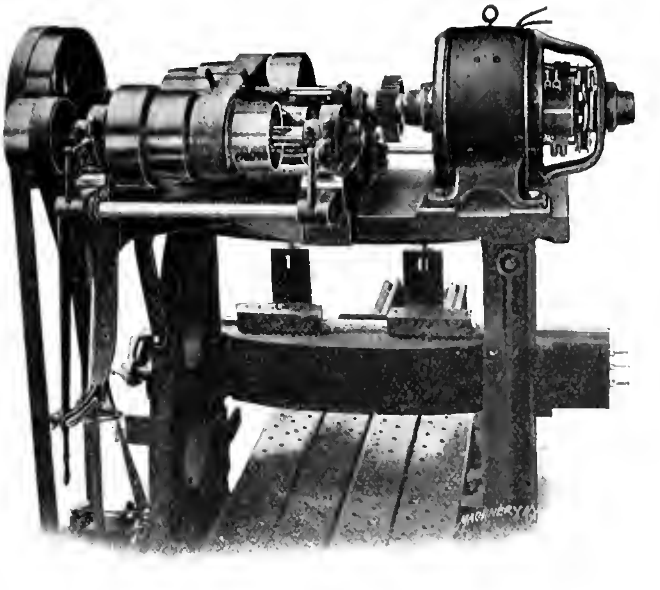

Fig. 3. Another Rear View of the Mechanism.

FERRACUTE ROLLING MILL.

The Ferracute Machine Co., Bridgeton, N. J., has recently built for the mint of a foreign government the rolling mill shown herewith. This mill was designed by Mr. Oberlin Smith, the president and mechanical engineer of the company. While the rolling mill as a machine is so simple that little latitude is allowed the engineer in designing it, the one here shown incorporates some features of interest and novelty.

As to general design, it will be noted, first, that the machine is motor-driven. A General Electric 50 H. P., 220-volt motor is used, the ratio of the gearing being 19.2 to 1, which gives 44 revolutions per minute to the rolls. The housings are bolted to the cast iron base or bed plate, and are provided with phosphor bronze boxes for the roller bearings. The rolls themselves are made of a substantial metal of a close texture. They are ten inches in diameter, and the distance between the housings is nine inches, thus adapting the mill for rolling strips of metal nine inches in width and from 0 to ½ inch in thickness. It will be noted that the gears and roller ends are protected by guards and all the working parts are accessible.

The adjustment of the rolls constitutes a particular point of interest in this machine. The upper roll is supported by four heavy springs under a compression considerably in excess of the weight of the roll so that it is supported at all times against its abutment, whether or not there is any stock passing through the mill. This prevents the formation of a film of oil between the journal and its bearing, and the consequent inaccuracy in the thickness of the rolled metal. The adjustment in each housing is effected by wedges. These wedges are shifted by a screw operated by the crank shown in the detail view, Fig. 1. The screw which moves the wedges in and out is connected by a train of gears with the dials, in such a way that these latter indicate accurately the thickness of the rolled strip. The dial at the left reads to hundredths of an inch, and the one at the right to ten-thousandths. One revolution of the crank moves the dial hand on the left one notch or 0.01 inch. If it should be desired, for instance, to roll a strip 0.2506 inch thick, the crank would be turned until the dial hand at the left pointed to 25, and the dial point at the right to 6.

Fig. 1. Dials for Reading the Adjustment of the Rolls.

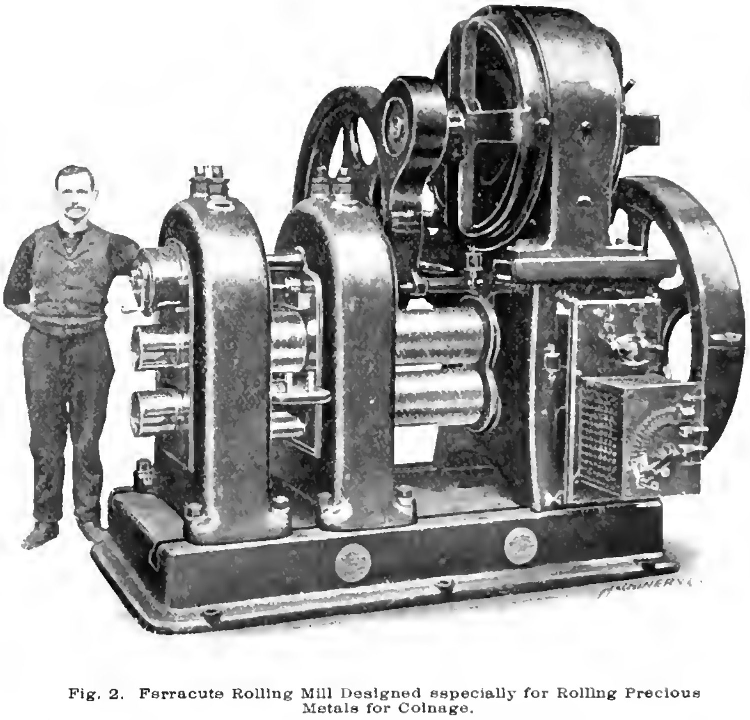

Fig. 2. Ferracute Rolling Mill Designed especially for Rolling Precious Metals for Coinage.

The extreme length of the machine from right to left is 8 feet 1 inch, the width is 6 feet 8 inches and the height 7 feet 9 inches. The total weight, including the motor, is 25,000 pounds.

BULLARD 24-INCH VERTICAL TURRET LATHE.

The Bullard Machine Tool Co. of Bridgeport, Conn., is building the 24-inch vertical turret lathe shown herewith. This machine is, in its general features, a smaller size of the 36-inch turret lathe, described in our department of "New Machinery and Tools" in the October, 1907, issue of MACHINERY, to which reference should be made for a general description of this type of machine. It has been found that this tool, on account of its smaller size, can be handled more rapidly than the 36-inch machine. This means that the production is materially increased on work within its range, as will be understood by anyone who has watched the operation of a turret lathe of this type, and has thus had an opportunity to see to what a remarkable extent the actual cutting time can be reduced.

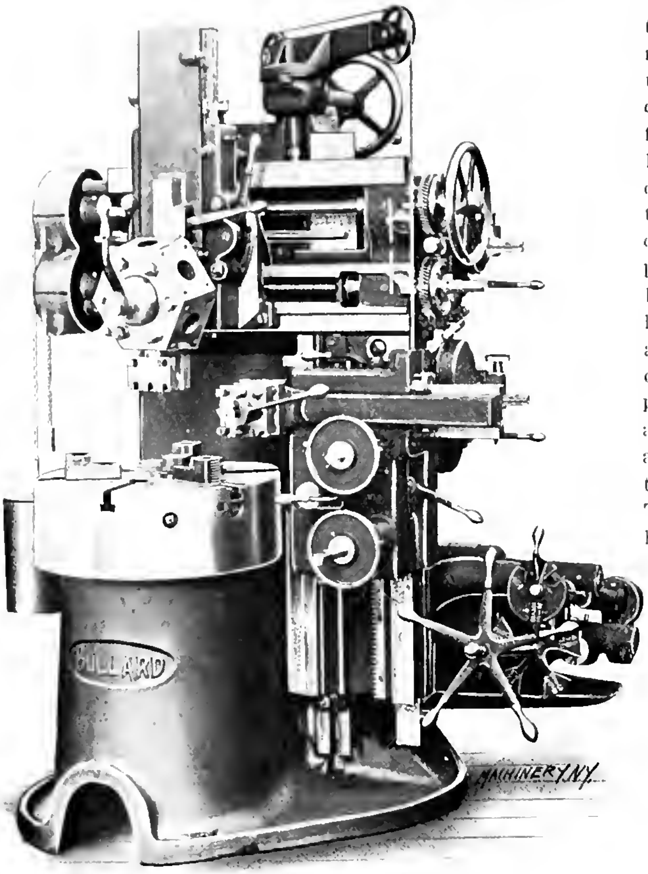

Fig. 1. Front View of the Bullard 24-inch Vertical Turret Lathe.

The arrangement of the controlling mechanism is identical with that of the larger machine. The speed changing mechanism was described in detail with reference to the first machine to which it was applied (see the December, 1907, issue of MACHINERY). As will be remembered, this gives 15 changes of speed, by means of handles which can be operated instantly, and which are so interlocked as to make it impossible to make a false move. A brake is incorporated in the mechanism, which stops the table automatically in making changes that cannot be effected at high speed. It gives the operator, as well, the use of the brake in stopping the table quickly for removing or adjusting the work. These speed changes are effected by means of the pilot wheel and levers shown at the right of the base of the machine in Fig. 1. The feed changes and control are entirely independent for the main and side turrets.

Improvements in Details.

Among the changes which have been made from the design of the larger machine, may be mentioned the improvement of the bed construction, which has been widened out to directly support the ways for the side rail, and to generally increase the stability of the machine. A heavy support has also been furnished for the lower end of the table spindle, which tends to reduce the torsional strains on the bed. The principle of providing narrow guiding surfaces for all sliding parts has been employed throughout the machine. The cross and side rails have been made a unit and are guided on one continuous narrow bearing which serves to maintain positive alignment at any height of adjustment.

Another improvement to which attention may be called, is the construction of the friction clutches used throughout the machine in the control of the feed and machine changes, and the rapid movements. This new form of clutch is shown in detail in Fig. 4, which illustrates the cone of gears giving the five spindle speeds controlled by the pilot wheel shown in Fig. 1. Each of these five gears *A*, revolves loosely on a clutch ring *B*, which is in turn supported on a collar *C* keyed to the hollow shaft *D*. Rings *B* are expanded to cause the different gears to drive the shaft, by levers *E* operated by a plunger *F* which passes through the shaft in its central bore. In this central bore is seated the plunger *G*, which is shifted lengthwise by rack teeth cut on its outer extension, engaging a pinion at the end of the pilot wheel shaft. The inner end of this plunger carries a series of five plugs *H* which, as the plunger is shifted lengthwise, raises the five plungers *F*, one after the other in succession, connecting the five gears, one after the other, to the shaft *D*. A particularly ingenious feature of this clutch is the means provided for adjusting it. These five plugs *H* back against adjustable headless screws, by means of which they may be set out more or less. In adjusting the clutch, therefore, the plunger is removed from the machine and taken to the bench, where the plugs for the clutches requiring adjustment are set out. The adjustment is then locked by means of the locking screws provided, after which the plunger is returned to the machine. It will be seen that the clutches themselves are adjusted by what may be called an "absent treatment." In the older machine, an adjustment was provided at the ends of clutch levers *E* which, however, were made slender enough to have considerable

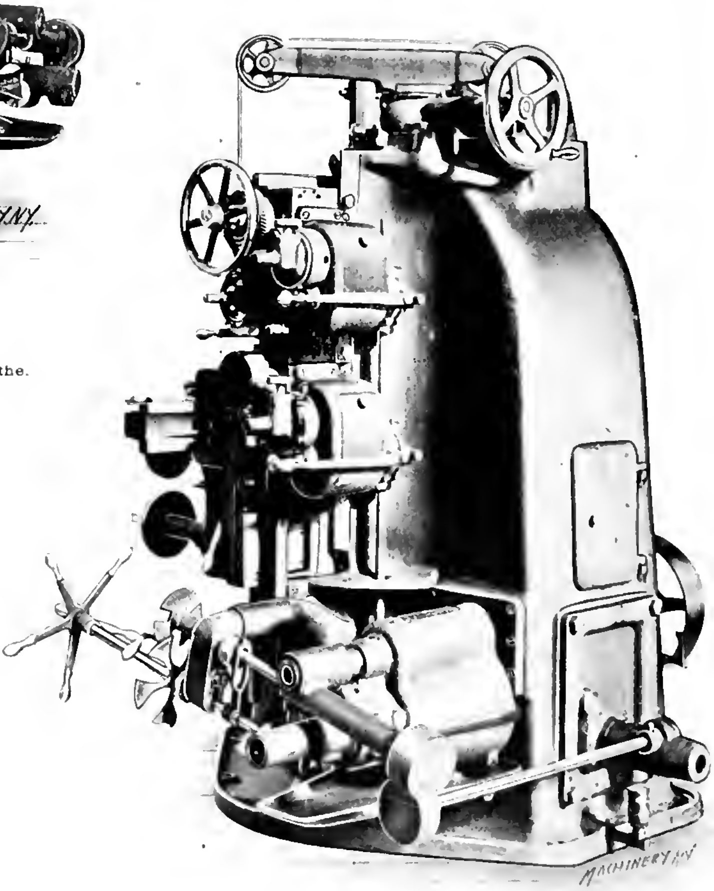

Fig. 2. The Driving and Feed Mechanism of the Bullard Turret Lathe.

spring, the idea being that it would thus not be necessary to adjust them during the life of the machine. It has been found more satisfactory, however, to make these levers stiff and strong, and to provide an easily effected adjustment.

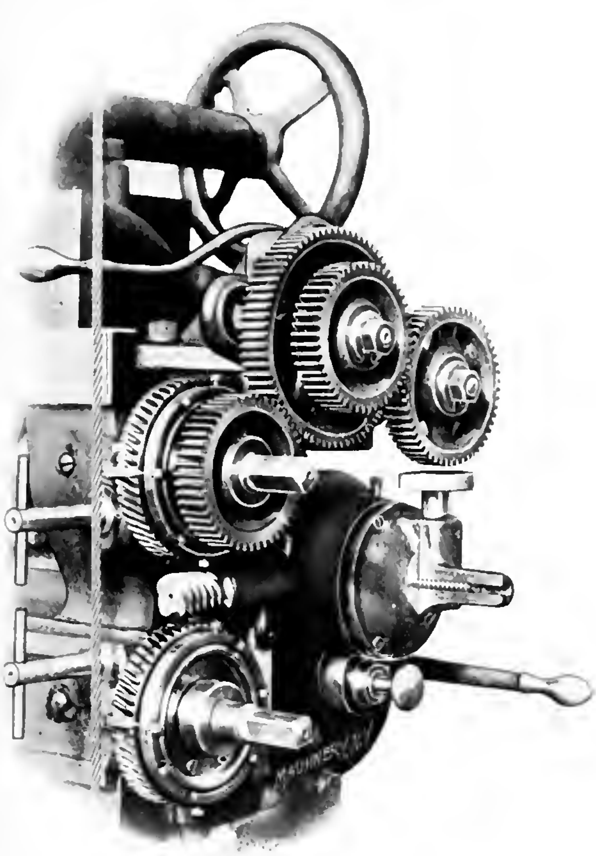

Fig. 3. View of Feed Gearing Set up for Thread Cutting; Indicator Clips for Setting Tools and Stopping Cuts are also shown.

The clamping of the side head has been improved. The clamp lever acts on the head by a cam movement, giving first a rapid action for bringing it down into place, and then a slower action for firmly locking it in position. It is unnecessary with this arrangement to swing the lever around so far that there is any possibility of interference with the work or the turret tools.

Another new feature is the provision made for running the turret head beyond the center stop on the cross rail. This is best seen in Figs. 6 and 8, the latter of which shows an example of an operation in which this comes into use. In this case it is convenient to move the head beyond the central position to allow the simultaneous use of the side head on the other side of the work. The center stop, as shown in Fig. 6, is in the form of a half bushing, which is swung into place between the nut on the turret slide, and an adjustable threaded nut abutment at the left-hand bearing of the cross-feed screw. This half bushing is thrown back out of the way by a conveniently placed knurled knob, whenever it is desired to move the turret beyond the central position.

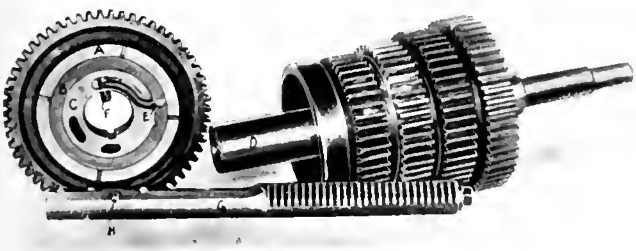

Fig. 4. Construction of the Clutch generally used in the Machine.

An improvment has also been made in the matter of gibbing the turret slide. This is now provided with a universal adjustment (see Fig. 5) so as to provide for taking up lost motion in any direction, making it possible to keep the holes accurately centered with the axis of the table throughout the whole life of the machine. Owing to the provision of an adjustable abutment for the center stop, no jib is necessary at the left-hand side surface.

Conveniences of Operation.

The usefulness of the rapid traverse for the vertical and cross movements of the turret on a machine as small as this, might perhaps be questioned by a mechanic who has never seen it operated to its full capacity. The use of multiple tools, high speeds, and heavy feeds, can be carried to such an extent that the operating time becomes a matter of the utmost importance. The workman easily gets into the habit of setting the tools entirely by the rapid traverse, throwing the power feed in as soon as he has thus brought the cutting tool to position. More important than this, however, is its relation to the matter of the accuracy and rigidity of the machine. As is well known to mechanics, where the slides have to be adjusted by hand the gibs are almost sure to be left much more loosely adjusted than is demanded by the requirements of accuracy and rigidity. By keeping the gibs firmly adjusted, and using power to move the slides rapidly against the resistance of this firm adjustment, the best results are obtained.

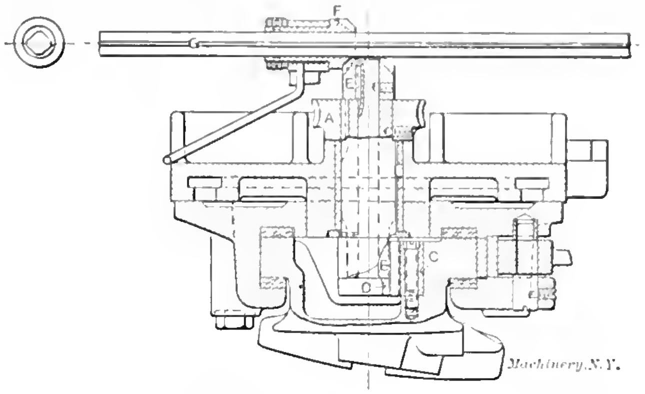

Fig 5. Horizontal Section through Turret Slide showing Counterbalance Connection.

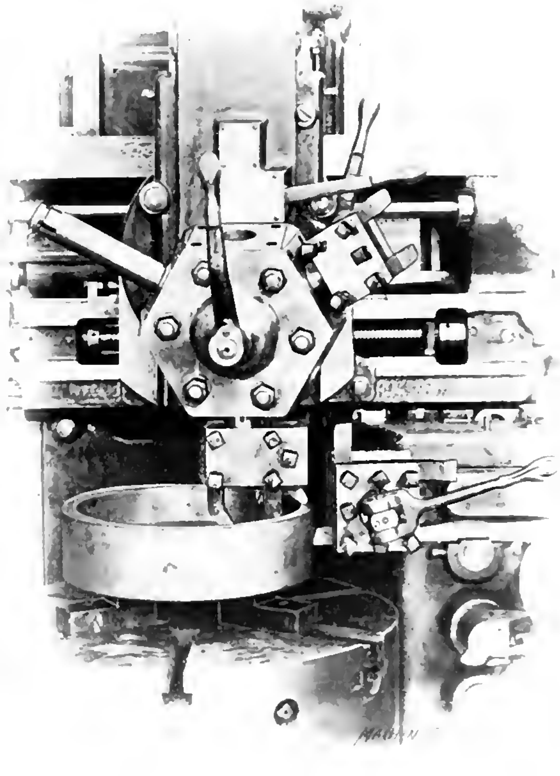

Fig. 6. The First Operation in Machining an Automobile Fly-wheel.

Fig. 3 shows the feeding end of the cross rail as arranged for thread cutting. When so arranged, the gear box is cut out and the connection between the feed shaft and cross feed screw is made by change gears, as shown. The feed shaft revolves with the work table in the ratio of 1 to 1, and the

connection with the screw is made by a one-tooth clutch. By using this clutch lever in connection with the rapid traverse device, it is not necessary to stop or reverse the spindle, the operation being similar to that which is possible on some makes of lathes where the corresponding mechanism is provided.

Fig. 3 also shows very plainly the indicator clips used on the large dials provided for each of the cross movements. These clips are numbered to correspond with corresponding faces in the cross and vertical turrets, and are used both for setting the tools, and for limiting the feeding movements. Automatic stops are not provided, as the workman is kept so busy that he could not run two machines under any circumstances, and it would be difficult to devise a system of automatic stops which would give the requisite range of action, and still preserve the accuracy which may be obtained by this method of reading the dials.

An ingenious method of counter-weighting the turret slide is used on this machine, which, so far as we know, has not been previously described. It is best seen in Fig. 5, which is a section on a horizontal plane through the rack pinion shaft which controls the turret slide. The feed for the turret slide is received from the splined shaft of the cross rail through worm gearing at *A*. Worm-wheel *A* is keyed to the sleeve *B*, whose inner end has pinion teeth cut on it meshing with the rack *C* of the turret slide. A narrow pinion *D* also meshes with this rack. This pinion has a shank extending through the sleeve *B*, and has keyed to it at the other end a bevel pinion *E*, meshing with a similar mate *F*, which is supported by the saddle and fits the squared shaft *G*. The outer extremity of this squared shaft at the left-hand end of the cross-rail, carries a sprocket over which runs the chain from which the counter-balance is hung (see Fig. 1). It will be seen that by this arrangement perfect freedom of position is allowed the slide, without interference with a system of wire loops and idler pulleys. At the same time, back lash is entirely taken up, as rack *C* is always firmly held against the resistance of pinion *B* in one direction, operated by the feed, and pinion *D* in the other direction, controlled by the counter-weight. It will be noted from Fig. 5 that the turret head is set at an angle in both the horizontal and vertical planes. This is done to clear, with over-hanging tools, both the rear of the tool slide and the side head as well.

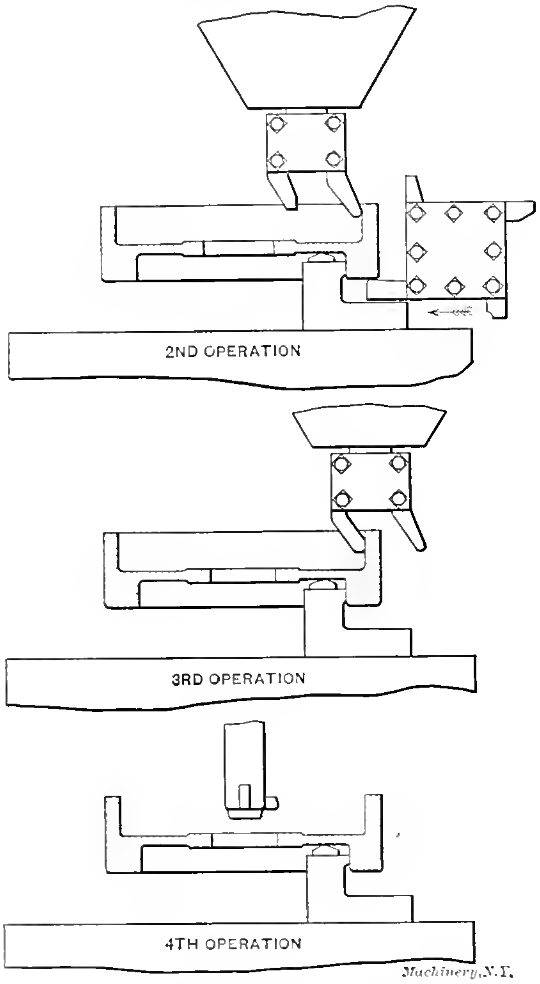

Fig. 7. The Remaining Operations on the First Setting.

Figs. 6, 7 and 8 illustrate typical operations on this machine. The work in question is the machining of an automobile flywheel which has to be finished all over. The first operation employs four tools acting simultaneously. The three in the main turret, face the hub, the web and the rim of the pulley, while the tool in the side head turns the outside diameter. The outside diameter is finished and carefully rounded by other tools in the side head. In the second operation, the under face of the rim is finished and the inner diameter of the rim is rough turned. In the next operation the side head is moved out of the way, and the same tool-holder in the turret is used for finishing the inside of the rim. The final operation at this setting is the boring of the central hole, which is done with the bar, noted in this department in the last month's issue of MACHINERY. It carries interchangeable single-ended and double-ended boring blades, making possible the complete finishing of a hole at one setting of the turret.

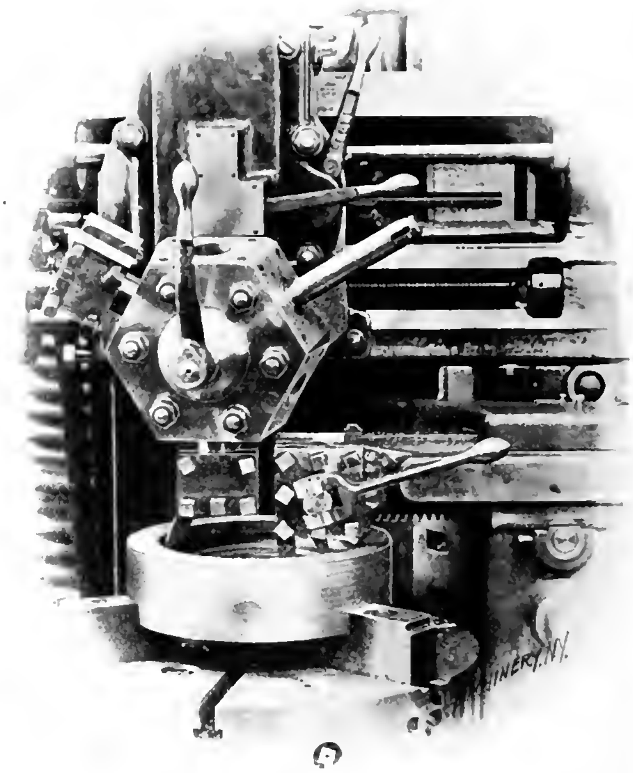

Fig. 8. The Machinery as arranged for Completing the Work on the Second Setting.

The remaining operations are made with the work reversed and held in soft jaws, accurately bored to fit the finished outside diameter of the wheel. The turret head, as shown in Fig. 8, finishes the inside of the rim, while the side head carries tools for facing the web and hub, and for rounding the corners of the rim.

General Features and Dimensions.

It will be seen that this machine is essentially, as the manufacturers claim, a turret lathe, the matter of its being vertical not changing its nature, and merely resulting in a rearrangement of the position of the handles and driving mechanism, and the rearrangement of some of the sliding surfaces. It is intended for exactly the work done on the horizontal turret lathe. The completeness of adjustment and facilities provided, are the result of long experience. It is not probable that any firm which had not been building machines of this type for many years, would have had the courage to carry all these adjustments and operative facilities into the design of a machine as small as this one.

The machine swings 26 inches in diameter, 18 inches in height under the cross rail, and 26½ inches under the turret

face. The main turret has a vertical movement of 18 inches, and will face work 26 inches in diameter. The side head has a vertical travel of 19 inches and a horizontal travel of 13 inches. The net weight of the machine is 7,800 pounds.

GENERAL ELECTRIC CO.'S ELECTRICAL FURNACE FOR HEAT TREATMENT OF STEEL.

The General Electric Co. of Schenectady, N. Y., has designed a furnace for general use in annealing, hardening, and tempering steel. The advantage of a furnace of this construction for annealing and hardening is that it gives the prime requirement—a furnace of constant temperature. It is difficult to do this with coal and gas furnaces, owing, for one reason, to the large area for radiation, exposed to the air. The electric furnace also presents the advantages of more simple and accurate temperature regulation. In this new design the work is placed in a bath of metallic salts which are reduced to the liquid state by means of an electric current. As soon as these salts reach a liquid condition, the temperature may be easily regulated by varying the amount of current passing through the bath. An alternating current is used, which is transformed to give the proper current strength for this work.

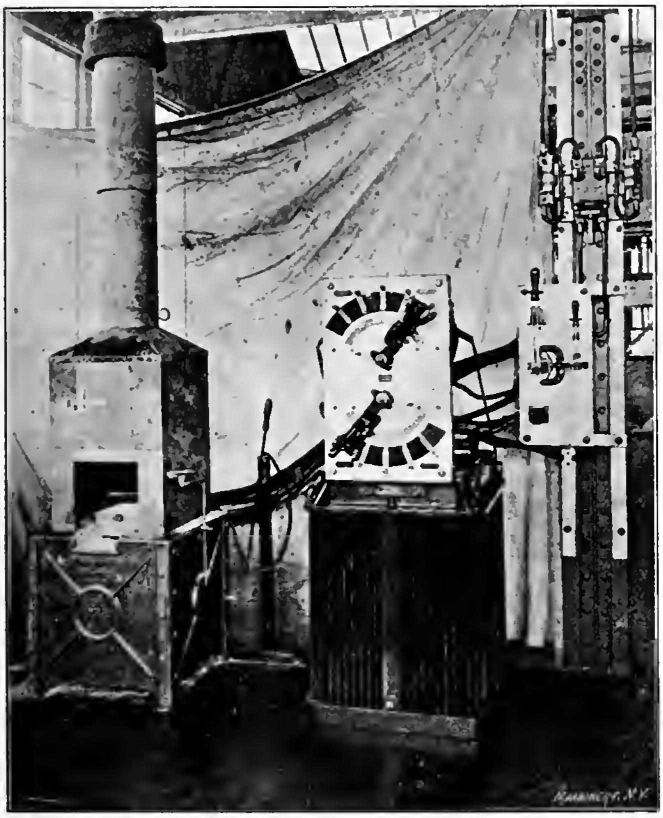

Fig. 1. Apparatus for the Treatment of Steel in an Electrically-heated Bath.

By means of this method of regulation, a temperature from 250 to 1,350 degrees Centigrade may be obtained. This temperature will remain uniform throughout the bath, except at the surface, where, owing to radiation, it is slightly lower.

The outfit, as shown in Fig. 1, is that installed in the die department of the Schenectady works of the builders. As may be seen, it consists of the furnace with its hood suspended from above; a regulating transformer with the controlling switch; the switchboard with the necessary ammeter and voltmeter; and the connecting line with its fuses. The regulating switch is provided with a sufficient number of contact points, to give, as stated before, practically any desired temperature between the limits of 250 and 1,350 degrees Centigrade.

A sectional view of the furnace is shown in diagram form in Fig. 2. It consists of a fire-clay crucible surrounded with an insulating material, usually asbestos, which rests in a fire-clay box. The whole is supported in an enclosing case of iron. Two electrodes are provided, one at each side of the crucible, and in direct contact with the bath at all times. To start the furnace, an arc is established across the broken mass of salts by means of an auxiliary electrode, as shown. In a very short time the solid mass is in a molten condition. After the bath has reached its proper temperature, that portion of the material which is to be hardened, is submerged in it and is allowed to remain until it attains the same color as the bath, when it is removed and tempered in oil or water, as the case may be. The bath completely fills the crucible and, in the Schenectady works, consists of equal portions of barium and potassium chloride. The ultimate temperature depends on the relative proportions of the chloride. The higher the percentage of barium used, the higher the temperature may be carried. When using the bath for softening steel, it should be maintained at a temperature of 250 degrees Centigrade.

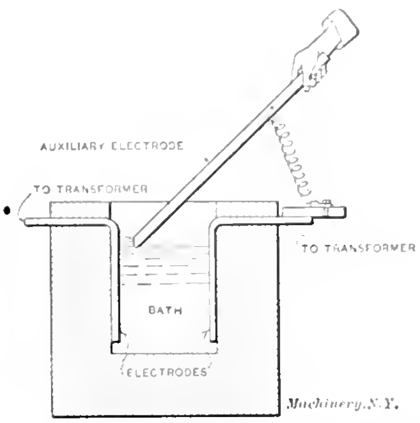

Fig. 2. Starting the Arc for Melting the Salts in the Bath.

The advantages of an electrical furnace for hardening and tempering may be summed up as follows: There is little chance of oxidation, as the material, while being heated, does not come in contact with the air. All parts of the tool are subjected to the same degree of heat at all times, thus preventing any possibility of over-heating or of internal strains due to differences of temperature. There is practically no danger from fire, as the outer walls of the furnace are never hot. In fact, when running at a temperature of 1,300 degrees Centigrade, the hand may be placed on the outside of the furnace without being burned. It is so simple and requires so little care and attention that it may be operated by an ordinary workman. The metallic salts have no effect on the composition of the steel, and the operator never comes in contact with dangerous fumes as in the cyanide bath. It is stated, also, that in efficiency and low cost of operation, it is superior to the gas furnace.

ELECTRIC CONTROLLER & MFG. CO.'S TYPE SA LIFTING MAGNETS.

The first commercial lifting magnet was designed about thirteen years ago by Mr. S. T. Wellman. The design was later improved upon by Mr. E. B. Clark, and the manufacture of lifting magnets of both the Wellman and Clark types was taken up by the Electric Controller & Mfg. Co., Cleveland, O., more than ten years ago. Magnets of the Clark type have given excellent results in the handling of smooth, homogeneous material such as plates, blooms, and slabs, but are useless for handling rough and detached material such as pig-iron and scrap. Many attempts were therefore made to perfect a magnet which would handle these materials, and the first commercially successful lifting magnet of this kind was placed on the market by the Electric Controller & Mfg Co., in March, 1905. An improvement on this magnet has now been brought out, and is shown in the accompanying line-engraving Fig. 1. This is known as the type SA magnet.

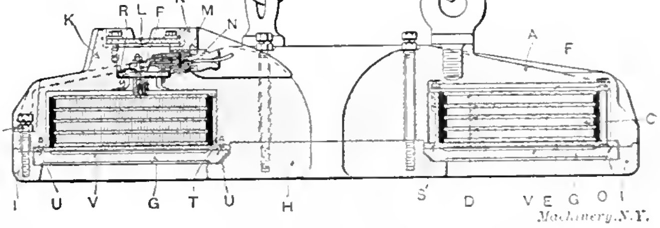

Fig. 1. Sectional View of the Type SA Lifting Magnets.

In the illustration *A* is the body or frame of the magnet. This frame is an angular casting of special "electrical" steel, substantially ribbed on both its upper and outer surfaces. Besides strengthening the casting, the ribs serve to dissipate the heat. The core of the magnet is surrounded by the winding *C* which is composed of a series of coils each wound with a conductor in the form of a copper ribbon or strap, the turns of which are insulated with asbestos ribbon. Neighboring coils are separated and insulated by the disks *D*. The coils are wound on a heavy brass form *E*, which resembles a spool having one head removed. This form supports the coils during the winding. After the last or uppermost coil is wound and the outer disk of insulation is in place, the winding is clamped to the form by means of straps *F*, thus making the winding and the brass form a rigid unit. The winding is then dried under vacuum and then impregnated with a plastic insulating compound, first under vacuum and then under compressed air, and finally again dried under vacuum. This makes the winding not only fire-proof but also thoroughly water-proof. The completed winding is then placed in the magnet case.

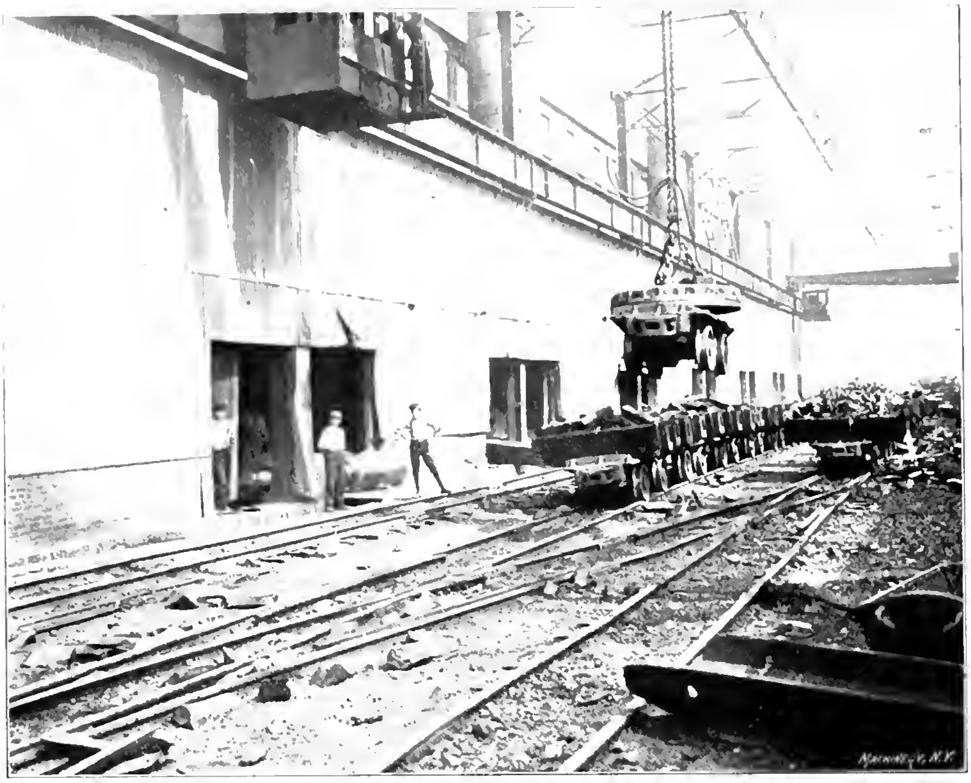

Fig. 2. Striking Example of the Capacity and Adaptability of Lifting Magnets.

It will be noted that the form *E* is provided with an outer flange *O* and an inner flange *S* in addition to the central flange *T* extending upward and supporting the winding. The inner and outer flanges are carefully finished and fitted to finished surfaces on the inner and outer pole faces of the magnet case. This seals the lower face of the winding chamber, and a water-tight joint is insured by clamping the flanges in place by the screws *U* which are spaced four inches apart all around the flanges *O* and *S*. This clamping arrangement, together with the clamps *F* already mentioned, holds the winding rigidly and prevents displacement.

Fig. 3. The Magnet used for Transferring Scrap from Shop Car to Railroad Car.

With the winding thus assembled in the magnet case, the lower face of the coil form *E* is covered by a heavy annular plate *G* of non-magnetic manganese steel, which in turn is held in place by the pole shoes *H* and *I*. Both of these pole shoes are provided with shoulders, thereby protecting the bolts from shearing stress. The heads of the outer clamping bolts *J* are protected by the ribs of the frame between which they are located. It will be noted that the manganese steel plate *G* is provided with raised shoulders around its inner and outer peripheries, which provides for a seat against the magnet poles and an air space or cushion under the winding at *V*. By this means the shocks taken by the outer plate *G* will be transmitted directly to the magnet frame instead of being taken by the winding. The magnet pole shoes are so constructed with regard to the outer plate *G* that none of the clamping surfaces can become battered, and, if required, the plate *G* can therefore always be easily renewed. The entire lower wearing face of the magnet can also be renewed without difficulty at any place where the magnet may be in use, there being no necessity of exposing or disturbing the winding, or breaking the water-tight joint between the coil form *E* and the frame of the magnet.

The terminals in the lifting magnet shown are also of interest. The terminal cavity is surrounded by raised walls *K* which are cast integral with the magnet case, and of sufficient strength to withstand any stresses which may be placed on the walls when the magnet is in use. The terminal cavity is closed at the top with a heavy steel cover *L* seating against a gasket and forming a water-tight joint. The heads of the bolts, by means of which this cover is held in place, are protected by the projecting walls of the cavity. The terminals themselves are of the plug type, which permits of quick

attachment and detachment of service wires. Several improvements have been made in the details of the construction over previous designs. The female members *M* of the terminal are enclosed in an insulating tube so that a ground or short circuit cannot result even if the service wires should be left hanging from the crane with the current on. The insulating tubes are each encased in a steel tube to prevent abrasion of the insulation. These steel tubes fit closely in babbitted openings *N* in the side of the terminal chamber. The male members *P* of the plug connectors are mounted upon a heavy plate *R* of fire-proof insulating material which closes the entrance to the winding chamber and is seated upon a gasket effecting a water-tight joint. The plugs and the plate *R* may be removed without throwing any strain on the connection to the winding, the connections consisting of loops of very flexible copper ribbon, as indicated in the engraving, and placed in the box-like ends of the terminal studs. This construction makes it impossible for the flexible leads which connect to the two ends of the magnet winding to come into accidental contact.

As an example of the capacity of these lifting magnets it may be mentioned that a magnet of the new type, 40 inches in diameter, known as No. 4 type SA magnet, lifts practically the same amount as a magnet 50 inches in diameter, of the older designs, but weighs 2,000 pounds less. This means that for the same power consumption the magnet can lift a much greater load, inasmuch as the dead weight of the magnet must constantly be taken into account.

The accompanying half-tones Figs. 2 and 3 show two interesting applications of these magnets. In Fig. 2 the capacity and adaptability of the magnet is strikingly illustrated; in Fig. 3 its capacity for lifting scrap is plainly in evidence.

YEMCO QUICK-ACTING WRENCH.

Figure 1 shows a quick-acting wrench made by the York Electric & Machine Co., 30-34 N. Penn St., York, Pa.; Fig. 2 shows the method of operating it. In closing the wrench, the construction is such that the sliding jaw may be pushed freely forward until it fits the nut, when it is securely locked in position. Pressure on the plunger in the sliding jaw releases it, so that it may be withdrawn from the nut and adjusted to a larger size. The operation of opening or closing may be performed with one hand.

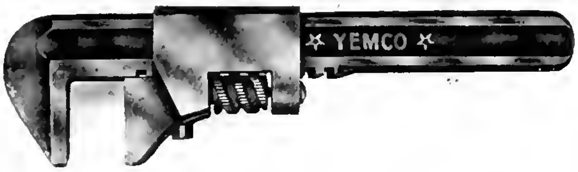

Fig. 1. Quick-acting Wrench made by the York Electric & Machine Co.

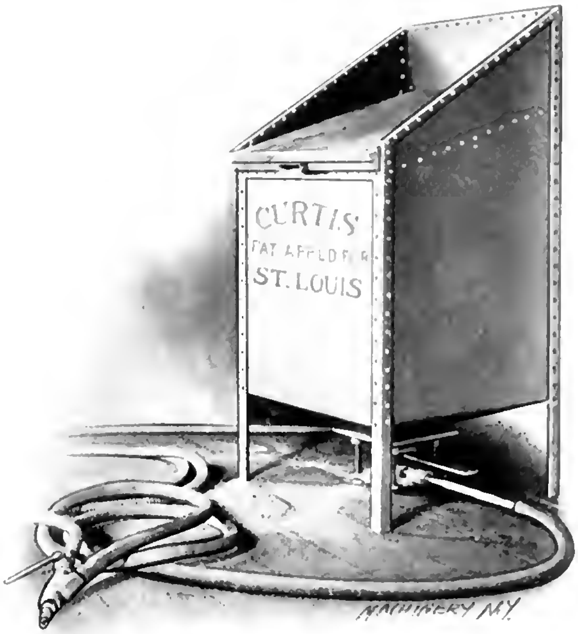
Fig. 2. Method of Operating the Quick-acting Wrench.

The construction is shown in Fig. 2. The screw is double-threaded and of steep pitch, engaging angular grooves cut in the body of the wrench; in pushing the jaw forward, this steep-pitch screw revolves freely. When reverse pressure comes on it, however, a coiled spring contained within the nut, presses it forward so that its conical front bearing is forced into its taper seat, with sufficient pressure to lock it by friction against any possible rotation from movement of the jaw. When sliding the jaw forward this screw is pushed by the pressure away from this taper seat, against the resistance of the spring, so that it is free to revolve. When it is desired to push the jaw backwards, the plunger shown is pressed. This pushes the ball against the conical bearing of the screw and forces it out of contact so that it is free to revolve and allow the jaw to be drawn back.

This wrench is eight inches long, made of a high quality of steel drop forging and is case-hardened with a mottled finish.

CURTIS SAND-BLAST OUTFIT.

The Curtis & Co. Mfg. Co., St. Louis, Mo., makes the improved form of sand blast shown herewith. It varies radically in its construction and operation from other apparatus of this kind on the market, particularly in the fact that the screening apparatus is incorporated in the design of the device, and in the fact that the sand is not under pressure either in the reservoir or in the hose which leads it to the nozzle.



A Sand Blast Apparatus in which the Supply is taken from an Open Tank.

The reservoir or tank is open at the top, but is covered with a screen of such mesh as to allow dust and sand of the proper size to fall through, while pieces of castings or other foreign matter roll down the incline and fall through the screen. Before the sand has a chance to drop into the tank, the dust is separated from it by means of a small air jet, so that only the sand itself, of the right size, enters the hopper. In the center of the cone-shaped bottom of the tank is an opening of about hand-hole size. Underneath this is the plate shown attached by four studs. The sand drops freely through the hole onto this plate, where the cone-shaped pile thus formed stops the opening and prevents overflowing. The air and sand hose are separate, being joined only at the nozzle. The blast of air through the nozzle creates a partial vacuum in the sand hose, which draws the sand by suction from the pile on the plate at the bottom of the tank. The air supply alone is regulated, and this is done by the air valve at the nozzle in the operator's hands. The supply of sand regulates itself automatically.

Among the advantages claimed for this arrangement are the following: A complete and effective screening attachment; the possibility of filling the machine when the blast is in operation; the avoiding of the trouble from moisture in the air, accomplished by keeping the sand out of contact with the air blast until it has reached the nozzle holder; the regulation of the machine from the operator's working position; the possibility of cleaning the sand blast hose while the machine is in operation, by pressing the nozzle to the floor for a few seconds; the use of a cheap grade of sand blast hose, made possible by the fact that the sand is drawn through by suction instead of forced through by high press-

ure, and a reversible construction for the nozzles. The New York address of the builders of this apparatus is 30 Church Street.

WIZARD QUICK-CHANGE DRILL-CHUCK AND COLLET.

The McCrosky Reamer Co. of Meadville, Pa., is manufacturing the "Wizard" quick-change drill chuck and collet shown in Figs. 1 and 2. This tool is of the type which permits drills, reamers, taps, counterbores, etc., to be placed in or removed from a machine spindle without stopping it. Its special advantages lie in the firmness with which the collets are held, and the ease with which they may be inserted. Special pains have also been taken to put the highest grade of material and workmanship into their construction.

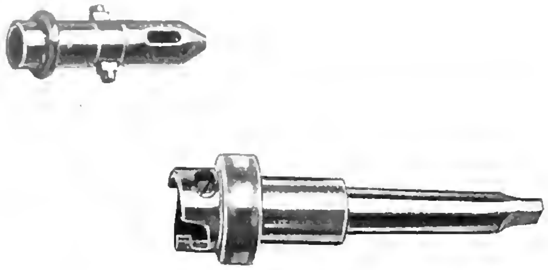


Fig. 1. The "Wizard" Quick-change Chuck and Collet.

The chuck and the collet, separated, are shown in Fig. 1. The chuck has a Morse taper shank, fitting the spindle of the machine, with a seat at the outer end to receive the collet. The latter is ground accurately on the outside diameter to fit this seat, and is provided, as well, with a conical point which assists in inserting it in the chuck, and firmly centers it after it is seated. When the collet is pushed into the chuck, as shown in Fig. 2, the driving lugs on the side of the collet ride up the inclined cam surfaces and strike against the entrance of an angle slot in the collar on the lower end of the chuck. The revolving spindle causes this collar to rotate slightly when grasped by the hand, as shown in Fig. 2, allowing the driving lugs of the collet to enter the slots in the chuck. The releasing of the hand then permits the sleeve to fly back under the influence of a spring contained within it, locking the lugs of the collet securely in place by a principle identical with the bayonet lock of the Springfield rifle. As the locking surface is made angular, the collet is forced with considerable pressure back into its seat, so that it is accurately centered by its tapered point. In releasing the collet, the collar is grasped by the hand, when the revolving of the spindle opens the lock and permits the collet to drop freely or be taken out. It will be noticed that the collets are provided with a collar, which is used against the hand as a shoulder, when placing the tools in the chuck or in catching them when released. The form of lock employed makes the chuck useful for back-facing as well as for straight drilling or counterboring.

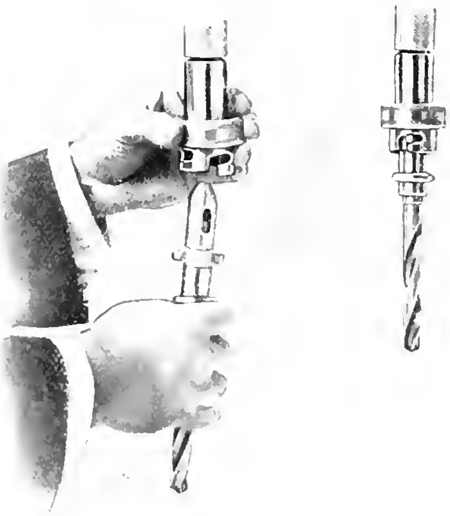

Fig. 2. Inserting a Collet in the Chuck.

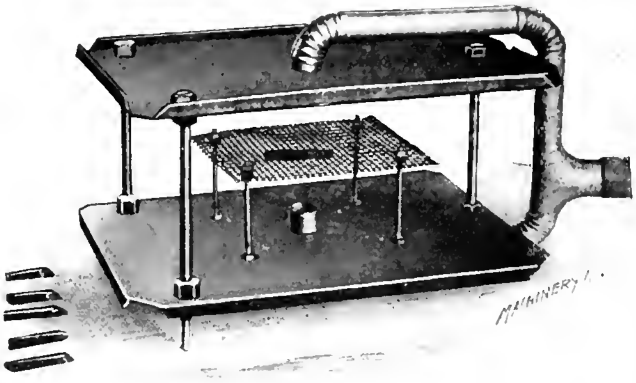
These collets are drop-forged from high grade steel, machined, hardened, and ground. The whole collet, including the driving lugs, is a solid piece of steel. They are furnished either with standard Morse holes or sent blank. The blank collets are not hardened, and may easily be bored to receive straight shanked drills, taps, reamers, etc. If desired, these are sent 0.003 inch over size so that they may be hardened and ground after being fitted to the tools. Various ways of fitting special tools to these collets may be employed. One of the most convenient ways is to drive a hardened pin through both collet and tool shank. Set-screws may also be used, or a tang and drift slot may be formed in the tool shank and the collet. In all cases it is best to bore blank collets to a driving fit. The chucks are hardened and ground inside and out.

Chucks are made in three sizes, for collets 15/16 inch in diameter with a maximum hole of Morse taper No. 2 for the smallest size up, to collets 1¾ inch in diameter with Morse hole No. 4 for the largest. When required, the chucks will be sent with the shank left blank, so that they may be turned to fit the tail-stock of a lathe, or other irregular taper holes.

KRIEGER TOOL & MFG. CO.'S AIR HARDENING STAND.

The Krieger Tool & Mfg. Co., 83 West Randolph St., Chicago, Ill., has designed a stand for the air cooling of cutters in hardening. The special purpose of the arrangement is to subject the tool being hardened to a blast of air from every side, and thus harden it evenly all over. As may be seen from the engraving, the cutter to be hardened is placed on a screen. This is supported between the openings of two blast pipes, which direct the air onto it from each side. By placing on the blast pipes special top and bottom nozzles having elongated openings, it is possible to harden several objects at a time, and thus increase the capacity of the device.



Air Cooling Stand arranged to Direct the Air Blast on all Sides of the Work.

DIAMOND AUTOMATIC DIE-HEAD.

The accompanying half-tone illustrates a new self-opening die-head brought out by the Diamond Power Specialty Co., Detroit, Mich. This die-head embodies several new features of which the four most important ones are: the arrangement for discharging the chips; the method of preventing unequal wear of the chasers; the range of the capacity of each size of head; and the relatively small size of the die-head for its capacity.

The first of these features, the discharging of the chips, is accomplished by providing ample openings back of the chasers through which the chips are flushed out by the oil used for cutting the thread. Unequal wear on the chasers is provided against by mounting them on pivots in the body of the die so that when they are drawn together by the adjusting ring, the outer end, where the heaviest wear takes place, closes in faster than the portion nearer the pivots, thus compensating for the unequal wear in the length of the chaser, and making possible the producing of threads of uni-

form diameter throughout their length. This is a most important improvement in this class of dies. The construction of the die-head permits right- and left-hand threads, whether of U. S. standard shape or square, Acme, Whitworth, pipe, or special threads of various pitches to be cut with the same die-head on stock within the limits for which the head is suited simply by changing chasers. The die-head can also be used as a forming tool for small articles by using special blades of required shape. The fourth feature of this die-head, to which special attention is called, is its small size in comparison with its range. The closing ring is placed outside of the chasers, and has its bearing on the latter immediately over the point where the greatest cutting stress comes. Any wear between this closing ring and the chaser holder is taken up in adjusting the die for size, so that this wear does not accumulate with the use of the die.

A Compact Self-opening Die-head.

The length of the thread cut is adjusted closely by an internal stop-pin actuated by the work, thus enabling it to be used in an ordinary turret or automatic screw machine. When the stop-pin is removed, a thread of any desired length can be cut. For heavy, rough work, a stop can be furnished which permits taking two cuts in producing the finished thread. The die-head is closed either by hand, or by fastening a small piece of steel on the turret slide, to actuate the closing lever on the backward motion of the turret.

WALTHAM AUTOMATIC ESCAPE-WHEEL CUTTING MACHINE.
